Another organization tried to solve the problem of confusing terminology as well. The International Society of Pharmacoeconomic and Outcomes Research (ISPOR) established a Medication Compliance and Persistence Special Interest Group which, for 3 years, explored the use and perceptions of these three terms by providers and patients. In a 2008 publication, Cramer et al. [11] found that the terms *compliance* and *persistence* were distinct from each other in concept and measurement and should be used in the literature; they also determined that *adherence* did not have a distinct definition and was, therefore, a synonym for *compliance* and not a separate concept. The authors did comment about earlier hypotheses that patients found the term *compliance* degrading: "We found no authoritative support for the assumption that 'adherence' is a less derogatory term or whether it is preferred by patients" (pp. 14–15). Unfortunately, the impact of these guidelines was no greater than that of the WHO document. Another search of *Web of Science*, this time including publications through 2011 (i.e., after the ISPOR guidelines had been published) found the following: *compliance* (194 hits), *persistence* (134 hits), and *adherence* (215 hits). Therefore we must conclude that there is no gold standard for the terminology used to describe medication-related behaviors.

It has been difficult enough to figure out what to call various medication-related behaviors. The use of adherence as a synonym for compliance is confusing but could be straightforward. Unfortunately, a number of researchers have chosen to operationalize adherence as the sum of compliance and persistence. For example, in a 2006 *Mayo Clinic Proceedings* editorial, Badamgarav and Fitzpatrick [12] say, "Adherence comprises compliance and persistence and refers to taking medications as instructed during a given period. Adherence is typically estimated by the medication possession ratio (MPR)" (p. 1009). This sentence actually contains an explicit contradiction. If compliance can be measured as MPR (see next section) and adherence equals compliance plus persistence, how can adherence be measured as MPR as well? As noted above, ISPOR suggests the use of adherence ONLY as a synonym of compliance and, therefore, measurable by MPR.

CONTROVERSY #2: HOW SHOULD WE MEASURE COMPLIANCE AND PERSISTENCE?

Measuring a patient's compliance and persistence with medications is extremely difficult, to say the least. Any prospective measurement that involves questioning a patient has the potential to influence that patient's behavior and discredit results.

Claims data

For this reason—and because retrospective data analyses avoid some of the pitfalls of ongoing data collection—many compliance and persistence studies have used retrospective analyses of claims data. For example, Siris et al. [13] used data from two claims databases over a 5-year period to assess medication behaviors and to determine the relationship between adherence and fracture prevention. They found that 43% of women with postmenopausal osteoporosis (PMO) were refill compliant (as determined by MPR) with their bisphosphonate therapy while only 20% were persistent across the entire study. Those who were refill compliant demonstrated significantly better fracture protection when compared to noncompliant patients ($p < 0.001$). An earlier study by Caro et al. [14] examined health services databases to assess compliance and persistence. Not surprisingly, Caro also found that compliant patients experienced a 25% ($p < 0.00001$) reduction in fractures. Compliance was defined as taking at least 80% of medication doses, and the better the compliance, the greater the fracture reduction. Finally, using administrative claims data from Medicare patients ($n = 19{,}987$), Patrick and colleagues [15] completed a cohort study in which adherence was assessed in sequential 60-day periods. Using various modeling techniques, they found that adherence was consistently associated with hip, vertebral, and overall osteoporotic fracture reduction.

McCombs et al. [3] looked at compliance in a slightly different way. Examining over 58,000 osteoporosis patients and their pattern of medication use, they examined compliance for different osteoporosis drugs (hormone replacement, bisphosphonates, and raloxifene were available at the time of this study). Sadly, 1-year compliance rates were below 25% for all osteoporosis medications. However, in this study—as in the two previously mentioned—investigators had no way to examine why noncompliance occurred. Given that noncompliance can often result from factors not related to osteoporosis, such information would be valuable in understanding reasons why this low level of compliance seems so widespread.

Prospective studies

In the early studies of compliance and persistence, there was virtually no use of prospective studies. One of the first was done by Papaioannou et al. [16]. In it, investigators measured adherence to three osteoporosis drugs [etidronate, alendronate and hormone replacement (HR)] using the Canadian Database of Osteoporosis and Osteopenia(CANDOO). Surprisingly, 1-year adherence rates were extremely high: 90% of etidronate users, 80% of HR users, and 78% of alendronate users. However, as time passed, persistence rates decreased; after 6 years, less than 50% of participants were still persistent with any medication. Unfortunately, the study did not assess reasons for discontinuation.

In 2007, Ringe et al. [17] conducted a 1-year prospective study of more than 5,000 patients on four osteoporosis medications: alendronate daily, alendronate weekly, raloxifene, and risedronate daily. They reported moderate levels of compliance after 1 year (76–80%) and found that side effects were the primary reason for discontinuation.

Measuring persistence

Persistence is the duration of time from initiation to discontinuation of pharmaceutical therapy. For some time, researchers in medication behaviors believed that compliance plus persistence equaled adherence, but there has been little support for this and much opposition to it.

MPR versus other measures

In studies of compliance and persistence, measurement of the two primary outcomes continues to be a challenge. Using something such as electronic pill bottle caps reminds patients that they are participating in a study. Pill counts at follow-up clinic visits can easily be made inaccurate either accidentally or deliberately. Patient diaries are often inaccurate and may be influenced by social desirability. Questionnaires are now available that can assess compliance and persistence, but they are only as accurate as the patients completing them [18]. There is no question that, currently, medication possession ratio (MPR) is the most commonly used measure of compliance. MPR is calculated as the number of days of medication supplied within the refill interval/number of days in the refill interval. This information is easily available and calculated using claims data; it is the standard in virtually all claims data analyses [e.g., 3, 13, 19] as well as in prospective studies.

But as theoretically accurate and easy as MPR is, there is a substantial difference between being in possession of medication and actually taking medication. Thus, MPR is not the gold standard we have looked for, although it may be better than other options. Unfortunately, no one has come up with a way to measure compliance and persistence directly without having patient behavior influenced by that measurement. This is a challenge that remains unsolved.

CONTROVERSY #3: DO PATIENTS FORGET TO TAKE THEIR MEDICINE, OR ARE NONCOMPLIANCE AND NONPERSISTENCE MORE COMPLEX?

In the literally dozens of studies of compliance and persistence with osteoporosis medications, no strong answer emerges to the question, "Why don't people with osteoporosis take their medications as directed?" After all, we currently have nine FDA-approved medications to prevent or treat this disease. Within this family of medications, we have different delivery systems (oral, nasal spray, subcutaneous injection by self or healthcare professional, intravenous infusion) and different dosing intervals (daily, weekly, monthly, every 3 months, every 6 months, yearly). This is an impressive menu of medication options and appears to offer something for everyone. Yet even though we have options in osteoporosis medications, patients are still not compliant or persistent.

Researchers differ in the reasons they give for poor compliance and persistence with these medications. These behaviors are not easily identified or explained, but it does appear that there are five primary ways in which people can be noncompliant and nonpersistent: (1) they do not fill the prescription, (2) they do not take the full dose, (3) they take the medication at the wrong time, (4) they forget to take the medication, and (5) they stop taking the medication. Barriers to compliance and persistence are also heterogeneous and include, but are not limited to, side effects of medication, cost, complex dosing schedule (e.g., oral bisphosphonates), forgetting, inadequate understanding of disease and need for medication, doubt that medication can help, and so on [20].

Which of these barriers to compliance and persistence is most common and problematic is still up for debate. Some researchers believe that forgetting is the major cause of not taking medication [e.g., 21]. However, others would dispute that and say that more often, patients make a conscious choice not to take their medicines. Recent evidence from a Harris poll confirms that [22]. According to this report, only 24% of patients reported forgetting to take their medications. Twenty percent reported not wanting to experience side effects; 17% said that cost was a problem; 14% did not believe they really needed the drug. Further, one in three patients reported taking their medications less frequently than prescribed. Other medications behaviors included taking smaller than prescribed doses, stopping the prescription before they were supposed to, delaying in filling a prescription, and not filling a prescription at all. These data strongly support the concept that *forgetting medication* is, in some ways, the least of our problem with compliance and persistence.

The concept of *intentional nonadherence* appeared in the early 1990s in an article by Donvan and Blake [23]. They noted that patients often made reasoned decisions not to take medicine, but the lack of communication between physicians and patients led to healthcare professionals not understanding such decisions. In a more recent examination of this proposition, Lowry et al. [24] reported that respondents in the Veterans' Study to Improve the Control of Hypertension who were nonwhite, had better education, were able to pay bills and had more side effects were significantly more likely to decide intentionally *not* to take their medication.

Although no studies of which I am aware have looked at the intentionally of not taking osteoporosis medications, experts in this field confirm theoretically that intentional nonadherence by osteoporosis patients may well be a strong factor in medication behaviors [4].

CONTROVERSY #4: IS THERE A HEALTHY ADHERER EFFECT?

In 1985, the *New England Journal of Medicine* published a paper by Stamfer and colleagues titled, "A Prospective Study of Postmenopausal Estrogen Therapy and Coronary Heart Disease"[25] in which the authors suggested that there were multiple causes of bias operating in observational studies. The bias of interest here was the *healthy user effect*. This occurs when patients choosing one preventive service also choose others; therefore, they are healthy adherers to preventive efforts in general rather than just to a single medication or disease. Another article in the *New England Journal* also discussed the *healthy adherer effect* [26] in which they suggested that people who adhere to one healthy behavior (such as taking a medication as prescribed) are more likely to adhere to other healthy behaviors. In fact, in this study, patients who adhered well to the placebo were found to have lower mortality rates and fewer cardiovascular events.

How are these concepts relevant to compliance and persistence with osteoporosis medications? Several relatively recent publications have suggested that the *healthy adherer effect* has contaminated the results of observational studies designed to examine medication compliance and fracture reduction. First, Cadarette and colleagues [27] noted that multiple studies of health utilization data have found strong, positive correlations between adherence to osteoporosis medications and fracture reduction [e.g., 28, 29]. Cadarette et al. [27] suggest that there is a plausible alternative hypothesis to that which says good adherers have reduced fractures, and that is the *healthy adherer bias*. Patients who adhere to medication may also adhere to calcium and vitamin D supplementation, exercise, and may avoid behaviors that could increase fracture likelihood. Using claims data from the Pennsylvania Pharmaceutical Assistance Contract for the Elderly (PACE), they looked at the relationship between adherence with medications and fracture rates. Although they found that adherence to bisphosphonates does lower nonvertebral fracture rates on the whole, there was no other evidence of a healthy adherer effect.

In contradiction to this finding, Curtis et al. [30] examined compliance with placebo in the Fracture Intervention Trial (FIT) (n = 3169 in the placebo arm) to see if there were evidence of a healthy adherer effect. Eighty-two percent of the women in the placebo group had 80% or better compliance and, compared to the low compliers in that arm, did show less bone mineral density (BMD) loss in the total hip ($p < 0.04$). Although there were fewer hip fractures in this group than in the low-adherence placebo group, the difference was not statistically significant. Despite the lack of significant findings, the authors still concluded, ". . . our findings provide some support for the existence of the healthy adherer effect in this population" (p. 687).

This conclusion is somewhat surprising and appears not to be supported by the data. In the same issue of *Journal of Bone and Mineral Research*, Silverman and Gold [31] question the findings of Curtis et al. [30]. Previous *observational* studies have shown a healthy adherer effect, despite that fact that the Cadarette et al. study [27] did not support this. But randomized clinical trials have not supported it in the past. Given that the findings of Curtis et al. [30] show only a nonsignificant reduction in fractures—the truly critical variable upon which medication success rests—the assumption that a healthy adherer effect exists seems to have been theorized beyond the data. Future research in this area is essential as little congruence of findings occurs, especially in studies of osteoporosis and fractures.

CONTROVERSY #5: DOES EXTENDING TIME BETWEEN DOSES OR CHANGING THE DELIVERY SYSTEM FOR OSTEOPOROSIS MEDICATIONS IMPROVE COMPLIANCE?

Prior to 1995, only two FDA-approved medications for osteoporosis were available: estrogen/hormone therapy [32] and injectable calcitonin [33]. Estrogen was a daily therapy; calcitonin was given several times a week. Both were hormonal. Although patients had some degree of success with both medications, estrogen/hormone therapy was approved for both prevention and treatment of postmenopausal osteoporosis (PMO), while calcitonin was approved for treatment of PMO in women who were at least 5-year postmenopausal.

With the approval of alendronate in 1995, prevention and management of osteoporosis changed dramatically, and compliance with medications became significantly more important AND challenging [34]. Because of the burden associated with taking daily oral bisphosphonates [35], pharmaceutical companies began to look at medications that would have longer intervals between doses. Between 1995 and 2007, four bisphosphonates were approved by the FDA (alendronate, risedronate, ibandronate, zoledronic acid) with increasing dosing intervals (i.e., daily to weekly to monthly to yearly). However, despite many predictions to the contrary, these changes did not unequivocally lead to improved compliance. While Emkey and colleagues [36] reported that significantly more postmenopausal women preferred monthly dosing to weekly dosing, this study received considerable criticism. In it, women were not told that the efficacy of weekly and monthly bisphosphonates differed in terms of anti-fracture efficacy. Subsequent studies [e.g., 37] did not support this, especially those in which participants were told in advance of efficacy differences.

Several studies also examined differences in drug delivery as a factor in medication compliance and consistence. Kendler and colleagues [38] found, in two large double-blind, double-dummy trials of postmenopausal women with bone loss, that significantly more women preferred and were more satisfied with a 6-month injection rather than a weekly tablet. Additionally, investigators who compared persistence with teriparatide (daily injection) to that with oral anti-osteoporosis therapies found that persistence levels with teriparatide were very high and likely higher than that with oral therapies [39], especially when patients participated in a concurrent educational program [40]. Although these findings may seem counterintuitive (after all, who would choose an injection over an oral medication?), the evidence appears to be robust. Perhaps women who agree to begin an injectable therapy are more committed to it than women who start oral therapies.

SUMMARY

Significant empirical evidence illustrates the problems we face in helping patients remain compliant and persistent with osteoporosis medications regardless of delivery system or dose duration. As noted earlier, this problem is not unique to osteoporosis. However, given the increasing awareness of the prevalence of this disease and its long-term impact when untreated, health care professionals realize that changing patient behavior is of paramount importance in continuing to master this major public health problem. Further, the controversies in the research findings leave both patients and professionals searching for the best way to combat the negative forces that cause many postmenopausal women to stop their osteoporosis therapy. Several well-researched controversies were not addressed; for example, the role of side effects of the osteoporosis drugs is well known and not directly addressed here. As a result, the problems caused by patients not taking medications as directed in osteoporosis may be significantly worse than it appears.

No single answer will solve this problem. Limited success with educational programs and provider–patient interactions suggest that additional efforts in those areas may have a positive effect. It is helpful to remind ourselves that we have not yet found the key to this problem and that healthcare professionals and educators must continue to search for it.

INTRODUCTION

Osteoporosis affects a large proportion of the elderly population and is associated with fractures that are costly in both human and economic terms [1]. In 2005, the United States (U.S.) population sustained an estimated 2 million incident fractures at a cost of $16.9 billion [2]. With annual fracture-related expenditures projected to increase to $25.3 billion by the year 2025, there is widespread recognition that growing elderly populations and constrained health care budgets will continue to challenge health care systems to find cost-effective approaches to osteoporosis care. Cost-effectiveness analysis is a form of economic evaluation that estimates the value of an intervention by weighing the expected net increase in cost of an intervention against its expected net gain in health [3]. The rationale for cost-effectiveness analysis is that when health care resources are limited, expenditures should be planned to maximize health outcomes within available resources. The cost-effectiveness of new treatments relative to current care standards is one attribute that policy makers may consider when making formulary coverage decisions. In this chapter, the methodology of cost-effectiveness analysis is described, recent developments in the cost-effectiveness of osteoporosis care are discussed, and key findings are highlighted.

OVERVIEW OF METHODS FOR COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness ratio

The incremental cost-effectiveness ratio (ICER), which estimates expected cost per unit of health gained, is the primary outcome measure used to characterize value in cost-effectiveness studies. Consider two alternative treatments, A and B, where the average cost of A is higher than the average cost of B. The ICER is defined as follows:

$$\text{ICER} = \frac{(\text{Cost}_A - \text{Cost}_B)}{(\text{Effectiveness}_A - \text{Effectiveness}_B)}$$

Using this definition, the value of each more costly intervention is judged relative to the improvement in health that it provides over and above health outcomes associated with the less costly alternative.

Choice of comparator

When assessing cost-effectiveness of a new osteoporosis intervention, the standard of care that is used as the basis for comparison (i.e., the comparator) may have a marked

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

impact on the intervention's estimated value. Cost-effectiveness analyses of osteoporosis prevention conducted prior to 2002, when the Women's Health Initiative findings were published [4], typically included hormone therapy as a comparator. The choice of comparator today depends on whether treatment is being considered for a man or woman and whether or not the individual has established osteoporosis. Unless cost-effectiveness is measured relative to a reasonable alternative, the estimated ICER may not provide a meaningful estimate of an intervention's value. While ICERs computed relative to "no intervention" have meaning for the minority of patients who have no other viable treatment option, for the majority of patients in whom less costly treatments are possible, these ICERs can be potentially misleading estimates of value. In general, when new interventions are compared with "no intervention" (technically an average rather than an ICER), they will have more favorable values than when compared with active treatment comparators.

Model-based analyses

Estimating an ICER typically requires mathematical modeling to project expected health and cost implications of alternative treatments over a longer time horizon than can be observed in any clinical trial [5], and/or to expand the treatments and/or population subgroups considered. Most analyses utilize Markov state-transition models [6], which comprise a discrete number of health states, each with an associated cost and health state value (i.e., health utility), along with annual probabilities of transition among the health states. Other modeling methods that detail the biological processes related to bone health have also been proposed [7].

Estimating the cost of osteoporosis treatment

To estimate the net difference in cost of a new treatment relative to a comparator, several types of direct medical costs should be considered (Table 55.1). The cost of medical care in future years of life may also be included. Against these costs, potential savings that may accrue due to fracture prevention are considered and include the cost of acute fracture care, rehabilitation services (if required), and costs of ongoing fracture-related disability (if present). Differences in the cost of providing health care from country to country make the generalizability of cost-effectiveness findings across countries challenging.

Indirect costs of an illness are those that are associated with a loss in productivity due to morbidity and mortality. Such costs may be incurred by the individual who sustains a fracture and/or by their caregivers. However, there is scant evidence available to address the latter. The human capital approach, which values productivity changes based on lost earnings [8], has been applied to assess the cost of fractures in some U.S. cost-of-illness studies [9–11], but to date such costs have not been included in cost-effectiveness analyses of osteoporosis treatment. Some argue that productivity costs are adequately reflected in the denominator of the cost-effectiveness ratio when quality-adjusted life years (QALYs) are used to measure effectiveness [3].

Table 55.1. Components of Direct Medical Costs to Consider When Assessing the Cost-Effectiveness of Osteoporosis Treatment

Cost Component
Medication
Acquisition
Health care services for routine monitoring
Health care services for treatment of side effects/ sequelae
Fracture
Acute care services
Rehabilitation services
Ongoing disability services
Extended Life Years
Health care services

Whether or not each of these potential costs/savings is included in the analysis depends on the perspective that is taken. For informing public policy decision makers, the societal perspective is generally most desirable. The marked impact that perspective may have on the cost-effectiveness of osteoporosis treatment under a health care system such as in the U.S., where different payers are responsible for health care at different ages, is shown by an example that underscores the disparity between who pays for the prevention and who realizes potential long-term savings. Consider 5-year treatment of high-risk 55-year-old women from two perspectives: (1) a private insurer who pays for health care services up until age 65, and (2) a government insurer who pays after age 65 (i.e., Medicare in the U.S.). For the private insurer who pays for the costs of the treatment and monitoring but will realize limited savings due to fractures averted, treatment does not appear cost-effective. In contrast, the government payer only benefits due to fractures averted and sees treatment as cost-saving. This simplistic example suggests that optimal decisions for public health require a broad perspective that considers the full time horizon of costs and benefits.

Estimating the effectiveness of osteoporosis treatment

Quality-adjusted life years

The recommended measure for assessing the effectiveness of health interventions is the quality-adjusted life year (QALY) [3], which takes both length of life and quality of life into account. The use of QALYs facilitates comparisons of economic value across disease areas (e.g., interventions to control diabetes can be compared with

osteoporosis treatments). Cost-effectiveness studies that report ICERs as cost per QALY gained are often referred to as cost-utility analyses, because to estimate QALYs, health state values or "utilities" that reflect preferences for various health states, are used.

While QALYs have the potential to incorporate the intangible fracture-related costs of pain and suffering, data on health state values for fracture-related health outcomes are required. Evidence on the impact of fractures on QALYs has been summarized in several reviews [12, 13]. The absolute QALY losses associated with fracture vary based on who is asked (e.g., a patient who sustained a vertebral fracture vs a patient imagining a vertebral fracture) and how they are asked (e.g., visual analog scale, time trade-off), yet published studies consistently report health state values for fracture-related outcomes that are significantly below ideal health. Although a growing literature addresses preference-based measures of health in osteoporosis, many cost-effectiveness studies continue to rely on expert opinion regarding the quality-of-life impact of fractures both initially and in the long term [14–16].

When evaluating the value of osteoporosis treatment, it is important to consider the potential adverse impact that treatment side effects may have on estimates of quality-adjusted life expectancy. The potential for side effects to offset quality-of-life gains due to fracture prevention was first highlighted in studies of the role of hormone therapy in osteoporosis prevention [17, 18].

Number of fractures prevented

The value of osteoporosis treatment is sometimes reported in disease-specific terms as number of fractures prevented, which is problematic for two reasons. First, some osteoporosis interventions, such as raloxifene, have extraskeletal health effects that go unaccounted for when value is reported in terms of cost per fracture prevented. Second, inherent differences in human and economic costs of different fracture types (e.g., wrist versus hip) make it challenging to interpret cost per fracture prevented. To address this, analysts sometimes report costs in terms of specific fracture types (e.g., cost per hip fracture prevented or per vertebral fracture prevented) or in "hip fracture equivalent units" [19].

THE COST-EFFECTIVENESS OF OSTEOPOROSIS TREATMENT

Cost-effectiveness analysis and clinical practice guidelines

As constraints are increasingly felt on health care budgets, guideline developers recognize that costs cannot be entirely ignored [20]. One approach to setting treatment thresholds that has seen growing application in the osteoporosis literature is to identify the absolute fracture risk at which the cost per QALY gained falls below a "willingness to pay" per QALY gained threshold [12, 14, 15, 19, 21, 22]. This approach was utilized by the National Osteoporosis Foundation (NOF) to identify a 10-year absolute hip fracture risk at which treatment cost $60,000 per QALY gained or lower for treatment relative to no intervention [22]. The World Health Organization (WHO) fracture risk assessment tool, FRAX®, facilitates such risk predictions for previously untreated populations [23] and a report from the NOF guide committee provided insight into specific clinical factors that meet the intervention thresholds (3% for 10-year hip fracture risk or 20% for hip, wrist, spine, and shoulder fracture risks combined) based on an adaptation of FRAX® for the U.S. population [24, 25].

Cost-effectiveness of osteoporosis treatment

Fracture risk, treatment cost, the impact that fractures have on health-related quality of life, treatment persistence, and the durability of treatment [26] all influence the value of osteoporosis treatment. A U.S. analysis of an unspecified treatment that reduces fracture incidence by 35% relative to no intervention [22] demonstrates the marked improvement in cost-effectiveness that average-risk women attain with advancing age due to their higher absolute fracture risk is shown in Fig. 55.1. For example, a treatment costing $900 per year costs in excess of $580,000 per QALY gained for a 50-year-old woman whose 10-year hip fracture risk is 2.5%, compared to only $4,000 per QALY gained for an 80-year-old white woman whose 10-year hip fracture risk is 4%.

Prior to 1993, most osteoporosis cost-effectiveness studies assessed the value of hormone therapy [27, 28]. More recently, several reviews and technology assessments have addressed the value of other osteoporosis treatments with evaluation of bisphosphonates being a frequent focus [28–32]. Studies also address the value of calcium and vitamin D [33], raloxifene [14, 34–38], teriparatide [39, 40], calcitonin [41], strontium ranelate [42, 43], vitamin K [44], and denosumab [45], as well as the cost-effectiveness of selective treatment strategies [46–48] and special populations [49].

Bisphosphonate treatment is generally cost-effective when used in moderately high-risk populations such as women over age 65 with osteoporosis [30]. While treatment of elderly populations with calcium and vitamin D is potentially cost-saving [33], studies of raloxifene differ in their findings depending on the comparators included, the side effects considered, and an individual woman's risks [34–37, 50]. Discrepant findings have also been reported for teriparitide use among women at high risk of fracture [39, 40]. Cost-effectiveness studies that distinguish between agents on the basis of treatment persistence are of relevance due to the advent of agents with differing modes of administration (e.g., weekly oral agent versus annual injection) [51]. Likewise, there is increasing interest in programs to support treatment adherence [52].

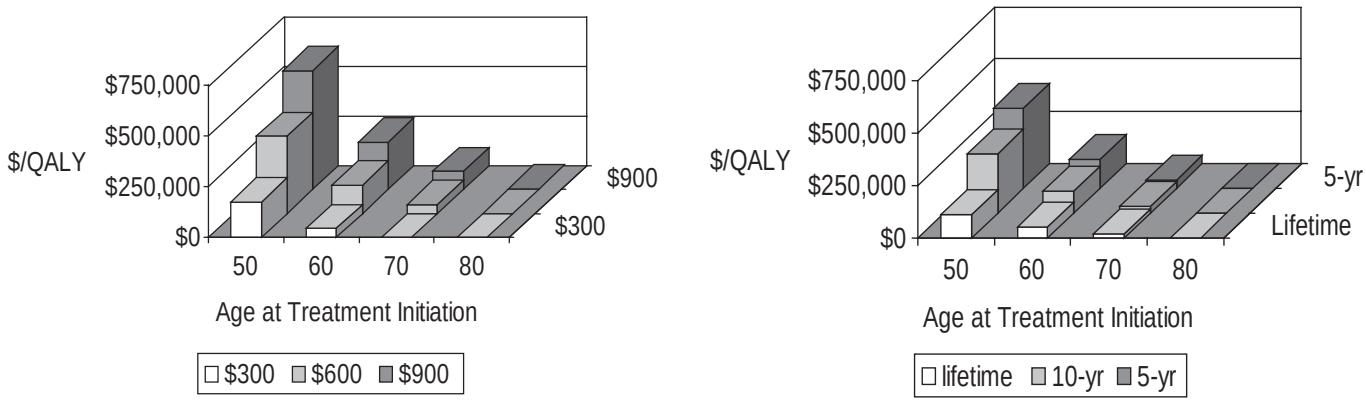

Fig. 55.1. The impact that annual treatment cost ($300, $600, or $900) has on cost per QALY gained at different ages of treatment initiation when treatment reduces fracture incidence by 35% and 5-year losses in health-related quality of life following fracture are modeled (Ref. 22).

SUMMARY

Due to the size of the elderly population that is at-risk for complications of osteoporosis-related fractures, it is imperative that cost-effective approaches to osteoporosis management be identified. While a growing literature addresses the value of specific treatments for various population subgroups, clinical practice guidelines identify cost-effective intervention thresholds on the basis of absolute 10-year fracture risk. For the U.S. population, cost-effective treatment intervention thresholds of 3% or greater for 10-year hip fracture risk, or 20% or greater for hip, wrist, clinical spine, and shoulder fracture risk combined, have been recommended [25]. Risk assessment tools for predicting 10-year fracture risk [53], provide a tool for efficiently targeting therapy to those individuals who stand to benefit most from osteoporosis treatment.

Future Therapies of Osteoporosis

Kong Wah Ng and T. John Martin

Antiresorptives 461
Anabolic Agents 463
Conclusion 464
References 465

Insights into the mechanisms that govern the formation and function of osteoblasts and osteoclasts and their communication processes have led to specific points of intervention that are guiding the development of current and next generation therapies for osteoporosis. The clinical outcomes of these new therapies may be predicted because the actions of the selected targets are known, and in some cases preclinical evidence is fulfilling those predictions. The aims are to develop therapies to improve fracture risk reduction if possible, to avoid the possibility of long-term effects on bone structure, to find drugs whose effects reverse with cessation of therapy, and drugs that stimulate bone formation or that inhibit resorption without inhibiting bone formation at the same time. This chapter will discuss several candidate molecules that have been identified with the potential to act as antiresorptive or anabolic agents. Studies with some of these molecules are still either in preclinical or in early investigational stages without fracture data. Nonetheless, preliminary results hold the promise that at least some of these new therapies may develop into effective means of treating and preventing osteoporosis.

ANTIRESORPTIVES

Several bisphosphonates and a selective estrogen receptor modulator (SERM) have been shown in careful, thorough clinical trials to reduce fracture incidence in osteoporosis by 30–50% [1]. Although it might be asked whether we need other antiresorptives, the real and potential limitations of existing therapies are sufficient to warrant the continued search for new approaches. Newer therapies may be better suited for particular indications or provide greater efficacy, safety, or convenience. There may be a limit to the safe reduction in fracture risk that can be achieved with resorption inhibitors, and it remains to be seen whether that limit can be reached simply by effecting more powerful inhibition of bone resorption [2]. The candidate resorption inhibitors to be considered below can be divided into those whose predominant action is to inhibit osteoclast formation, those that inhibit osteoclast activity, and a potentially interesting new class that might inhibit resorption without concomitant inhibition of bone formation.

Inhibition of osteoclast formation

Monoclonal antibody inhibiting RANKL action

Osteoblasts express a membrane protein, receptor activator of NF-κB ligand (RANKL) regulated by osteotropic hormones, parathyroid hormone (PTH) and calcitriol, as well as cytokines such as interleukin-6. RANKL plays a critical role in osteoclast differentiation, activation, and survival. The binding of RANKL to its receptor, RANK, expressed in mononuclear hematopoietic precursors, initiates the processes that ultimately leads to the formation of multinucleate osteoclasts. Osteoprotegerin (OPG) acts as a decoy receptor for RANKL to suppress osteoclast formation. Studies in genetically altered mice have clearly established the essential physiological roles of RANKL and OPG in controlling osteoclast formation and

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

activity, and revealed a pathway obviously rich in targets for pharmaceutical development. Denosumab (Amgen) is a fully human monoclonal antibody that binds with high affinity and specificity to RANKL to inhibit its action. In the phase III study, subcutaneous injections of denosumab to postmenopausal women with low bone density (T-score below 2.5 at the spine) every 6 months for 36 months was associated with significant reduction in fractures of vertebrae (relative decrease 68%), hip (relative decrease 40%) and nonvertebral sites (relative decrease 20%) [3]. In this clinical trial with 7,868 women, no significant side effects involving the immune system were noted and no cases of osteonecrosis of the jaw. The earlier phase II study had shown that neutralizing RANKL with denosumab resulted in an exceptionally prolonged and powerful action to decrease bone resorption and increase bone mineral density (BMD) at the lumbar spine, hip, and distal third of radius [4]. Bone resorption marker indices decreased rapidly following denosumab injection, as did markers of bone formation, reflecting the coupling of formation to resorption. Extension of this study to 6 years resulted in progressive gain in BMD and sustained reduction in resorption markers [5].

Thus neutralization of RANKL presents as a resorption inhibitor at least as powerful as the most effective bisphosphonates, with a prolonged action, but one that is clearly different in its pharmacodynamics and more readily reversible than is the case with bisphosphonates [6]. Indeed, cessation of denosumab treatment results in rapid reversal of resorption markers to levels even above those of control subjects, and significant BMD decrease within 12 months [7].

Inhibition of osteoclast action

Can formation be uncoupled from resorption?

With existing marketed resorption inhibitory drugs, the coupling of bone formation to resorption is illustrated by the decrease in bone formation that accompanies resorption inhibition, e.g., with bisphosphonates, estrogens, and SERMs. This is the case also with the anti-RANKL, denosumab. Will it be possible to develop drugs that inhibit bone resorption without inhibiting formation—in other words, uncoupling bone formation from resorption? There are some indications that it might be possible.

An essential component of osteoclastic bone resorption is acidification of the resorption lacuna, which reduces the pH to about 4 in order to dissolve the bone mineral. Passive transport of chloride through chloride channels preserves electroneutrality in the course of the acidification process, and preventing chloride transport will lead to a rapid hyperpolarization of the membrane, preventing further secretion of protons, thus resulting in an inhibition of further bone resorption. A vacuolar H^+ATPase in the osteoclast membrane plays a key role in this process by mediating the active transport of protons. Inhibitors of this enzyme, for example, bafilomycin, have been shown to inhibit osteoclastic bone resorption *in vitro* and *in vivo*. A relatively osteoclast-selective H^+ATPase inhibitor has been shown to inhibit ovariectomy-induced bone loss in rats [8]. In mice deficient for either *c-src* [9] or the chloride-7 channel (*CLCN7*) [10] bone resorption is inhibited without any inhibition of the rate or extent of formation. In each of these mouse mutations, osteoclast numbers are maintained, but the osteoclasts are unable to resorb bone. This is the case also in human subjects with inactivating mutations either of *CLCN7* (OMIM 166600 and OMIM 25900) [11] or the vacuolar H^+ATPase [12].

One possibility is that osteoclasts are able to generate a factor (or factors) that can contribute to bone formation, but are not involved in bone resorption [13–15]. Early data with an orally delivered CLCN7 inhibitor showed that it inhibited bone loss in the ovariectomized rat without inhibiting bone formation [10]. A target in a related category is Src, a protein tyrosine kinase. $Src^{-/-}$ mice formed increased numbers of osteoclasts, but the cells failed to resorb bone because they did not form ruffled borders [16]. In a phase I study in healthy males, AZD0530, a highly selective, dual-specific, orally available inhibitor of Src and Abl kinases was shown to suppress bone resorption markers reversibly with variable changes in bone formation markers [17].

It is possible that such inhibitors of resorption, at the moment cathepsin K, CLCN7, vacuolar H^+ATPase, and Src, might conceivably provide a new class of resorption inhibitory drug that does not inhibit bone formation. If they are safe and at least as effective in fracture reduction as other inhibitors, they could provide a real advance. For example they might more effectively be combined with anabolic therapy than those resorption inhibitors (e.g., bisphosphonates and, likely, anti-RANKL) that lead to inhibition of bone formation.

Cathepsin K is selectively expressed in osteoclasts and is the predominant cysteine protease in these cells. It accumulates in lysosomal vesicles and is localized at the ruffled border in actively resorbing osteoclasts, discharging into the acidified, sealed resorption space beneath the osteoclast when the lysosomal vesicles fuse with the cell membrane. Defects in the gene encoding cathepsin K are linked to the clinical condition pycnodysostosis (OMIM 265800), an autosomal recessive dysplasia characterized by skeletal defects including dense, brittle bones, short stature and poor bone remodeling [18]. Similarly, the deletion of the cathepsin K gene in mice results in osteopetrosis [19]. Preclinical data confirms that cathepsin K inhibition effectively inhibits bone resorption. In preclinical models in mouse and rabbit and in some monkey studies, cathepsin K inhibition reduced bone resorption without inhibiting bone formation [20].

Cathepsin K inhibitors; current studies with odanacatib

Peptide inhibitors designed to inhibit cysteine proteases by binding at the substrate site to mimic a cathepsin

K-substrate complex have been in clinical development [21, 22]. Preclinical studies showed that cathepsin K inhibitors act as antiresorptive agents that prevent bone loss while allowing bone formation to continue. A 12-month study with an orally bioavailable specific inhibitor of human cathepsin K, balicatib (compound AAE581, Novartis), in postmenopausal women showed an increase in lumbar spine and hip BMD associated with statistically significant decreases in markers of bone resorption but not in those of bone formation [23]. Other potent cathepsin K inhibitors investigated include SB-462795 (relacatib, GlaxoSmithKline) and CRA-013783 (Merck). The most advanced in development is odanacatib (Merck, MK-0822), which has completed phase II and is now in a phase III clinical trial.

Odanacatib is a potent, selective cathepsin K inhibitor with a long half-life (45–50 hours) that has allowed it to be used in weekly oral dosage in clinical study. In a phase II study in postmenopausal women with spinal BMD T-scores between –2.0 and –3.5, treatment for 3 years at the highest (50 mg) dose resulted in significant increases in BMD at the hip and spine, with a 50% reduction in a urinary resorption marker but no change in bone-specific alkaline phosphatase [24]. That treatment is reversible is shown by the rapid increase in a resorption marker and the loss of bone toward baseline values at all sites when drug treatment was stopped.

The phase III fracture study, due to be completed in the second half of 2012, is awaited with great interest. Assuming its positive outcome, among features of great interest with this new class of compound will be how well maintained bone formation is, what will this mean for effects on bone quality, and whether combination therapy with PTH will be more effective with a resorption inhibitor that does not inhibit bone formation.

ANABOLIC AGENTS

Antiresorptive agents do not reconstruct the skeleton, but until recently no therapeutic approach was available to restore bone once it had been lost. That situation has changed with the development of PTH as a highly effective anabolic therapy for the skeleton, despite its better-known action as a resorptive hormone. The anabolic effectiveness of PTH requires that it be administered intermittently, and this has been achieved with the use of daily injections that rapidly achieve a peak level in blood, which is not maintained [25].

Recent research has shed new light on the control of bone formation, and the effect of PTH treatment is such that it is important to learn from the action of PTH and to determine whether any of the newly recognized pathways play any part in PTH action. Such studies are at a very early stage, but some potential targets are emerging for development of anabolic agents. There is particular interest in the possibility of modulating the activity of components of the Wnt canonical signaling pathway to produce a net anabolic effect. The first link between Wnt signaling and human bone disease came from observations that inactivating mutations in the low density lipoprotein receptor-related protein 5 (LRP5) cause the osteoporosis-pseudoglioma syndrome (OPPG, OMIM 259770) characterized by severely decreased bone mass [26]. Conversely, a syndrome of high bone mass was found to be caused by a gain-of-function mutation of LRP5 (OMIM 601884) [27]. These genetic syndromes were reproduced with the appropriate genetic manipulations in mice [28, 29].

Wnt signaling targets

The Wnt/β-catenin signaling pathway offers several targets that may be suitable for pharmacological intervention at a number of specific points. These include extracellular agonists and the points of interaction of antagonists, especially the secreted frizzled-related proteins (SFRPs), dickkopf (DKK) proteins, and sclerostin, as well as regulation within the cell of glycogen synthase kinase-3β (GSK-3β), the enzyme that plays a crucial role in determining availability of β-catenin for the transcriptional effects that are essential for Wnt signaling (see http://www.stanford.edu/group/nusselab/cgi-bin/wnt/). The primary aim of these interventions is to increase Wnt/β-catenin canonical signaling in order to increase bone mass. Initial success in animal models has been reported with the inhibition of DKK-1, GSK-3, and sclerostin. Another potential target is SFRP-1. Deletion of *Sfrp-1* enhances osteoblast proliferation, differentiation and function, while it suppresses osteoblast and osteocyte apoptosis [30].

Inhibition of dickkopf 1 (DKK-1) action

LRP5 can form a ternary complex with DKK-1 and Kremen (a receptor for DKK), which triggers rapid internalization and depletion of LRP5, leading to inhibition of the canonical Wnt signaling pathway. Inhibition of the interactions between DKK-1 and LRP5 would release LRP5 to activate the Wnt pathway. Genetic studies with mice lacking a single allele of DKK-1 showed a markedly increased trabecular bone volume and elevated trabecular bone formation rate [31], while transgenic overexpression of DKK-1 under the control of the *Col1A1* promoter caused severe osteopenia [32]. The production of DKK-1 by multiple myeloma cells has been invoked as a contributing factor to the reduced bone formation in the lytic bone lesions of myeloma [33]. A study using antibodies raised against DKK-1 in the treatment of a mouse model of multiple myeloma showed increased numbers of osteoblasts, reduced number of osteoclasts, and reduced myeloma burden in the antibody-treated mice [34]. Initial drug development attempts in osteoporosis also use monoclonal anti-DKK-1 reagents, but the possibility of directing small molecules to prevent the DKK-1-LRP5 interaction is being explored.

Inhibition of GSK-3

Inhibition of GSK-3 would prevent the phosphorylation of β-catenin, leading to stabilization of β-catenin independently of Wnt interactions with the receptor complex. Mice treated with lithium chloride as a GSK-3 inhibitor showed increased bone formation and bone mass [35]. Treatment of ovariectomized rats with an orally active dual GSK α/β inhibitor, LY603281-31-8, for 2 months resulted in an increase in the number of trabeculae and connectivity as well as trabecular area and thickness. Bone mineral density at cancellous and cortical sites was increased, and this was associated with increased strength. The increased bone formation shown on histomorphometric analysis was associated with increased expression of mRNA markers of the osteoblast phenotype, such as bone sialoprotein, type 1 collagen, osteocalcin, alkaline phosphate, and runx-2 [36]. When the same drug was compared with PTH in a cDNA microarray study, ovariectomy in 6-month-old rats resulted in decreased markers of osteogenesis and chondrogenesis, as well as increased adipogenesis, both of which were reversed by PTH and the GSK-3 α/β inhibitor [37].

Inhibition of sclerostin

Sclerostin, the protein product of *SOST*, is produced in bone exclusively by osteocytes and is a circulating inhibitor of the Wnt-signaling pathway that achieves this by binding to LRP5 and LRP6 [38]. High bone density in sclerosteosis is caused by an inactivating mutation in *SOST* gene (OMIM 607363) [39]. Inhibition of production or action of sclerostin resulting in enhanced Wnt canonical signaling would be predicted to lead to increased bone mass. Indeed, in preclinical studies, monoclonal antibody against sclerostin has been shown to promote bone formation rapidly in monkeys and ovariectomized rats. Considerable increases in bone formation rates and in the amounts of trabecular bone took place rapidly without increases in resorption parameters [40].

At the time of writing, a phase I study of anti-sclerostin (AMG 785, Amgen) has been published [41], in which healthy men and women were treated for up to 85 days with escalating doses of AMG 785, resulting in dose-related increases in bone formation markers and a decrease in the resorption marker, serum CTx. The latter observation is interesting, with the authors suggesting that it contributes to a "large anabolic window." It may relate to changes in osteoblast differentiation, with less RANKL-producing cells of the osteoblast lineage available for presentation to osteoclast precursors. In this short study, BMD increased significantly at the spine (5.3%) and hip (2.8%), with five subjects at the highest dose developing detectable antibodies, two of which were neutralizing. The treatment with AMG 785 was generally well tolerated, and further clinical studies will be expected with what appears to be a most promising way of increasing the amount of bone.

Of particular interest is the fact that PTH rapidly reduces sclerostin mRNA and protein production by osteoblasts *in vitro* and in bone *in vivo* [42, 43], raising the possibility that transient reduction of sclerostin output by osteocytes in response to intermittent PTH could mediate enhanced osteoblast differentiation and bone formation [44] and reduced osteoblast apoptosis [45]. Such a mechanism would offer real possibilities as a drug target, and the mechanism of this inhibition is all the more interesting with the recent finding [46] that the cyclic AMP-mediated effect of PTH to diminish sclerostin production operates through a long range enhancer, MEF2, the discovery of which came from the pursuit of the nature of the sclerosteosis mutation. There may be small molecule approaches amenable to sclerostin regulation, in addition to antibody neutralization of its activity.

Safety and specificity

Any new therapy emerging from manipulation of the Wnt canonical signaling pathway will need to ensure firstly that it is safe, and secondly, that its action can be targeted specifically to bone. Wnt proteins are critical signaling proteins involved in developmental biology, with roles in early axis specification, brain patterning, intestinal development, and limb development. In adults, Wnt proteins play a vital role in tissue maintenance, with aberrations in Wnt signaling leading to diseases such as adenomatous polyposis [47]. Inhibition of GSK-3 results in increased cyclin D1, cyclin E, and c-Myc, and overexpression of these cell cycle regulators has been linked to tumour formation [48]. All relevant possibilities of side effects of enhanced Wnt signaling need to be kept in mind throughout preclinical studies.

CONCLUSION

The approach of targeting specific peptides that are known to play important roles in osteoblast formation or osteoclast action have yielded several promising candidates with the potential to become effective antiresorptive or anabolic agents to treat osteoporosis. Exciting possibilities of new anabolic therapies are evident, and the benefit of this approach is clear from the satisfactory increase in bone formation that is achieved with parathyroid hormone treatment. The early evidence that it might be possible to develop resorption inhibitors that can uncouple bone resorption from bone formation is exciting, potentially offering an advantage over currently available antiresorptive agents. Nonetheless, all these predictions are based largely on preclinical data, and it is hoped that properly conducted clinical trials in the coming years will see the emergence of new therapies that are effective, durable, and safe, at an affordable cost.

INTRODUCTION

Taken literally, the phrase "juvenile osteoporosis" means "osteoporosis in children and adolescents," and thus does not refer to any particular form of osteoporosis in this age group. However, in the scientific literature and in clinical practice, the term "juvenile osteoporosis" is usually used to refer to idiopathic juvenile osteoporosis (IJO). This chapter therefore discusses IJO as a primary disease rather than the entirety of largely secondary osteoporotic conditions that may occur in young people.

Osteoporosis in childhood and adolescence may result from mutations in genes principally affecting the amount and quality of the fibrous component of bone, presenting clinically as osteogenesis imperfecta (OI), or secondary to a spectrum of diverse conditions, such as prolonged immobilization, and chronic inflammatory disease. Bone loss may be worsened by treatment with anticonvulsants and steroids, respectively, but may also improve as the underlying condition improves. Life-threatening diseases such as leukemia also may present with osteoporotic fractures, particularly of the vertebrae. It is clearly important to exclude such causes of osteoporosis. If no underlying cause can be detected, IJO is said to be present.

IJO was first described as a separate entity by Dent and Friedman [1] 4 decades ago. According to the classical description, IJO is a self-limiting disease that develops in a prepubertal, previously healthy child, leads to metaphyseal and vertebral compression fractures, and is characterized radiologically by radiolucent areas in the metaphyses of long bones, dubbed "neo-osseous osteoporosis" [2]. This implies a disorder of trabecular bone architecture and mass, possibly related to changes in the hormonal milieu around the time of the growth spurt.

It is clear, however, that there are many children and adolescents who have low bone mass [defined as a body size-adjusted bone mineral content (BMC) or bone mineral density (BMD) measured by DXA at the spine or total body that is more than 2 SD below the mean; i.e., a Z-score below –2)] and who sustain recurrent fractures after minimal trauma, but whose clinical findings do not correspond to the classical description of Dent and Friedman.

In the Pediatric Position Statements of the International Society for Clinical Densitometry published in 2007, these patients would simply fulfill the diagnosis of "osteoporosis." Thus, it may be useful to distinguish "classical IJO" (for patients whose presentation is similar to the description of Dent and Friedman) from "osteoporosis in the wider sense" (for patients who do not match the description of Dent and Friedman but nevertheless have unexplained fractures with low bone mass).

Most reviews on the topic state that IJO is an extremely rare disease, because fewer than 200 patients have been published under that label. This is probably because few patients present with the classical picture. However, most clinicians who see children and adolescents with

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

fractures could probably list a few of their patients who have osteoporosis without recognizable etiology. In our clinical settings, IJO is approximately 10 times less common than OI.

PATHOPHYSIOLOGY

The etiology of IJO is unknown. One study found a normal rise in serum osteocalcin in six IJO patients after calcitriol was administered orally, which was postulated to indicate "normal osteoblast function " [3]. However, the fact that osteoblasts in this test released normal amounts of osteocalcin into the circulation does not necessarily mean that they also deposited matrix on the bone surface in a normal fashion. Early histomorphometric reports on IJO were limited to static methods to quantify bone metabolism, described single cases, [4–8] or did not have adequate control data. No conclusive picture emerged from these reports.

More recent studies using dynamic histomorphometry showed that IJO was characterized by a markedly reduced activation frequency and, therefore, low remodeling activity [9]. In addition, the amount of bone formed at each remodeling site was abnormally low. No evidence was found for increased bone resorption. Interestingly, the bone formation defect was limited to bone surfaces that were exposed to the bone marrow environment; no abnormalities were detected in intracortical and periosteal surfaces [10].

These results suggested that, in IJO, impaired osteoblast performance decreases the ability of cancellous bone to adapt to the increasing mechanical needs during growth. This results in load failure at sites where cancellous bone is essential for stability. Nevertheless, the initial trigger of the decrease in osteoblast performance remains elusive. Two recent reports have indicated that heterozygous mutations in the low-density lipoprotein receptor-related protein 5 (LRP5) can result in low bone mass with fractures in some children [11, 12]. The frequency of such mutations in children with classical IJO, as opposed to childhood osteoporosis, generally remains to be determined.

CLINICAL FEATURES

Classical IJO typically develops in a prepubertal (mostly between 8 and 12 years of age), previously healthy child of either sex [13]. However, in one series, 21 children who were presented as having IJO were recorded as having a mean age at onset of 7 years with a range of 1–13 years [14].

Symptoms generally begin with an insidious onset of pain in the lower back, hips, and feet, and difficulty walking. Knee and ankle pain and fractures of the lower extremities may be present, as well as diffuse muscle weakness. Vertebral compression fractures are frequent, resulting in a short back (Fig. 57.1). Long bone fractures, mostly at metaphyseal sites, may occur. Physical examination may be entirely normal or show thoracolumbar kyphosis or kyphoscoliosis, pigeon chest deformity, loss of height, deformities of the long bones, and limp.

Fig. 57.1. Lateral lumbar spine radiograph of a 10-year-old girl with IJO. Compression fractures of all vertebral bodies and severe osteoporosis are evidence. At the time of this radiograph, lumbar spine areal BMD Z-score was –4.9 (at a height Z-score of –2.5).

RADIOLOGICAL FEATURES

Children with fully expressed classical IJO present with generalized osteopenia and collapsed or biconcave vertebrae. Disc spaces may be widened asymmetrically because of wedging of the vertebral bodies. Long bones usually have normal diameter and cortical width, unlike the thin, gracile bones of children with OI. The typical radiographic finding in IJO is neoosseous osteoporosis, a

radiolucent band at sites of newly formed metaphyseal bone. This localized metaphyseal weakness can give rise to fractures, often at the distal tibias and adjacent to the knee and hip joints. Nevertheless, "neoosseous osteoporosis" is not a prerequisite for diagnosing IJO.

BIOCHEMICAL FINDINGS

Biochemical studies of bone and mineral metabolism have not detected any consistent abnormality in children with IJO [15, 16]; bone resorption was increased in a young woman prior to pregnancy and increased further, with associated bone loss (25% decrease in spine BMD) and vertebral crush fractures [17].

BONE BIOPSY

Iliac bone biopsies show low trabecular bone volume but largely preserved core width (i.e., a normal outer size of the biopsy specimen) and cortical width [9, 10]. Tetracycline double labeling shows a low extent of mineralizing surface (a sign of decreased remodeling activity) and low mineral apposition rate (a sign of weakness of the individual osteoblast team at a remodeling site). There is no indication of a mineralization defect. Osteoclasts are normal in appearance and number.

DIFFERENTIAL DIAGNOSIS

The diagnosis of IJO is made by the exclusion of known etiologies for low bone mass and fractures. The list of conditions that may be associated with bone fragility in children and adolescents is shown in Table 57.1. The exclusion of most of these disorders is usually not difficult. The most frequent diagnostic problem facing a clinician is probably to separate IJO from OI type I.

Table 57.2 presents the typical distinguishing features between IJO and OI type I. Apart from bone fragility and low bone mass, most patients with OI type I have associated extraskeletal connective tissue signs, such as blue or grey scleral hue, dentinogenesis imperfecta, joint hyperlaxity, and Wormian bones (on skull X-rays). However, the extraskeletal involvement can be absent or too subtle to be clinically recognizable in some OI patients. In this situation, genetic analysis of the genes that code for the two collagen type I α-chains (*COLIAI* and *COLIA2*) can be helpful. Mutations affecting a glycine residue in either gene or those leading to a quantitative defect in *COL1A2* expression are diagnostic of OI. DNA-based collagen type I analysis now detects mutations in more than 99% of those individuals where mutations exist. LRP5 sequencing may be informative in 10–15% of cases [11, 12].

Table 57.1. Forms of Osteoporosis in Children, According to Current Literature

I. Primary
Osteogenesis imperfecta
Idiopathic juvenile osteoporosis
II. Secondary
Endocrine disorders
Cushing syndrome
Thyrotoxicosis
Anorexia nervosa
Inflammatory disorders
Juvenile arthritis
Dermatomyositis
Systemic lupus erythematosis
Inflammatory bowel disease
Cystic fibrosis
Chronic hepatitis
Malabsorption syndromes
Biliary atresia
Inborn errors of metabolism
Homocystinuria
Glycogen storage disease type 1
Immobilization
Cerebral palsy
Duchenne dystrophy
Hematology/oncology
Acute lymphoblastic leukemia
Thalassemia
Severe congenital neutropenia

An iliac bone biopsy, preferably after tetracycline double labeling, may also contribute to clarifying the diagnosis. Microscopically, a "lack of activity" is usually noted in IJO, whereas there is "hypercellularity" in OI. In histomorphometric terms, this translates into low activation frequency and bone surface based remodeling parameters in IJO and an increase in these values in OI. Also, hyperosteocytosis is a common feature in OI, whereas the amount of osteocytes appears to be normal in IJO.

Fractures and low bone mass may also occur in healthy prepubertal children. Indeed, during late prepuberty and early puberty, fracture rates are almost as high as in postmenopausal women [18–20]. Similar to IJO, such fractures frequently involve metaphyseal bone sites, especially the distal radius. This may reflect problems in the adaptation of the skeleton, in particular the metaphyseal cortex, to the increasing mechanical needs during growth [21]. Growing children and adolescents who have had a few forearm fractures and who have borderline low areal BMD at the spine are frequently encountered in pediatric bone clinics. We propose that classical IJO should only be diagnosed when vertebral compression fractures are present (with or without extremity fractures).

Table 57.2. Differential Diagnosis Between Idiopathic Juvenile Osteoporosis (IJO) and Osteogenesis Imperfecta (OI) Type I

	IJO	OI type I
Family history	Negative	Often positive
Onset	Late prepubertal	Birth or soon after
Duration	1–5 yr	Lifelong
Clinical findings	Metaphyseal fractures	Long bone diaphyseal fractures
	No signs of connective tissue involvement	Blue sclerae, joint hyperlaxity, sometimes abnormal dentition
	Abnormal gait	
Growth rate	Normal	Normal or low
Radiologic findings	Vertebral compression fractures	Vertebral compression fractures
	Long bones: predominantly	"Narrow bones" (low diameter of metaphyseal involvement ["neodiaphyses osseous osteoporosis"]
	No Wormian bones	Wormian bones (skull)
Bone biopsy	Decreased bone turnover	Increased bone turnover
	Normal amount of osteocytes	Hyperosteocytosis
Genetic testing	Patients	Mutations affecting collagen type I in most patients

TREATMENT

There is no treatment with proven benefit to the patient. The effect of any kind of medical intervention is difficult to judge in IJO, because the disease is rare, has a variable course, and is said to resolve without treatment. Long-term outcome studies are lacking, however.

Given the current enthusiasm for pediatric bisphosphonate therapy, many IJO patients probably are receiving treatment with such drugs. We would normally restrict such an intervention to those children with multiple vertebral crush fractures, who may also experience debilitating chronic bone pain.

A number of case reports have described increasing BMD and clinical improvement after treatment with bisphosphonates was started [22–24]. Medical therapies should complement orthopedic and rehabilitative measures such as physiotherapy in all such cases. Review at 6-month intervals is also warranted in children who are not receiving bisphosphonates. Changes in the shape of the spine should be monitored carefully, and early referral to a specialist pediatric spine surgeon should be made in any progressive cases; it is unclear whether bisphosphonate therapy prevents scoliosis or its progression once established in these cases.

PROGNOSIS

The disease process appears to be active only in growing children, and spontaneous recovery is the rule after 3–5 years of evolution [14]. However, in some of the most severe cases reported to date, deformities and severe functional impairment persisted, leaving the children with cardiorespiratory abnormalities and confined to wheelchairs. Preventing such deformities with attendant loss of function should be the focus of attention during the active phase of the disease.

INTRODUCTION

Glucocorticoid-induced osteoporosis (GIO) is the second most common form of osteoporosis and is the most common iatrogenic form of the disease [1, 2]. Fractures may occur in 30% to 50% of patients receiving chronic glucocorticoid therapy and many are asymptomatic, possibly due to glucocorticoid-induced analgesia [3, 4]. However, even asymptomatic prevalent vertebral fractures are important because they further reduce vital capacity in patients with chronic lung disease and increase the risk of subsequent fractures independently of bone mineral density (BMD) [1, 3]. Bone loss in GIO is biphasic, with a reduction in BMD of 6–12% within the first year, followed by a slower annual loss of about 3%; however, there is more to consider than just the reduction in BMD [5]. Bone quality is also an issue [6, 7]. The risk of fracture escalates by as much as 75% within the first 3 months of therapy, typically before a significant decline in BMD, suggesting a glucocorticoid-induced defect in bone strength not captured by bone densitometry [3, 6, 7]. GIO is diffuse, affecting both cortical and cancellous bone, but there is a distinct predilection for fractures in regions of the skeleton with abundant cancellous bone such as the lumbar spine. Several large case-controlled studies show strong associations between glucocorticoid exposure and fracture [8–10]. In a cohort study of patients receiving glucocorticoids for a variety of disorders, continuous treatment with prednisone, 10 mg/day, for more than 90 days was associated with a 7-fold increase in hip fractures and a 17-fold increase in vertebral fractures [10]. Furthermore, in addition to fractures, glucocorticoid administration is the most common cause of nontraumatic osteonecrosis [11].

CLINICAL FEATURES

The occasional patient who becomes Cushingoid when treated with relatively small amounts of glucocorticoids while other patients appear to be remarkably resistant has long perplexed physicians. Another puzzle is that glucocorticoid-induced fractures or osteonecrosis may occur without a Cushingoid habitus. The explanation may be that the sensitivity to exogenous glucocorticoids in different tissues is mediated by inherited or acquired gradations in the local activity of the 11β-hydroxysteroid dehydrogenase (11β-HSD) system. This remarkable system is a natural pre-receptor modulator of corticosteroid action. Two isoenzymes, 11β-HSD1 and 11β-HSD2, catalyze the interconversion of hormonally active glucocorticoids (such as cortisol or prednisolone) and inactive glucocorticoids (such as cortisone or prednisone). The 11β-HSD1 enzyme is an activator, and the 11β-HSD2 enzyme is an inactivator. The ability of any glucocorticoid to bind to the glucocorticoid receptor (GR) depends on the presence of a hydroxyl group at C-11. Therefore, any tissue expressing 11β-HSDs can regulate

Table 58.1. Risk Factors for Glucocorticoid-Induced Osteoporosis

Advancing age
Low body mass index (<24 kg/m2)
Underlying diseases (e.g., rheumatoid arthritis, polymyalgia rheumatica, inflammatory bowel disease, chronic pulmonary disease, and transplantation)
Family history of hip fracture, prevalent fractures, smoking, excessive alcohol consumption, frequent falls
Polymorphisms in the glucocorticoid receptor gene
11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) expression increases with aging and glucocorticoid administration
Glucocorticoid dose (peak, current or cumulative; duration of therapy)
Glucocorticoid-induced fractures occur independently of a decline in bone mass but patients with very low bone density may be at higher risk

the exposure of the resident cells to active glucocorticoids. The increased risk of fractures due to GIO in the elderly may be due to increases in 11β-HSD1 that occur with aging and glucocorticoid exposure [12]. In addition, increased glucocorticoid sensitivity has also been postulated to result from polymorphisms in the GR gene [13]. An additional explanation for individual susceptibility to fractures is the underlying condition that requires glucocorticoid therapy [1, 2, 9]. Fractures may be more common with high dose glucocorticoids and other immunosuppressive drugs used in transplant recipients [14], inflammatory bowel disease and the accompanying malabsorption [15–17], severe rheumatoid arthritis and the relative immobilization in addition to the systemic inflammation [18], and chronic pulmonary disease and the rib fractures provoked by fits of coughing [19] than with myasthenia gravis [20] or multiple sclerosis [21]. Additional risk factors [22–24] are listed in Table 58.1.

However, the absence of severe underlying disease or the presence of youth does not convey protection from glucocorticoid-induced bone disease. Osteoporosis and osteonecrosis have been reported in young as well as older patients receiving depot, topical, or nasal glucocorticoids for dermatitis, rhinitis, or hay fever, and even with modest over-replacement for pituitary or adrenal insufficiency or congenital adrenal hyperplasia [25–34]. In addition, replacing oral with inhaled glucocorticoids, alternate day regimens and high-dose intermittent therapy have failed to prevent GIO [35–38].

BASIC SCIENCE

The adverse effects of glucocorticoids on the skeleton are exerted directly on the osteoblasts, osteocytes, and osteoclasts, decreasing the production of both osteoblasts and osteoclasts and increasing the apoptosis of osteoblasts and osteocytes while prolonging the lifespan of osteoclasts [39–43]. This is evident from a series of experiments in transgenic mice overexpressing the inactivating enzyme 11β-HSD2 [40]. Mice harboring the transgene in osteoblasts and osteocytes are protected from prednisolone-induced apoptosis and the resultant decrease in osteoblast number and bone formation, but still lose BMD because the osteoclasts remain exposed to the prednisolone. However, bone strength is preserved in these animals in spite of the loss of BMD, suggesting that osteocyte viability independently contributes to bone strength. Using the same approach, overexpression of 11β-HSD2 in osteoclasts preserves BMD, but does not prevent the prednisolone-induced decrease in osteoblast lifespan, osteoblast number, and bone formation [41]. Glucocorticoids also have indirect actions on the production of osteoblasts, enhancing the expression of Dickkopf-1, an antagonist of the wingless signaling pathway (Wnt) important for bone formation [2, 9] and suppressing bone morphogenetic proteins and runt-related transcription factor 2, factors required to induce osteoblast differentiation. Glucocorticoids increase production of peroxisome proliferator-activated receptor γ, a transcription factor that induces terminal adipocyte differentiation while suppressing osteoblast differentiation, contributing to an increase in marrow fat at the cost of osteoblasts and cancellous bone [2, 9].

BONE HISTOMORPHOMETRY

Histomorphometric studies in patients receiving long-term glucocorticoid treatment consistently show reduced numbers of osteoblasts on cancellous bone and diminished wall width, a measure of the work performed by these cells [39, 44, 45]. The decreased osteoblasts are due to glucocorticoid-induced reductions in the production of new osteoblast precursors as well as to premature apoptosis of mature, matrix-secreting osteoblasts [39]. Therefore, a decrease in the rate of bone formation is an expected histological finding in glucocorticoid-treated patients [1]. Inadequate numbers of osteoblasts are also an important cause of the reduction in cancellous bone area and decrease in trabecular width, a result of incomplete cavity repair during bone remodeling [1, 39, 44]. With glucocorticoid excess, cancellous bone area is often less than 12% (normal is 21.6% ± 4.5 SD) and correlates with the decreased wall width, thus supplying additional evidence of the glucocorticoid-induced adverse effects on osteoblasts [45]. Increased cortical and cancellous osteocyte apoptosis also occurs and is associated with decreases in vascular endothelial growth factor, skeletal angiogenesis, bone interstitial fluid, hydraulic support, and bone strength [46]. Therefore, glucocorticoid-induced osteocyte apoptosis could account for the loss of bone strength that occurs before the loss of BMD [2, 6, 7] and the mis-

match between BMD and fracture risk in patients with GIO [3]. Cortical bone at the iliac crest demonstrates increased porosity while cortical width ranges from clearly subnormal to within normal limits [47].

Some clinical histomorphometric studies of GIO have reported moderate increases in the cancellous erosion perimeter (the crenated cancellous margin with or without the presence of osteoclasts), but others showed no significant change. However, increased erosion perimeter may occur merely because of a glucocorticoid-induced delay in the appearance of osteoblasts and start of bone formation [39]. When carefully measured, osteoclast numbers in patients receiving chronic glucocorticoid treatment are within the normal range or just slightly above normal [39, 44]. This occurs because glucocorticoid excess directly reduces osteoclast production but, in contrast to the glucocorticoid-induced increase in osteoblast apoptosis, the apoptosis of osteoclasts is decreased [41, 43]. The histological features of GIO are quite distinct from those found in other forms of osteoporosis. Loss of gonadal function and secondary hyperparathyroidism are characterized by marked increases in osteoclasts, osteoblasts, and the rate of bone formation. These different histological features, along with the evidence that the skeletal effects of glucocorticoid excess override those caused by sex steroid deficiency, that fracture prevalence is similar in amenorrheic and eumenorrheic women with Cushing's syndrome, and that parathyroid hormone levels are normal with glucocorticoid administration, clearly indicate that, in contrast to prior teaching, hypogonadism and secondary hyperparathyroidism are not central to the pathogenesis of GIO. [48–53].

OSTEONECROSIS

A devastating accompaniment of long-term glucocorticoid therapy is osteonecrosis (also known as aseptic necrosis, avascular necrosis, or ischemic necrosis). Osteonecrosis of the femoral neck, distal femur and proximal tibia, or proximal humerus occurs in as many as 40% of patients who receive high-dose or long-term therapy, although it may also occur with short-term exposure to high doses, after intra-articular injection, and without osteoporosis [11]. The name, "osteonecrosis," is misleading, since it has not been demonstrated that the bone cells die by necrosis with glucocorticoid excess. Indeed, the cell swelling and inflammatory responses that characterize necrosis in soft tissues usually do not occur in glucocorticoid-induced osteonecrosis. The disorder has been attributed to fat emboli, microvascular tamponade of the blood vessels of the femoral head by marrow fat or fluid retention and poorly mending fatigue fractures. However, abundant apoptotic osteocytes have been identified in sections of whole femoral heads obtained during total hip replacement for glucocorticoid-induced osteonecrosis, whereas apoptotic bone cells were absent from femoral specimens removed because of traumatic or sickle cell osteonecrosis, suggesting that the so-called glucocorticoid-induced osteonecrosis actually is osteocyte apoptosis [54, 55]. The apoptotic osteocytes were found juxtaposed to the subchondral fracture crescent in femurs from the patients with glucocorticoid excess. Apoptotic osteocytes persist because they are anatomically unavailable for phagocytosis, and, with glucocorticoid excess, decreased bone remodeling retards their replacement. Glucocorticoid-induced osteocyte apoptosis, a cumulative and unrepairable defect, could uniquely disrupt the mechanosensory function of the osteocyte–lacunar–canalicular system and thus start the inexorable sequence of events leading to collapse of the femoral head. Glucocorticoid-induced osteocyte apoptosis would also explain the correlation between total steroid dose and the incidence of osteonecrosis and its occurrence after glucocorticoid administration has ceased [11, 56, 57]. Persistent hip, knee, or shoulder pain, especially with joint movement, tenderness, or reduced range of motion, in patients receiving glucocorticoid therapy, warrants magnetic resonance imaging to exclude osteonecrosis [1].

MANAGEMENT

Responsibilities of glucocorticoid therapy

Under some circumstances (vasculitis, rheumatoid arthritis, lupus, status asthmaticus, inflammatory bowel disease), high-dose glucocorticoid therapy is an emergency; the clinician always hopes that the course of treatment will be brief, and, therefore, does not address the complications of these drugs. However, it is the responsibility of physicians who prescribe glucocorticoids to educate their patients about these side effects and complications including osteoporosis and osteonecrosis, cataract and glaucoma, hypokalemia, hyperglycemia, hypertension, hyperlipidemia, weight gain, fluid retention, easy bruisability, susceptibility to infection, impaired healing, myopathy, adrenal insufficiency, and the steroid withdrawal syndrome. All patients receiving long-term glucocorticoid therapy should carry a steroid therapy card or medication identification jewelry. Malpractice suits for failure to document disclosure of the skeletal complications to patients are not rare [11]. In spite of this, the bone complications are ignored by more than 50% of the specialists who prescribe glucocorticoids [58].

General measures

Laboratory testing should include measurement of serum 25-hydroxyvitamin D, creatinine, and calcium (in addition to glucose, potassium, and lipids). Bone turnover after long-term glucocorticoid therapy is low, so biochemical markers of bone metabolism are not usually

helpful. If biomarkers have been already obtained and are elevated, another problem may be present. Adequate calcium (1,200–1,500 mg/day) and vitamin D (2,000 units/day) supplementation should be recommended, but the evidence is against any substantial effect of these measures to prevent fractures [1, 9]. Prevalent fractures, vertebral morphological assessment, spinal radiographs, or a loss of height as determined using a stadiometer may help identify patients at risk of additional fractures but the disparity between bone quantity and quality in GIO makes BMD or ultrasound measurements inadequate for identifying which patients are at risk [1, 3]. However, yearly BMD measurements may be useful after therapeutic intervention to prevent fractures. The World Health Organization fracture prevention algorithm (FRAX®) underestimates the risk of glucocorticoid-induced fractures as the current and cumulative glucocorticoid dose and duration of therapy are not considered. Furthermore, the algorithm uses femoral neck BMD, but vertebral fractures are more common than hip fractures in GIO, and inclusion of the common risk factors for postmenopausal osteoporosis in the algorithm may not be applicable to GIO [59]. More data are needed to establish the minimum dose and duration of treatment that requires protection from fractures and to develop strategies to ensure the incorporation of this knowledge into clinical practice. There is insufficient evidence to begin anti-fracture medication with sporadic dose-pack prescriptions, annual short-term (e.g., 7 to 10 days) intravenous treatment, or replacement therapy for patients with hypopituitarism, adrenal insufficiency, or congenital adrenal hyperplasia, provided the replacement doses and increases during stress are not excessive. However, the available evidence strongly suggests that any patient who receives or whose physician plans to administer 10 mg or more per day of prednisone for more than 3 months should be given specific treatment to prevent glucocorticoid-induced fractures [8–10].

Specific treatments

Bisphosphonates are considered first-line options for GIO even though they do not directly address the decreased bone formation characteristic of the disorder [1, 39] (Table 58.2). Randomized, placebo-controlled trials have shown that alendronate, risedronate, and zoledronic acid are effective in GIO [60–62]. Nitrogen-containing bisphosphonates induce apoptosis of osteoclasts and inhibit bone resorption [63], but glucocorticoids antagonize this effect [43] and this may account for the limited ability of these antiresorptive agents to protect BMD in GIO as compared to other forms of osteoporosis [60, 64, 65]. In addition, alendronate decreases glucocorticoid-induced osteocyte apoptosis [66], which may play a role in the preservation of bone strength [6, 7]. The evidence for the use of anti-fracture regimens in GIO is not as strong as that for postmenopausal osteoporosis because the primary end point in the glucocorticoid treatment trials was BMD rather than fracture, and glucocorticoids induce a susceptibility to fracture that is independent of BMD. In addition, most studies were only 12 to 18 months in duration, and insufficient numbers of patients were recruited to study hip fractures.

Oral bisphosphonates can be stopped if glucocorticoids are discontinued. However, compliance with oral therapy is poor. Yearly infusions of zoledronic acid solve this problem and provide rapid skeletal protection. If glucocorticoid administration has already been long-term, there may not be time to wait for the more gradual protective effects of oral bisphosphonates with their average oral absorption of 0.7%, weekly dosage, and lower molar potency as compared with intravenous zolendronate. For example, 63 mg of alendronate is absorbed after 90 days of therapy with the typical 70 mg/week dosage as compared to 5 mg of zoledronic acid after a 15-min infusion, but the potency of alendronate is about tenfold less than that of zoledronic acid [67]. Substantial BMD loss occurs in patients who discontinue bisphosphonates while receiving glucocorticoids, so the recommended duration of therapy is typically at least as long as the steroids are prescribed and "drug holidays" are not recommended [68]. About 15% of patients with GIO who are receiving their first infusion of zoledronic acid experience an acute phase reaction within 2 to 3 days and lasting 3 days or less [62]. The mild pyrexia, musculoskeletal pains, and flu-like symptoms are effectively managed with acetaminophen or ibuprofen and seldom occur with subsequent infusions.

In patients with glucocorticoid-induced osteonecrosis of the femoral head, a 2-year, randomized, placebo-controlled, open-label trial showed decreased pain, delayed lesion expansion, and less need for surgery with alendronate [69]. An 8-year, prospective, observational study reported sustained improvement in pain and ambulation in patients with osteonecrosis within months of initiating alendronate and with courses lasting only 1–3 years [70]. Although bisphosphonates may be useful in the treatment of osteonecrosis of the hip, the drugs are associated with osteonecrosis of the jaw (ONJ) [71]. Distinctly different from osteonecrosis of the hip, ONJ is characterized by exposed maxillofacial bone for at least 8 weeks, poor dental hygiene, typical presentation after a dental extraction or other invasive procedure, and infection with Actinomyces. ONJ occurs mainly in patients with osteolytic breast cancer or multiple myeloma who receive frequent (often monthly) high-dose intravenous bisphosphonates. In patients with osteoporosis treated with bisphosphonates, the risk of ONJ is between 1 in 10,000 to 100,000 patient-years. Glucocorticoid use may slightly increase the risk for ONJ. Before prescribing bisphosphonates, the clinician should perform an oral examination and encourage patients to be seen by a dentist. Bisphosphonates may also be associated with atypical subtrochanteric femoral fractures, but if so, the risk is small [72].

An alternative treatment for GIO is teriparatide, recombinant human parathyroid hormone [rhPTH 1-34].

Table 58.2. Pharmaceutical Agents for Glucocorticoid-Induced Osteoporosis (GIO)

Intervention	Advantages	Disadvantages
Oral bisphosphonates *Alendronate 10 mg/day or 70 mg/week; *Risedronate 5 mg/day or 35 mg/week	Osteoclast inhibition reduces bone loss. Alendronate also prevents glucocorticoid-induced osteocyte apoptosis. If glucocorticoids are discontinued, these drugs may be stopped.	Antiresorptive agents do not directly address the decreased bone formation characteristic of GIO and have not been shown to reduce hip fractures. Additional problems include gastrointestinal side effects, rare uveitis, poor compliance with oral therapy, and the time required to obtain skeletal protection. Avoid in patients with a creatinine clearance less than 30 mL/min.
Intravenous bisphosphonate *Zoledronic acid (5 mg IV/year)	Osteoclast inhibition reduces bone loss. Increased compliance compared with oral treatment and rapid onset of skeletal effects. Gastrointestinal side effects are unlikely.	Does not address the reduced bone formation caused by glucocorticoid excess. Avoid in patients with a creatinine clearance less than 30 mL/min. Acute phase reaction (flu-like syndrome) may occur within 2 to 3 days and lasting ≤3 days, particularly with the first dose; effectively managed with acetaminophen or ibuprofen.
*Teriparatide rhPTH 1-34 (20 µg subcut/day)	Directly addresses the increase in osteoblast and osteocyte apoptosis and decrease in osteoblast number, bone formation, and bone strength characteristic of GIO. Rapid onset of skeletal effects. Reduces vertebral fractures.	Costs (greater than oral or IV bisphosphonates), daily injections are required, reduced response with high dose glucocorticoids. Not studied in patients with elevated parathyroid hormone levels. Adverse effects: mild hypercalcemia, headache, nausea, leg cramps, dizziness. Caution with preexisting nephrolithiasis. Check serum calcium at least once ≥16 hours after injection and adjust oral calcium intake as needed.
Denosumab (60 mg subcut every 6 months)	Potent inhibitor of osteoclasts with ease of administration. Can be stopped if glucocorticoids are discontinued. Can be used in patients with creatinine clearance ≤30 mL/min or with intolerance to other treatment options.	Does not address the reduced bone formation caused by glucocorticoid excess. Hypocalcemia and vitamin D deficiency must be treated prior to the use of denosumab.

*FDA approved for glucocorticoid-induced osteoporosis. In Europe, only the once-daily oral bisphosphonate regimens, zoledronic acid, and teriparatide are approved for GIO.

In an 18-month randomized, double-blind, controlled, head-to-head trial, teriparatide increased spinal BMD faster and to a greater extent than alendronate and also reduced vertebral fractures (0.6% vs 6.1%, P = 0.004) [73]. Teriparatide represents a particularly rational approach to GIO by counteracting several fundamental aspects of its pathophysiology. The expected glucocorticoid-induced increase in osteoblast and osteocyte apoptosis and decrease in osteoblast number, bone formation, and bone strength are prevented by teriparatide. Decreased osteoblast apoptosis is related to an increase in bone formation and decreased osteocyte apoptosis is associated with preservation of bone strength [74, 75]. Furthermore, teriparatide abrogates the negative impact of glucocorticoids on Akt (protein kinase B) phosphorylation, and Wnt signaling [75]. However, the effect of teriparatide is somewhat compromised by high-dose glucocorticoid therapy [75–77]. In addition, host factors such as severity of the underlying illness, weight loss, concurrent medications, renal function, and low insulin-like growth factor I levels may contribute to the diminished efficacy of teriparatide in GIO as compared with other forms of osteoporosis [1, 75]. Disadvantages of teriparatide include the need for daily subcutaneous injections, refrigeration, cost, side effects (headache, nausea, dizziness, leg cramps), occasional mild hypercalcemia, and the caution required in patients with nephrolithiasis or elevated levels of parathyroid hormone [78].

Another potential treatment option is denosumab, a humanized monoclonal antibody to the receptor activator of nuclear factor-κB ligand (RANKL), approved for the prevention of vertebral, nonvertebral, and hip fractures in women with postmenopausal osteoporosis, but not as yet for GIO [79]. In a randomized, double-blind, placebo-controlled trial of denosumab in 61 patients with rheumatoid arthritis who received concurrent prednisone (15 mg/day or less) and methotrexate, the BMD of the spine and hip increased with denosumab to the same extent as in 88 patients receiving methotrexate and denosumab alone [80]. Furthermore, there was no difference

in adverse effects as compared with placebo and methotrexate. Denosumab may be considered for glucocorticoid-treated patients with renal insufficiency and stable serum calcium levels who are not candidates for bisphosphonates or teriparatide or who are intolerant of other treatment options. The ease of administration as a subcutaneous injection every 6 months may increase compliance.

In patients with GIO, incapacitating adjacent vertebral fractures have been reported days after kyphoplasty, suggesting that great caution should be exercised before recommending the procedure in patients receiving glucocorticoid therapy [81, 82].

Inflammation-Induced Bone Loss in the Rheumatic Diseases

Steven R. Goldring

Rheumatoid Arthritis 483
Ankylosing Spondylitis 484
Systemic Lupus Erythematosus 485
Acknowledgment 485
References 486

The inflammatory joint diseases include a diverse group of disorders that share in common the presence of inflammatory and destructive changes that adversely affect the structure and function of articular and periarticular tissues. In many of these disorders, the inflammatory processes that target the joint tissues may affect extra-articular tissues and organs, and, in addition, there may be generalized effects on systemic bone remodeling. Attention will focus on rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and the seronegative spondyloarthropathies, which include ankylosing spondylitis, reactive arthritis (formerly designated as Reiter's syndrome), the arthritis of inflammatory bowel disease, juvenile-onset spondyloarthropathy, and psoriatic arthritis. The discussion will be limited to ankylosing spondylitis, which is the prototypical spondyloarthropathy.

In RA and SLE, the synovial lining is the initial site of the inflammatory process. Under physiological conditions, the synovium forms a thin membrane that lines the surface of the joint cavity and is responsible for generation of the synovial fluid that contributes to joint lubrication and nutrition for the chondrocytes that populate the articular cartilage. In patients with RA and SLE, the synovium becomes a site of an intense immune-mediated inflammatory process that results in synovial proliferation and production of potent inflammatory cytokines and soluble mediators that are responsible for the clinical signs of joint inflammation [1, 2]. In patients with RA, this inflammatory process ultimately leads to destruction of the joint tissues. Although the clinical signs of inflammation in SLE and RA are similar, the synovitis associated with SLE characteristically does not lead to direct destruction of articular cartilage and bone. Of interest, Toukap et al. [3] have reported that patients with SLE exhibit a synovial gene profile that is distinct from the patterns observed in RA and osteoarthritis, suggesting that differential inflammatory and immunologic process are involved in the pathogenesis and biologic activity of the synovium in these conditions. The potential mechanisms involved in the differential effects on bone resorption in SLE and RA will be reviewed in the following discussion. Despite the absence of destructive changes, joint deformities (referred to as Jaccoud's arthritis) do develop in patients with SLE, but these are attributable to alterations in the integrity of periarticular connective tissues rather than destruction of the articular cartilage and bone [4].

Synovial inflammation is also present in the seronegative spondyloarthropathies. Unlike the pattern of joint inflammation in RA and SLE, the joint inflammation is most often asymmetrical, involving distal as well as proximal joints, and, importantly, the axial skeleton is also affected. Anatomic and histopathological analyses have established that the entheses, which are the sites of tendon or ligament attachment to bone, are the initial sites of inflammation in the spondyloarthropathies [5]. Subsequently, the extension of the inflammatory process to the joint margins and the development of synovial pannus may be accompanied by the development of marginal joint erosions. In contrast to the findings in RA, the inflammatory process in the spondyloarthropathies may be associated with calcification and ossification at the

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

enthesis and eventual bony ankylosis of the joint [6]. A similar inflammatory process may affect the axial skeleton leading to enhanced bone formation and fusion or ankylosis of adjacent vertebrae and the formation of so-called syndesmophytes [5–7].

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic inflammatory disorder characterized by symmetrical polyarthritis. Four major forms of pathologic skeletal remodeling can be observed in this disorder, including focal marginal articular erosions, subchondral bone loss, periarticular osteopenia, and systemic osteoporosis. The focal marginal erosions are the radiologic hallmark of RA. Histopathologic examination of these sites of focal bone loss reveals the presence of inflamed synovial tissue that has attached to the bone surface forming a mantle or covering referred to as "pannus." The interface between the pannus and adjacent bone is frequently lined by resorption lacunae containing mono- and multinucleated cells with phenotypic features of authentic osteoclasts, thus implicating osteoclasts as the principal cell type responsible for the focal synovial resorptive process [8, 9]. Similar sites of focal bone loss are present on the endosteal surface of the subchondral bone, and cells with phenotypic features of osteoclasts also are present on these bone surfaces. Erosion of the subchondral bone at these sites contributes to joint destruction by providing access to the deep zones of the articular cartilage, which is subject to degradation by the invading inflammatory tissue. These regions of subchondral bone erosion frequently conform to sites of so-called bone marrow edema visualized by magnetic resonance imaging. Histologic analysis of the bone marrow in these regions reveals that the bone marrow has been replaced by a fibrovascular stroma populated by inflammatory cells [10]. Importantly, the presence of bone marrow lesions is strongly predictive of the subsequent development of local bone erosions at these sites [11, 12].

More definitive evidence implicating osteoclasts in the pathogenesis of focal articular bone erosions has come from the use of genetic approaches in which investigators have induced inflammatory arthritis with features of RA in mice lacking the ability to form osteoclasts [13–15]. In these models, the inability to form osteoclasts results in protection from focal articular bone resorption despite the presence of extensive synovial inflammation.

The propensity of the synovial lesion in RA to induce osteoclast-mediated bone resorption can be attributed to the production by cells within the inflamed tissue of a wide variety of products with the capacity to recruit osteoclast precursors and induce their differentiation and activation. These include a spectrum of chemokines, as well as receptor activator of nuclear factor-κB ligand (RANKL), interleukin-1 (IL-1), IL-6, IL-11, IL-15, IL-17, monocyte colony-stimulating factor, tumor necrosis factor-α (TNF-α), prostaglandins, and parathyroid hormone-related peptide [1, 2]. Among these products, particular attention has focused on RANKL, which is produced by both synovial fibroblasts and T cells within the synovial tissue [16–18]. The critical role of this cytokine in the pathogenesis of focal bone erosions is suggested by the observations that blocking the activity of RANKL in animal models of RA with osteoprotegerin (OPG) results in marked attenuation of articular bone erosions [17, 19, 20]. The pivotal role of RANKL in the resorptive process is further supported by the results obtained in the genetic models in which deletion of RANKL [14] or disruption of its signaling pathway [15] protects animals from articular bone erosions in models of inflammatory arthritis. More recently, blockade of RANKL with denosumab, a monoclonal antibody that blocks RANKL activity, was shown to significantly reduce articular bone erosions in a group of patients with RA, providing further evidence that osteoclasts and osteoclast-mediated bone resorption represent a rational therapeutic target for preventing articular bone destruction in RA [21, 22]. Interestingly, bisphosphonates, which demonstrate beneficial effects in protecting from systemic bone loss in RA, have not been effective in reducing focal joint destruction [23], with the exception of a publication in which the investigators used a protocol involving the sequential administration of zoledronic acid [24]. Although there may be limitations with respect to the use of these agents to prevent joint destruction, as discussed below, there clearly is a role for bisphosphonates in treating and preventing systemic bone loss in RA [23]. In addition, several recent studies have also shown beneficial effects of targeting RANKL with denosumab in the prevention of systemic bone loss in patients with RA, including patients concomitantly treated with glucocorticoids [25, 26].

An additional striking feature of the focal marginal and subchondral bone loss in RA is the virtual absence of bone repair. The recent studies of Diarra et al. [27] have provided insights into the mechanism involved in the uncoupling of bone resorption and formation in this form of inflammatory arthritis. They demonstrated that cells in the inflamed RA synovial tissue produced dickkopf-1 (DKK-1), the inhibitor of the wingless (Wnt)-signaling pathway that plays a critical role in osteoblast-mediated bone formation. Studies by Walsh et al. have confirmed these observations and identified additional Wnt family antagonists, including members of the DKK and secreted Frizzled-related protein families in the RA synovium [28]. In the Diarra studies, synovial fibroblasts, endothelial cells, and chondrocytes were the principal sources of the DKK-1 [27]. They furthermore showed that TNF-α was a potent inducer of DKK-1, thus implicating this proinflammatory mediator in both bone formation and bone resorption. An additional, somewhat surprising observation was that inhibition of DKK-1 with a blocking antibody produced beneficial effects not only on bone formation, but also suppressed osteoclast-mediated bone resorption. The effects on suppression of bone resorption were attributed to downregulation of RANKL production

by the inflamed synovium and upregulation of OPG. These observations have clear implications with respect to future therapeutic strategies to prevent bone loss in RA [29].

Focal marginal bone erosions are the radiographic hallmark of RA, but the earliest skeletal feature of RA is the development of periarticular osteopenia. Of importance, there is evidence that the juxta-articular bone loss has high predictive value with respect to the subsequent development of marginal joint erosions in the hand [30–32]. There are few studies examining the histopathologic changes associated with periarticular osteopenia. Shimizu et al. [33] examined the periarticular bone obtained from a series of patients with RA who underwent joint arthroplasty and observed evidence of both increased bone resorption and formation based on histomorphometric analysis. Examination of the bone marrow in the juxta-articular tissues frequently reveals the presence of focal accumulations of inflammatory cells, including lymphocytes and macrophages, and these cells are a likely source of cytokines and related proinflammatory mediators that could adversely affect bone remodeling [34]. Immobilization and reduced mechanical loading are additional factors that have been implicated in the pathogenesis of periarticular bone loss.

The final skeletal feature of RA is the presence of generalized osteoporosis. Numerous studies have documented that patients with RA have lower bone mineral density and an increased risk of fracture compared to disease controls [35–38]. In patients with RA, the presence of multiple confounding factors that influence bone remodeling has made it difficult to define in a given patient the underlying pathogenic mechanism responsible for the reduced bone mass. These include the effects of sex, age, nutritional state, level of physical activity, disease duration and severity, and the use of medications such as glucocorticoids that can adversely affect bone remodeling. Lodder et al. [37] evaluated the relationship between bone mass and disease activity in a cohort of patients with RA with low to moderate disease activity and observed that disease activity was a significant contributory factor to systemic bone loss, supporting the earlier observations made by several other investigators. Solomon and coworkers [39] recently examined the relationship between focal bone erosions and generalized osteoporosis in a cohort of postmenopausal women with RA. Although they observed an association between low hip bone mineral density (BMD) and joint erosions, the association disappeared after multivariable adjustment, suggesting that the relationship between erosions and BMD is complex and influenced by multiple disease- and treatment-related factors.

Several different approaches have been utilized to gain insights into the mechanism responsible for systemic bone loss in RA, including histomorphometric analysis of bone biopsies, measurement of urinary and serum biomarkers of bone remodeling and the assessment of serum cytokine levels. Earlier studies employing histomorphometric analysis suggested that the decrease in bone mass was attributable to depressed bone formation [40]. In contrast, Gough et al. [41], as well as several other investigators, observed the presence of increased bone resorption based on assessment of urinary markers. Of interest, Garnero et al. observed that a high urinary CTX-1 level (a marker of bone resorption) predicted risk of radiographic progression of joint damage independent of rheumatoid factor or erythrocyte sedimentation rate [42]. More recently, several groups of investigators have used the indices of bone remodeling and/or serum cytokine levels to assess the effects of treatment interventions on focal articular and systemic bone loss in RA patients [25, 43–46]. Results indicate that suppression of signs of inflammation and improved functional status are reflected in improvement in the level and pattern of bone remodeling indices.

The disturbance in systemic bone remodeling in RA has been attributed to the adverse effects of proinflammatory cytokines that are released into the circulation from sites of synovial inflammation and act in a manner similar to endocrine hormones to regulate systemic bone remodeling. Although the serum levels of multiple osteoclastogenic cytokines are elevated in RA patients, particular attention has focused on the levels of RANKL and OPG. Geusens and colleagues have recently reported results from a cohort of patients with RA and shown that circulating OPG/RANKL in early RA predicted subsequent bone destruction over an 11-year follow-up [47, 48]. In another study, Vis et al. [43] showed that anti-TNF therapy with infliximab was accompanied by decreased systemic bone loss, and these effects correlated with a fall in serum RANKL levels. There also is evidence that cytokines and mediators released from inflamed joints can adversely affect bone formation. This conclusion is supported by the observations of Diarra et al. [27], who detected elevated levels of DKK-1, an inhibitor of bone formation, in the sera of patients with RA. Similar findings have been reported by other authors [49, 50]. Of interest, in the Diarra study, the authors observed that levels of DKK-1 were not increased compared to controls in patients with AS, which is associated with focal increases in periarticular bone formation, as discussed in the following section.

These studies and the related investigations described in the preceding discussion highlight the importance of monitoring patients with RA for evidence of systemic bone loss and for the institution of early therapeutic interventions that have been shown to reduce the long-term risks of fracture and disability. Similar approaches should be considered in patients with SLE and related forms of inflammatory arthritis who also are at risk for the development of systemic osteoporosis and fracture.

ANKYLOSING SPONDYLITIS

As described above, ankylosing spondylitis (AS) is characterized by inflammation in the entheses, as well as the

synovial lining of peripheral joints. Examination of the synovial lesion reveals many of the same features as the RA synovium, including synovial lining hyperplasia, lymphocytic infiltration and pannus formation. In contrast to the pattern of articular bone remodeling in RA, in patients with AS, the inflammatory process may be accompanied by evidence of increased bone formation. This is particularly the case at sites of entheseal inflammation, such as ligament and tendon insertion sites, especially in the spine. To investigate the mechanism responsible for the enhanced bone formation, Braun and coworkers [51] obtained biopsies from the sacroiliac joints of patients with AS. They noted the presence of dense infiltrates of lymphocytes, similar to the RA synovial lesion, but unlike the RA synovium, they also detected foci of endochondral ossification. Using *in situ* hybridization, they noted the presence of increased expression of TGF-β_2 mRNA in these regions and speculated that the upregulation of this growth factor could be responsible for the enhanced bone formation. Lories et al. [52] analyzed synovial tissues from a series of patients with AS or RA and noted the presence of elevated levels of bone morphogenic proteins–2 and –6 in tissues from both patient populations. They speculated that the differential pattern of new bone formation in AS could be related to the localization of the inflammatory process to the periosteal bone at the entheses. Lories and coworkers [53] have extended these observations in DBA/1 mice, which spontaneously develop an inflammatory arthritis that recapitulates the excessive bone formation characteristic of AS and showed that systemic delivery of noggin, a bone morphogenetic protein (BMP) antagonist, attenuated the new bone formation. Direct evidence supporting a role for BMPs in the new bone formation associated with AS was provided by immunohistochemical analysis of entheseal biopsies from patients with AS demonstrating the presence of phosphorylated smad 1/5, consistent with local activation of the BMP signaling pathway.

Maksymowych and coworkers [54] have examined the relationship between inflammation and new bone formation in the axial skeleton in patients with AS. MRI and radiographs of the spine revealed that new syndesmophytes developed more frequently at the vertebral body margins with inflammation than in sites without inflammation. Importantly, they noted that syndesmophytes continued to develop despite resolution of the inflammation with anti-TNF therapy. These observations are supported by results reported by van der Heijde and coworkers [55, 56] who showed that anti-TNF therapy, although producing significant benefit with respect to axial skeletal inflammation, did not prevent the development of syndesmophytes.

Despite the tendency of patients with AS to produce excessive bone formation at sites of inflammation, many individuals exhibit evidence of spinal osteopenia. This has been attributed to the adverse effects of immobilization that results from spinal ankylosis, although decreased bone density also has been detected in patients even in the absence of bony ankylosis [57–59]. These authors and others have suggested that, as in the other forms of inflammatory arthritis, the bone loss is related to the adverse effects of inflammation on systemic bone remodeling.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE), similar to RA, is a systemic inflammatory disease, which, in addition to targeting joint structures, may be associated with widespread extra-articular organ damage. Although the pattern and distribution of joint inflammation in SLE and RA are similar, the joint inflammation in SLE most often does not result in extensive articular bone erosions or cartilage destruction. Joint deformity and subluxation do occur, but these have been attributed primarily to ligamentous laxity related to persistent periarticular soft tissue inflammation. This pattern of arthritis has been referred to as Jaccoud's arthritis and is characterized by the presence of "hook" erosions that occur on the radial aspect of metacarpal bones [60]. These local bone changes are distinct from the marginal erosions seen in RA. A similar pattern of joint deformity has been described in other inflammatory disorders, including rheumatic fever and sarcoid, and so the condition is not unique to SLE. As described above, analysis of the transcriptome in synovial tissue from patients with SLE reveals a gene profile that exhibits substantial differences from the patterns observed in RA [3]. The most prominent finding in the SLE synovial tissue is the upregulation of interferon inducible genes. A type I interferon signature has been reported in the peripheral blood cells from patients with SLE compared to disease control subjects [61, 62]. Of interest, both interferon-α and -β have been shown to inhibit osteoclastogenesis *in vitro*, and the upregulation of these genes and their products in the SLE synovium could contribute to the protection from the development of osteoclast-mediated bone erosions [63]. Studies by Mensah et al. [64] in the (NZB×NZW)F1 mouse model of SLE provide experimental support implicating synovial-derived interferon-α in the inhibition of osteoclast-mediated bone erosion in SLE. They showed that interferon-α shifted osteoclast precursors toward myeloid dendritic cell differentiation and away from osteoclast formation both *in vivo* and *in vitro*. Similar to patients with RA, SLE patients also are at risk for the development of systemic osteoporosis and associated fragility fractures [65]. In addition to the adverse effects of chronic inflammation on bone remodeling, additional factors, including use of glucocorticoid therapy, renal impairment, and vitamin D insufficiency likely contribute to the low bone mass.

INTRODUCTION

Bone loss is an inevitable consequence of aging, starting some years before menopause, accelerating after its onset, and continuing throughout life in both men and women. A very large number of heterogeneous causes, collectively grouped as "secondary causes of osteoporosis" may also lead to bone loss through a number of mechanisms, independently of age or estrogen deficiency. A secondary cause for osteoporosis can be found in about two-thirds of men, in more than half of premenopausal women, and in about one-fifth of postmenopausal women [1, 2]. Secondary causes of osteoporosis are legion, ranging from easily identifiable specific disease states such as systemic inflammatory disorders, malignancy, endocrinopathies, and use of medication, particularly glucocorticoids, to more "occult" conditions such as vitamin D deficiency, hypercalciuria, and hyperparathyroidism. Although these latter secondary causes of osteoporosis are the most frequently encountered causes of unexpected bone loss, they can only be diagnosed by a high degree of suspicion, easily confirmed by undertaking the appropriate investigations [2–4]. A large number of these secondary osteoporoses are individually discussed elsewhere in the *Primer*. This chapter focuses on osteoporosis associated with systemic inflammatory diseases, diabetes mellitus, and mastocytosis.

OSTEOPOROSIS ASSOCIATED WITH SYSTEMIC INFLAMMATORY DISORDERS

The RANKL/OPG (receptor activator of nuclear factor-κB ligand/osteoprotegerin) ratio is the primary determinant of osteoclastogenesis and therefore of the maintenance of bone mass [5, 6]. In inflammatory disorders, T-cell activation leads to increased expression of T-cell-derived RANKL [7, 8]. Glucocorticoids, often used to control disease activity, decrease osteoblast number and function and inhibit OPG expression [9]. In these disorders, underlying disease activity alters the RANKL/OPG ratio, and this is further exacerbated by the use of glucocorticoids to control the inflammatory process, the combined effect of which potentially leads to significant bone loss.

Inflammatory arthritis

Rheumatoid arthritis, discussed elsewhere in the *Primer*, represents the prototype of a systemic inflammatory disorder, in which inflammation triggers the increased expression of RANKL from activated T cells and from synovial fibroblasts, which is not matched by an increase in OPG, resulting in local bone loss (joint erosions) and generalized bone loss (osteoporosis) [10].

Inflammatory bowel diseases

In Crohn's disease, the pathophysiology of osteoporosis is multifactorial, including the effect of inflammatory cytokines mediating disease activity [interleukin-6 (IL-6), IL-1, tumor necrosis factor-α (TNF-α)], intestinal malabsorption due to disease activity or intestinal resection, the use of glucocorticoids, inability to achieve peak bone mass when the disease starts in childhood, malnutrition, immobilization, low body mass index (BMI), smoking, and hypogonadism [11, 12]. Ileum resection has been identified as the single most significant risk factor for osteoporosis, followed by age, which is of relevance in predicting overall lifetime risk, as Crohn's disease peaks in the second and third decade of life, with osteoporosis potentially becoming clinically significant only as patients grow older [13]. Patients with Crohn's disease are indeed relatively young, and the exact relationship between the host of factors potentially deleterious to the skeleton and the increased risk for osteoporosis and fractures remains unclear. Opinion is also divided on the prevalence of fractures [13–19], and on bone loss in the long term [13, 20–24]. Maintaining a vitamin D-replete status prevents bone loss, and the judicious use of corticosteroids may counteract the deleterious effects of cytokine-driven disease activity on the skeleton [13, 25]. Pharmacodynamic studies suggest that in patients with reasonably well-controlled disease activity, the nitrogen-containing bisphosphonate alendronate is adequately absorbed from the gut and retained in the skeleton, despite underlying chronic inflammatory gut changes and/or gut resection [26]. It is not clear whether this also applies during an exacerbation of Crohn's disease, as acute gut inflammation may be potentially associated with decreased or indeed increased absorption of an orally administered bisphosphonate. Whether all patients with Crohn's disease should be treated with bone protective agents, or whether these agents should be restricted to patients at increased risk for fracture is as yet to be established.

Chronic obstructive pulmonary disease

In chronic obstructive pulmonary disease (COPD), pro-inflammatory cytokines, particularly TNF-α, are the driving force behind the pathophysiology of the disease process [27]. Elevated inflammatory markers reflect not only the severity of lung disease but also the likelihood of increased risk for comorbidities, particularly cardiovascular disease, diabetes, and osteoporosis [28, 29]. A high prevalence of osteoporosis was thus observed within the first year after diagnosis among 2,699 COPD patients from the United Kingdom General Practice Research Database (GPRD) [30]. Data from over 9,500 subjects from the Third National Health and Nutrition Examination Survey conducted in the U.S. between 1988 and 1994 also showed that airflow obstruction was associated with increased odds of osteoporosis compared with no airflow obstruction [odds ratio (OR) 1.9; 95% CI 1.4 to 2.5] and that these odds increased with increased severity of airways obstruction (OR 2.4; 95% CI 1.3 to 4.4, $p < 0.005$) [31]. Loss of bone mass appears to be associated with increased excretion of bone collagen protein breakdown products, suggesting a protein catabolic state, which may not only lead to bone loss, but also to loss of skeletal muscle mass and function and progressive disability [32]. Continuous users of systemic glucocorticoids are more than twice as likely to have one or more vertebral fractures compared with nonusers [33]. In a large case-controlled study including more than 100,000 cases from the GPRD, an association between inhaled corticosteroids at daily doses equivalent to more than 1,600 μg beclomethasone and increased fracture risk disappeared after adjustment for disease severity, suggesting that in COPD, it is disease severity rather than inhaled corticosteroids that increase fracture risk [34]. Factors other than chronic inflammation and corticosteroid use also contribute to bone loss and increased fracture risk in patients with COPD. These include vitamin D deficiency or insufficiency, reduced skeletal muscle mass and strength, immobilization, low BMI and changes in body composition, hypogonadism, reduced levels of insulin-like growth factors (IGFs), smoking, increased alcohol intake, and genetic factors [35]. The morbidity associated with vertebral fractures is particularly high in patients with COPD as these are associated with restrictive changes in pulmonary function, significant decreases in forced expiratory volume, and up to 9% reduction of predicted lung vital capacity for each additional thoracic vertebral compression fracture [36, 37].

OSTEOPOROSIS ASSOCIATED WITH DIABETES MELLITUS

The deleterious effects of diabetes mellitus (DM) on the skeleton are multifactorial and both types 1 and 2 DM are associated with increased fracture risk [35–41]. Data from the Iowa Women's Health study suggest that women with type 1 DM are 12 times more likely to sustain hip fractures than women without DM and that women with type 2 DM have a 1.7-fold increased risk of sustaining hip fractures despite maintaining a normal bone mass [40]. The high prevalence of fractures in type 2 DM is likely to be influenced by long-term complications such as retinopathy-induced visual impairment and neuropathy-induced decreased balance, both increasing the risk for falls [41]. The osteoporosis of DM is one of low bone turnover, with the main mechanism of bone loss being decreased bone formation [42, 43]. Insulin and amylin have an anabolic effect on bone and their decrease in type 1 DM may lead to impaired bone formation, primarily because of a decrease in IGF-1 concentrations. *In vitro* studies also demonstrate that sustained exposure to high glucose concentrations results in osteoblast dysfunction, and poor metabolic control has a clear negative impact on bone mass. In type 1 DM, decreased peak bone

mass also plays a role when the disease manifests itself before skeletal growth is complete. Microvascular complications and decreased mechanical stress due to neuropathy and/or myopathy contribute to the increased fracture risk at later stages of the disease [44]. In DM, there is increased bone marrow adiposity, which has also been linked with the osteoporosis of aging, glucocorticoid use, and immobility [45]. Several members of the nuclear hormone receptor family control the critical adipogenic and osteogenic steps, and evidence has been mounting for a clear interdependence of adipogenesis and osteogenesis [45, 46]. In the bone marrow microenvironment, the inverse relationship between adipogenic and osteogenic differentiation was shown to be mediated at least in part through cross talk between pathways activated by steroid receptors (estrogen, thyroid, corticosteroid and growth hormone receptors), the peroxisome proliferator activator receptors (PPARs), and other cytokine and paracrine factors. PPARs play a central role in initiating adipogenesis in bone marrow and other stromal-like cells *in vitro* and *in vivo* [47], and their ligands (rosiglitazone and pioglitazone) play a prominent role in the treatment of type 2 DM. These ligands induce adipogenesis and inhibit osteogenesis *in vitro*, which may explain the increased incidence of fractures reported in patients with DM using these agents [48, 49].

OSTEOPOROSIS ASSOCIATED WITH MASTOCYTOSIS

In all forms of mastocytosis, the proximity of the mast cell to bone remodeling surfaces and the production by this cell of a large number of chemical mediators and cytokines capable of modulating bone turnover translates into skeletal involvement, ranging from severe osteolysis to significant osteosclerosis, with osteoporosis being the most frequently observed pathology [50, 51]. Bone loss is also exacerbated by the use of glucocorticoids. An important clinical manifestation of skeletal involvement includes generalized bony pain, which may be incapacitating, and is often resistant to conventional analgesia, particularly in cases of extensive bone marrow involvement or rapidly progressive disease. Osteoporosis may be associated with systemic manifestations of enhanced mast cell activity such as flushes and gastrointestinal symptoms [51], or may also be the sole presentation of bone marrow mastocytosis [52–54], in which case the osteoporotic process may be severe and progressive. The diagnosis can only be confidently established by histologic examination of bone marrow biopsies that demonstrate the pathognomonic feature of bone marrow infiltration with a large number of morphologically abnormal mast cells, individually or in aggregates of more than 15 cells [51]. Bone marrow mastocytosis is an important "occult" cause of secondary osteoporosis, shown to be present in up to 9% of men with "idiopathic osteoporosis" [54]. Serum tryptase may be normal and the measurement of the 24-hour urine excretion of N-methyl histamine represents a valuable noninvasive surrogate to bone marrow biopsies in establishing the diagnosis and evaluating the degree of mast cell load [54, 55].

WHO NEEDS TO BE SCREENED FOR SECONDARY CAUSES FOR OSTEOPOROSIS?

The high prevalence of potentially reversible secondary causes for osteoporosis, which may be identified with a sensitivity of 92% by cost-effective laboratory investigations [56], dictates that the majority of patients with osteoporosis would require a basic battery of laboratory tests before the start of treatment, including a full blood count, serum biochemistry panel, 24-hour urine calcium excretion, and 25 hydroxy-vitamin D measurements [2, 57]. Secondary causes for osteoporosis should be particularly sought in young patients [58], premenopausal women [59], men under the age of 65 [60], in all patients with unexpected or severe osteoporosis, in those with accelerated bone loss, and in those experiencing bone loss under treatment with conventional osteoporosis therapy. Further laboratory tests should be requested to confirm or exclude hypogonadism, thyrotoxicosis, celiac disease, hypercortisolism, mastocytosis, and multiple myeloma. If suspicion remains high, or in the case of fragility fractures in the presence of a normal bone mineral density (BMD), a double tetracycline-labeled transiliac bone biopsy with bone marrow evaluation may be indicated to establish a mineralization defect, or a bone marrow disorder, particular a nonsecretory myeloma or mastocytosis.

CONCLUSIONS

Secondary causes of osteoporosis are very common, particularly in premenopausal women and in men with osteoporosis, while also being the cause of accelerated bone loss in postmenopausal and age-related osteoporosis. In addition to representing significant comorbidity in specific disease entities such as inflammatory disorders, malignant disease, bone marrow disorders, and endocrinopathies, secondary osteoporosis is also commonly associated with often silent disturbances in calcium homeostasis such as vitamin D deficiency, hypercalciuria, and hyperparathyroidism, all of which are easily detectable by standard laboratory testing. The ubiquitous nature of "secondary osteoporosis" suggests that diverse medical disciplines need to better interact to meet some of the challenges presented by osteoporosis as a chronic comorbidity of specific disease entities. Screening for secondary causes for osteoporosis should represent an

intrinsic part of the optimal management of any patient with osteoporosis.

ABSTRACT

Transplantation is an established therapy for end-stage diseases of the kidney, endocrine pancreas, heart, liver and lung, intestines, and for many hematological disorders. Current immunosuppressive regimens with glucocorticoids and calcineurin inhibitors produce excellent patient and graft survival rates. This has resulted in both increases in transplant numbers and an increased recognition of previously neglected long-term complications of transplantation such as fractures and osteoporosis. Both pre-transplantation bone disease and immunosuppressive therapy result in high bone turnover, rapid bone loss, and increased fracture rates, particularly early after transplantation. The bone health of candidates for organ transplantation should be assessed with bone densitometry of the hip and spine. Spinal X-rays should be performed to diagnose prevalent fractures. Secondary causes of osteoporosis should be identified and treated. Vitamin D deficiency should be corrected to achieve a serum 25(OH)D concentration 30 ng/mL or higher. Patients with kidney failure should be evaluated and treated for chronic kidney disease–mineral and bone disorder (CKD–MBD), including renal osteodystrophy. Secondary hyperparathyroidism, in particular, should be treated.

Treatment is indicated in the immediate post-transplantation period irrespective of bone mineral density, since further rapid bone loss will occur in the first several months after transplantation. The duration of therapy will depend on the type of transplant. Long-term organ transplant recipients should also have bone mass measurement and treatment of osteoporosis.

Oral and intravenous bisphosphonates are the most promising approach for the management of transplantation osteoporosis and reduction of the number of patients with vertebral fractures following transplantation. Active vitamin D metabolites may have additional benefits in reducing hyperparathyroidism, particularly after kidney transplantation.

INTRODUCTION

Transplantation is an established therapy for end-stage diseases of the kidney, endocrine pancreas, heart, liver and lung, intestines, and for many hematological disorders. Improved survival rates, due to the addition of calcineurin inhibitors, cyclosporine A, and tacrolimus to immunosuppressive treatment, have been accompanied by a greater awareness of the long-term complications of transplantation such as fractures and osteoporosis [1, 2].

PREEXISTING BONE DISEASE

Chronic kidney disease

Renal osteodystrophy or chronic kidney disease–bone and mineral disorder (CKD-MBD) is the most complex

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

form of pre-transplant bone disease. One or more types of bone disease may be present, including osteitis fibrosa cystica as a result of secondary hyperparathyroidism (SHPT), low turnover bone disease (osteomalacia, adynamic bone disease, or aluminum bone disease), osteoporosis, mixed bone disease, and β_2-microglobulin amyloidosis. In addition, hypogonadism, both in men and women, metabolic acidosis, and certain medications (loop diuretics, heparin, warfarin, glucocorticoids, or immunosuppressive agents) also adversely affect bone health. Patients with chronic kidney disease (CKD) who have low bone mineral density (BMD) and bone turnover markers in the upper half of the normal premenopausal range are at the highest risk of fracture [3].

Adynamic bone disease needs exclusion prior to treatment with bisphosphonates, which reduce bone turnover further. It is commonly associated with osteoporosis and occurs early in CKD. On bone histomorphometry, there is a scarcity of bone cells, reduced osteoid thickness, and a low bone formation rate [4]. The factors reducing bone turnover are a low vitamin D system, high phosphate, and FGF-23, which override the stimulatory effect of parathyroid hormone (PTH) in early CKD. The use of cinacalcet, calcium, and calcitriol may also reduce bone turnover. The perturbation in bone turnover in CKD therefore needs careful evaluation before treatment is initiated. Bone histomorphometry is the best method. The combination of a low bone formation marker and a slightly increased or normal PTH level is less specific.

In hemodialysis patients, the prevalence of both low BMD and fractures is increased. All skeletal sites are affected, including the spine, hip, and distal radius. Vertebral fracture prevalence is as high as 21%, and the relative risk of hip fracture is increased 2-fold to 14-fold. Fracture risk is increased with older age, female gender, Caucasian race [5], duration of hemodialysis [6], diabetic nephropathy, peripheral vascular disease [7], low spine BMD, and low bone turnover states.

Congestive heart failure

Osteoporotic BMD affects up to 40% of patients with congestive heart failure (CHF), with a 2.45-fold increase in fracture risk in one study [8]. In another study of patients awaiting heart transplantation, lumbar spine (LS) osteopenia was found in 43%, and osteoporosis in 7% [9]. Mild renal insufficiency, vitamin D deficiency, SHPT, and increased bone resorption markers, and use of loop diuretics may contribute.

End-stage liver disease

Osteoporosis and fractures commonly accompany chronic liver disease and low BMD is seen in the majority of patients undergoing liver transplantation. Osteoporosis at the spine or hip has been reported in 11–52% of patients awaiting liver transplantation [1, 10]. Low body mass index (BMI) prior to lung transplantation (LT), cholestatic liver disease, and older age are important risk factors [11, 12] for osteoporosis.

Chronic respiratory failure

Osteoporosis may be most common in patients awaiting lung transplantation. Hypoxia, hypercapnia, smoking, and glucocorticoids all contribute. Fragility fractures are extremely common in cystic fibrosis (CF) because additional risk factors (pancreatic insufficiency, vitamin D deficiency, calcium malabsorption, hypogonadism, genetic factors, and inactivity) exist. Up to 61% of patients with end-stage pulmonary disease have osteoporosis. Chronic glucocorticoid use, low BMI, and decreased pulmonary function are all associated with low BMD [13].

Candidates for bone marrow transplantation

Bone loss in bone marrow transplantation (BMT) recipients is related both to the underlying diseases and to chemotherapeutic drugs. These include glucocorticoid (GC)-induced decreases in bone formation and serum 1,25-$(OH)_2D_3$, as well as hypogonadism secondary to the effects of high-dose chemotherapy, total body irradiation (TBI), and GCs. Women are particularly sensitive to the adverse effects of TBI and chemotherapy on gonadal function. Ovarian insufficiency occurs in the majority [14, 15], although some young, premenarchal women may recover ovarian function. Testosterone levels decline acutely after BMT related to a reduction in luteinizing hormone, then return to normal in most men [16–18]. There may be long-term impairment of spermatogenesis with elevated follicle stimulating hormone (FSH) occurring in 47% of men [14, 15]. In patients studied after chemotherapy but before BMT, osteopenia was present in 24% and osteoporosis in 4% [18].

Candidates for intestinal transplantation

Osteoporosis occurs in 36% of candidates for intestinal transplantation, with age and duration of parenteral nutrition being significant risk factors. Bone density at the spine and hip is reduced by about 1.5 standard deviations below normal age- and sex-matched mean levels [19].

SKELETAL EFFECTS OF IMMUNOSUPPRESSIVE DRUGS

Glucocorticoids

Exposure to glucocorticoids (GCs) varies with the organ transplanted and the number of rejection episodes. High doses are commonly prescribed immediately after trans-

plantation and are weaned rapidly. Doses are increased at the time of rejection episodes. The highest GC-associated rates of bone loss are in the first 3 to 12 months post transplant. Trabecular sites are predominantly affected. The use of calcineurin inhibitors and more recent immunosuppressive regimens both have limited GC use. As a result, more recent studies show lower rates of post-transplant bone loss.

However, even small doses of glucocorticoids are associated with marked increases in fracture risk in epidemiological studies [20]. Glucocorticoids reduce bone formation by decreasing osteoblast replication and differentiation, and increasing apoptosis. Osteoblast genes including type I collagen, osteocalin, insulin-like growth factors, bone matrix proteins, transforming growth factor β (TGFβ) are downregulated, whereas receptor activator for nuclear factor-κB ligand (RANKL), is upregulated. Direct and indirect effects of GCs to increase bone resorption also contribute to the rapid increase in fracture risk post transplant. The immediate post-transplant period is characterized by high bone remodeling and increased bone resorption. Hyperparathyroidism may result from GC-induced reductions of intestinal and renal calcium absorption.

More recently, data from the United States Renal Data System have shown the use of early steroid withdrawal after kidney transplantation has been associated with a 31% fracture risk reduction [21]. Fractures associated with hospitalization were also significantly lower with regimens that withdraw corticosteroids. As this study likely underestimated overall fracture incidence, prospective studies are needed to determine the differences in overall fracture risk in patients managed with and without corticosteroids after kidney transplantation.

Calcineurin inhibitors

Cyclosporine (CsA) has independent adverse effects to increase bone turnover [22]. Although CsA treatment could result in high bone turnover after transplantation, it is reassuring that kidney transplant patients receiving CsA without GCs [23, 24] do not lose bone, and fractures are also reduced [21].

Tacrolimus (FK506), another calcineurin inhibitor (CI), also causes trabecular bone loss in the rat [22]. Both cardiac [25] and liver [26] transplant recipients sustained rapid bone loss with tacrolimus. However, tacrolimus may cause less bone loss in humans than CsA [27, 28] and may also protect the skeleton by reducing GC use.

Other immunosuppressive agents

Limited information is available regarding the effects of other immunosuppressive drugs on BMD and bone metabolism. However, azathioprine, sirolimus (rapamycin), mycophenelate mofetil, and daclizumab may also protect the skeleton by reducing GC use. *In vitro* studies suggest rapamycim inhibits osteoblast proliferation and differentiation [29], but more clinical data are required.

MANAGEMENT OF TRANSPLANTATION OSTEOPOROSIS

Diagnostic strategies

Before organ transplantation

All candidates going onto the waiting list for organ transplantation should have bone densitometry by dual energy X-ray absorptiometry (DXA) of the hip and spine. Spinal X-rays should be performed to diagnose prevalent fractures. Any secondary causes of osteoporosis should be identified and treated. Common secondary causes include hyperparathyroidism, hypogonadism, smoking, use of loop diuretics, low dietary calcium intake, and vitamin D deficiency (less than 20 ng/mL).

Vitamin D deficiency may be related to disease-related factors, decreased sunlight exposure and low dietary intakes [30]. Vitamin D deficiency should be corrected and all patients should receive adequate calcium and vitamin D (1,000–1,300 mg of calcium and at least 800 IU of vitamin D per day). Replacement doses of vitamin D may need to be higher (2,000 IU of vitamin D per day), but should be selected to achieve a 25(OH)D concentration of 20–30 ng/mL or greater. Patients with kidney failure should be evaluated and treated for renal osteodystrophy and secondary hyperparathyroidism, in particular.

Individuals with osteoporosis awaiting solid organ transplants should be evaluated and treated similarly to others with this condition, with the exception of patients awaiting kidney transplantation, in whom CKD–MBD is more complex. In this group, it is important to diagnose and treat secondary hyperparathyroidism and to exclude adynamic bone disease.

After organ transplantation

Risk factors for post-transplant bone loss and fractures are shown in Table 61.1. Bone loss is most rapid immediately after transplantation. Fractures often occur in the first year after transplantation and may affect patients with either low or normal pre-transplant BMD. Therefore, the majority of patients may benefit from treatment instituted immediately after transplantation, with exception of patients with CKD–MBD and adynamic bone disease. Patients who present after being transplanted months or years before should also be assessed for treatment.

Vitamin D deficiency is common post transplantation and in long-term graft recipients. Vitamin D status is partly determined by demographic and lifestyle factors and deficiency is associated with poorer general health, lower serum albumin levels, and even decreased survival in these groups [30].

Table 61.1. Risk Factors for Post-Transplant Bone Loss and Fractures

Contributing Factors	Mechanisms
Aging	**Low pre-transplant BMD**
Low body mass index	
Hypogonadism	
Calcium and vitamin D deficiency	
Tobacco	
Alcohol abuse	
Cholestasis (liver disease)	
Organ failure (heart, lung, liver, kidney)	
Pancreatic insufficiency (cystic fibrosis)	
Physical inactivity	
High dose prednisone	**Decreased bone formation**
	Direct effect
	Decreased gonadal function
	Reduced intestinal and renal calcium transport
Calcineurin inhibitors	**Increased bone resorption**
Cyclosporine or FK506	Decreased renal function and $1,25(OH)_2D$
	Increased PTH secretion
	Possible direct effect
Calcineurin inhibitor	**Decreased bone formation**
Sirolimus	Possible direct effect

Most therapeutic trials have focused on the use of active vitamin D metabolites and antiresorptive drugs, particularly oral and intravenous bisphosphonates. Hormone therapy with estrogen ± progestin helps protect the skeleton in women receiving liver, lung, and bone marrow transplantation. Because amenorrhea is a common sequela of BMT in premenopausal women, they should receive hormone replacement therapy (HRT). However, it does not prevent bone loss after BMT. Hypogonadism is common in male cardiac and bone marrow transplant recipients, due to chronic illness and hypothalamic-pituitary-adrenal suppression by GCs and CsA. Testosterone levels fall immediately after transplantation and normalize 6 to 12 months later. However, testosterone treatment alone does not prevent bone loss after cardiac transplantation or BMT in men.

Recent studies examined prevention of bone loss after transplantation (Table 61.2).

Kidney transplantation

Renal osteodystrophy improves after transplantation; however, hyperparathyroidism (HPT) may persist. Bone resorption remains elevated in a substantial proportion of kidney transplant recipients, and there is GC-induced osteoblast dysfunction [31, 32]. Cross-sectional studies of patients evaluated several years after kidney transplantation have reported osteoporosis in 17–49% at the spine, 11–56% at the femoral neck, and 22–52% at the radius [1]. There is a correlation between cumulative GC dose and BMD. Rates of bone loss are greatest in the first 6–18 months after transplantation, and range from 4% to 9% at the spine and 5% to 8% at the hip. Bone loss has not been consistently related to gender, patient age, cumulative GC dose, rejection episodes, activity level, or PTH levels. Although increasing time since transplantation is considered to be a risk factor for low BMD, studies examining BMD after the first year or two do not consistently show ongoing bone loss; however, BMD remains low up to 20 years after transplantation. Secondary HPT and low $1,25(OH)_2D$ levels also often persist [3, 33].

Fractures affect appendicular sites (hips, long bones, ankles, feet) more commonly than axial sites (spine and ribs) [33]. Women and patients transplanted for diabetic nephropathy are at particularly increased risk of fractures. The majority of fractures occur within the first 3 years; however, fractures continue to increase the longer the post-transplant period [34].

Prevention and treatment

Calcium and vitamin D supplementation alone does not prevent bone loss in renal transplant patients [35]. Bisphosphonates reduce bone loss after kidney transplantation (KT) [36]. In a small study, the combination of alendronate (10 mg/day), calcium carbonate (2 g/day), and calcitriol (0.25 µg/day) resulted in a 6.3% increase in spinal BMD in the first 6 months after KT, compared with a 5.8% decrease with calcium and calcitriol alone [37]. Alendronate, calcitriol, and calcium treatment was also superior to calcitriol and calcium treatment alone, beginning 5 years post KT [38]. Intermittent calcitriol (0.5 µg/48 hours) during the first 3 months after renal transplantation, preserved total hip BMD more than calcium (500 mg/day) supplementation alone over 1 year [39].

Renal safety issues and dosing schedules are different for intravenous bisphosphonates. Zoledronic acid (ZA) may cause acute renal failure, with the induction of acute tubular necrosis related to the rate of its infusion rather than the dose. The risk of renal failure is also increased by preexisting renal impairment, so the infusion rate should be reduced to half the recommended rate in patients with a glomerular filtration rate (GFR) less than 30 mls/min or baseline serum creatinine concentration greater than 2 mg/dL [40]. The former measurement is the more accurate.

Intravenous ibandronate was effective at preventing spinal and hip bone loss post KT [41]. There were also fewer spinal deformities in the ibandronate group after 12 months. A small, randomized study compared the long-term effects of two infusions of 4 mg of ZA or placebo at 2 weeks and 3 months after KT. Although early bone loss was prevented by ZA, both treatment groups had significant and similar later increases in femoral neck (FN) BMD [42].

Table 61.2. Randomized Controlled Trials Using Vitamin D Analogues or Bisphosphonates for Prevention of Bone Loss After Heart, Lung, Liver, and Bone Marrow Transplantation

Transplant type	First author, yr	n	Duration	Treatment regimen	Control regimen	Findings/ Summary
Heart and Lung	Sambrook (2000) (Ref. 51)	65	24 months	**Calcitriol** 0.5–0.75 μg for 12 months or 24 months Calcium 600 mg/day	Placebo Calcium 600 mg/day	BMD: FN (but not LS) bone loss was attenuated in the calcitriol groups at 12 months. LS bone loss was similar among all 3 groups. Fracture: Not powered.
Lung (CF)	Aris (2000) (Ref. 47)	37	24 months	**Pamidronate** 30 mg IV q 3 months Calcium 1000 mg/day Vitamin D 800 IU/day	Calcium 1,000 mg/day Vitamin D 800 IU/day	BMD: LS and TH BMD increased significantly more in the pamidronate group vs controls. Fracture: No difference.
Heart	Shane (2004) (Ref. 58)	149[a]	12 months	**Alendronate** 10 mg/day or **Calcitriol** 0.5 μg/day Calcium 945 mg/day Vitamin D 1,000 IU/day	Non-randomized reference group	BMD: Similar small losses at LS and TH in both groups. Significantly less bone loss at LS and TH than reference group. Fracture: No difference.
Heart	Gil-Fraguas (2005) (Ref. 56)	87	12 months	**Alendronate** 10 mg/day	**Calcitonin** 200 IU/day	BMD: Less bone loss from FN in the alendronate group. Fracture: Fewer vertebral fractures than in calcitonin group (6 vs 15).
Heart	Fahrleitner-Pammer (2009) (Ref. 57)	35	12 months	**Ibandronate** 2mg IV q 3 months calcium 1000 mg/day Vitamin D 400 IU/day	Placebo calcium 1,000 mg/day Vitamin D 400 IU/day	BMD: Bone loss from LS and FN prevented in ibandronate group. Fracture: Fewer vertebral fractures than in control group (2 vs 17).
Liver and multivisceral	Hommann (2002) (Ref. 63)	36	12 months	**Ibandronate** 2 mg IV q 3 months Calcium 1,000 mg/day Vitamin D 1,000 IU/day	Calcium 1,000 mg/day Vitamin D 1,000 IU/day	BMD: LS, FN and forearm BMD decreased initially in both groups. Reversal of bone loss with ibandronate seen after 12 months.
Liver	Ninkovic (2000) (Ref. 62)	99	12 months	**Pamidronate** 60 mg IV given once prior to transplantation	No treatment	BMD: Significant, comparable bone loss at FN in pamidronate and control groups Fracture: No difference.
Liver	Crawford (2006) (Ref. 64)	62	12 months	**Zoledronic acid** 4 mg IV administered within 7 days of transplantation and at 1, 3, 6, and 9 months after transplant Calcium 600 mg/day Vitamin D 1,000 IU/day	Placebo Calcium 600 mg/day Vitamin D 1,000 IU/day	BMD: At 3 months, difference in bone loss from baseline was decreased in ZA group vs placebo. At 12 months, the differences in % bone loss was less. Fracture: Not powered.
Liver	Bodingbauer (2007) (Ref. 65)	69	12 months	**Zoledronic acid** 4 mg IV 1–6, 9, and 12 months Calcium 600 mg/day Vitamin D 1,000 IU/day	Calcium 600 mg/day Vitamin D 1,000 IU/day	BMD: Less bone loss from LS (but not FN) in Zoledronic acid group. Fracture: Fewer vertebral facture than in control group (4 vs 11).

(*Continued*)

Table 61.2. (*Continued*) Randomized Controlled Trials Using Vitamin D Analogues or Bisphosphonates for Prevention of Bone Loss After Heart, Lung, Liver, and Bone Marrow Transplantation

Transplant type	First author, yr	n	Duration	Treatment regimen	Control regimen	Findings/ Summary
Liver	Monegal (2009) (Ref. 66)	79	12 months	**Pamidronate** 90 mg IV 0 and 3 months Calcium 1,000 mg/day Vitamin D 16,000 IU q 15 days	Calcium 1,000mg/day Vitamin D 16,000 IU q 15 days	BMD: Increase at LS in pamidronate group. Decrease at FN in both groups. Fracture: More fractures in pamidronate group (15 vs 3).
Liver	Kaemmerer (2010) (Ref. 67)	74	12 months	**Ibandronate** 2 mg IV q 3 months Calcium 1,000 mg/day Vitamin D 800–1,000 IU/day	Calcium 1,000 mg/day Vitamin D 800–1,000 IU/day	BMD: Increase at LS and less bone loss from FN in ibandronate group. Fracture: fewer fractures in ibandronate group (2 vs 8).
BMT	Tauchmanova (2003) (Ref. 78)	34	12 months	**Risedronate** 5 mg/day Calcium 1 g/day Vitamin D 800 IU/day	Calcium 1 g/day Vitamin D 800 IU/day	BMD: LS BMD significantly increased in risedronate group at 6 and 12 months and decreased in the control group at 6 months. FN BMD decreased significantly in control group at 6 months only.
BMT	Tauchmanova (2005) (Ref. 79)	32	12 months	**Zoledronic acid** 4 mg IV administered at 1, 2, and 3 months Calcium 500 mg/day Vitamin D 400 IU/day	Calcium 500 mg/day Vitamin D 400 IU/day	BMD: LS and FN BMD significantly increased in ZA group and did not change in the control group at 12 months.
BMT	Kanenen (2005) (Ref. 17)	99	12 months	**Pamidronate** 60 mg IV administered prior to transplant and 1, 2, 3, 6, and 9 months after transplant Calcium 1,000 mg/day Vitamin D 800 IU/day estrogen – women testosterone – men	Calcium 1,000 mg/day Vitamin D 800 IU/day estrogen – women testosterone - men	BMD: At 12 months, difference in bone loss from baseline at LS and TH was decreased in pamidronate group vs no infusion. No difference in bone loss from baseline at the FN. Fracture: Not powered.
BMT	Grigg (2006) (Ref. 80)	116	24 months	**Pamidronate** 90 mg IV administered prior to transplant and every month after transplant for 12 months Calcium 1,000 mg/day Calcitriol 0.25 µg/day for 24 months	Calcium 1000 mg/day Calcitriol 0.25 µg/day	BMD: At 12 months, difference in bone loss from baseline was decreased at LS, FN and TH in pamidronate group vs no infusion. At 24 months, the difference in bone loss from baseline was only significant at the TH (3.9%). Fracture: Not powered.

[a]Number randomized to alendronate or calcitriol, 27 prospectively recruited non-randomized patients served as a reference group.

A large, recent systematic review of 24 trials with 1,299 patients showed any treatment for bone disease reduced the risk of fracture by 49% (95%; CI 0.27–0.99) compared with placebo [43]. Bisphosphonates and active vitamin D analogues had beneficial effects on the BMD at the spine and FN. Bisphosphonates were better at preventing bone loss compared with vitamin D analogues. An unexpected finding was a reduction in the risk of graft rejection associated with bisphosphonate therapy. A trial using fractures as a primary end point is now required to compare treatment with oral or parenteral bisphosphonates with calcitriol after KT.

Kidney-pancreas transplantation

Severe osteoporosis complicates kidney-pancreas transplants in recipients with type 1 diabetes, occurring in 23% and 58% at the LS and FN, respectively. Vertebral or nonvertebral fractures were documented in 45% [1]. Other retrospective studies have documented a fracture prevalence of 26–49% up to 8.3 years after transplantation [44].

A prospective study addressed osteoporosis and secondary hyperparathyroidism in simultaneous pancreas-kidney transplantation (SPK) recipients before transplant and 4 years after. Prior to transplantation, 68% had hyperparathyroidism. After 6 months, bone loss of 6.0% and 6.9% occurred at both LS and FN sites, respectively, and fractures were related to low pre-transplant FN BMD [45].

Lung transplantation

The prevalence of osteoporosis is as high as 73% in lung transplantation (LT) recipients. During the first year after lung transplantation, rates of bone loss at the LS and FN range from 2% to 5% [1]. Fracture rates are also high during the first year, ranging from 18% to 37%. Bone turnover is also increased [46]. Repeated doses of intravenous pamidronate prevented LS and FN bone loss in LT recipients [47, 48].

Cardiac transplantation

The most rapid rate of bone loss occurs in the first year post transplant. Spinal BMD declines by 6–10% during the first 6 months, while FN BMD falls by 6–11% in the first year and stabilizes thereafter in most cases. BMD declines at the largely cortical proximal radius site over the second and third years, perhaps reflecting post-transplant SHPT. Vitamin D deficiency and testosterone deficiency (in men) are associated with more severe bone loss. Testosterone levels fall immediately after cardiac transplantation (CT) and normalize after 6–12 months. Some studies have found correlations between GC dose and bone loss. Vertebral fracture incidence ranges from 33% to 36% during the first 1 to 3 years after CT [49, 50].

Prevention and treatment

Vitamin D and calcitriol. Calcium and vitamin D alone do not prevent bone loss after CT [1]. Early studies showed calcitriol was effective at reducing bone loss, particularly at the FN, after CT [51]. Another study compared rates of bone loss in patients randomized to receive calcitriol (0.5 μg/day) or two cycles of etidronate during the first 6 months after CT or LT [52]. Significant and similar bone loss (3–8%) occurred at the spine and FN in both treatment groups, but was less than in historical controls [51, 52].

Other studies observed that CT recipients randomized to either alphacalcidol or cyclic etidronate sustained considerable bone loss at the spine and FN during the first year after transplantation [1], while another study of calcitriol [53] found no protective benefit. Thus, data regarding calcitriol and prevention of post-CT bone loss are inconsistent. Monitoring of serum and urine calcium levels is also required.

Intranasal calcitonin. One small study showed spinal BMD was higher 1–3 years, but not 7 years after CT in those treated with intranasal salmon calcitonin [54].

Testosterone. Because low post-transplant testosterone concentrations are often transient, only hypogonadal men should receive testosterone therapy.

Bisphosphonates. An open-label study of a single intravenous dose of pamidronate (60 mg) followed by four cycles of etidronate (400 mg every 3 months) and daily low-dose calcitriol (0.25 μg), prevented spinal and FN bone loss and reduced fracture rates in CT recipients compared with historical controls [55]. Compared with calcitonin (200 IU/day), alendronate (10 mg/day) treatment reduced hip bone loss and resulted in fewer vertebral fractures [56]. In a small study of 35 men post CT, intravenous ibandronate (2 mg every 3 months) prevented spine and hip bone loss and resulted in fewer morphometric vertebral fractures [57].

In the largest study, where 149 patients were randomized immediately after CT to receive either alendronate (10 mg/day) or calcitriol (0.25 μg twice daily) for 1 year, bone loss at the spine and hip was prevented by both regimens compared with a prospectively recruited, non-randomized reference group who received only calcium and vitamin D [58]. After 1 year of treatment withdrawal, BMD did not change in either the former alendronate or calcitriol group, but bone resorption increased in the calcitriol group [59]. This suggests that antiresorptive therapy may be discontinued 1 year post transplant in CT recipients without inducing rapid bone loss. However, these patients still require observation to ensure that BMD remains stable in the long-term.

Exercise. Resistance exercise significantly improved lumbar spine BMD after lung [60] and heart [61] transplantation when used alone and in combination with alendronate. However, these small studies utilized highly variable lateral BMD measurements.

Liver transplantation

Bone loss and fracture rates after liver transplantation (LIT) are highest in the first 6–12 months. Spine BMD declines by 2–24% during the first year in earlier studies.

In more recent studies, rates of bone loss have been lower or absent. Fracture rates range from 24–65%, and the ribs and vertebrae are the most common sites. Women with primary biliary cirrhosis and the most severe preexisting bone disease appear to be at greatest risk. Older age and pre-LIT spinal and FN BMD predicted post-LIT fractures in one recent prospective study, while the presence of pre-LIT vertebral fractures also predicted post-LIT vertebral fractures [1, 62]. Post LIT, bone turnover is increased compared with low bone turnover pre-LIT.

Prevention and treatment

Both oral and intravenous bisphosphonates are effective in reducing post-LIT bone loss, although one early study of intravenous pamidronate was ineffective due to insufficient dosing [62]. A randomized trial of intravenous ibandronate in liver [63] transplant recipients found a significant protective effect on BMD at 1 year. In a randomized, double-blind trial, 62 LIT recipients received treatment with either infusions of 4 mg ZA or saline within 7 days of transplantation and again at 1, 3, 6, and 9 months post LIT [64]. All patients also received calcium and vitamin D. ZA significantly prevented bone loss from the LS, FN, and total hip by 3.8–4.7%, with differences being greatest 3 months post LIT. At 12 months post LIT, differences only remained significant at the total hip. Similar findings were identified in another study using 4 mg intravenous ZA at 1–6, 9, and 12 months post LIT. Bone loss from the spine (but not hip) was prevented and fewer vertebral fractures occurred in the ZA group [65]. Vitamin D deficiency should be corrected before giving bisphosphonates post LIT to prevent hypocalcemia.

One study using two intravenous doses of pamidronate (90 mg) at baseline and 3 months post LIT showed an increase in spinal BMD in the pamidronate group, but more fractures in the pamidronate group [66]. Intravenous ibandronate given every 3 months post LIT resulted in increases in spinal BMD and less bone loss from the FN, and fewer fractures in the ibandronate group [67].

Two studies examined effects of alendronate on bone after LIT. An uncontrolled, prospective study of 136 LIT patients showed alendronate prevented bone loss in patients with osteopenia and led to an increase in BMD at the spine and FN in patients with osteoporosis over 4 years [9]. Another study of 59 LIT patients used historical controls to examine effects of alendronate combined with calcium and calcitriol 0.5 µg daily [68]. Increases in spinal, FN, and total hip BMD at 12 months were higher than in historical controls.

Small bowel transplantation

Small bowel transplantation (SBT) is being increasingly used for severe inflammatory bowel disease. It may also include concomitant liver, pancreas, and stomach transplantation. In a cross-sectional study of 81 patients who had SBT 2.2 years previously, BMD at the spine, total hip, and FN was reduced by about 0.8 SD compared with age- and sex-matched controls with similar small bowel diseases. Long-term SBT recipients are at risk of both osteoporosis (44%) and fractures (20%) [19]. In a small longitudinal study of nine patients, significant bone loss occurred at both the spine (2.6%) and the total hip and FN (by about 15%) 1.3 years after SBT [69]. A larger longitudinal study (n = 24) documented acceleration ($p = 0.025$) of bone loss after SBT with a decline of 13.4% (FN), 12.7% (total hip), and 2.1% (spine) over 2.5 years. Alendronate reduced ($p < 0.05$), but did not prevent bone loss [19].

Bone marrow transplantation

Bone marrow or stem cell transplantation (BMT) is the treatment of choice for patients with many hematological malignancies, the majority of whom will survive for many years. However, up to 29% and 52% of survivors have osteopenia at the spine or FN, respectively [1]. Osteoporosis is more common at proximal femur sites. The pathogenesis of post-BMT osteoporosis is complex, relating both to effects of treatment and effects on the bone marrow stromal cell (MSC) compartment [70, 71]. Bone resorption increases while bone formation decreases [1, 16], resulting in early, rapid bone loss. In addition to osteoporosis, osteomalacia, and avascular necrosis may occur.

Dramatic bone loss from the proximal femur occurs within the first 12 months of allogeneic BMT [1, 72, 73]. Spinal bone loss is less. Most studies suggest that little additional bone loss occurs after this time. Studies of long-term survivors of BMT have shown that losses from the proximal femur are not regained [74]. After autologous BMT, bone loss from the proximal femur is less (about 4%), occurs as early as 3 months and persists at 2 years, while spine BMD returns to baseline [75].

Bone loss after BMT is related to both cumulative GC exposure and duration of CsA exposure [72]. There may also be a direct effect of graft versus host disease (GVHD) itself on bone cells. Abnormal cellular or cytokine-mediated bone marrow function may affect bone turnover and BMD after BMT [1]. Both myeloablative treatment and BMT stimulate the early release of cytokines. BMT also has adverse effects on bone marrow osteoprogenitors. Osteocyte viability is decreased after BMT and bone marrow stromal cells are damaged by high-dose chemotherapy, TBI, GCs, and CsA, thereby reducing osteoblastic differentiation from osteoprogenitor cells [76]. In this regard, colony forming units-fibroblasts (CFU-f) are reduced for up to 12 years after BMT [1] .

Avascular necrosis develops in 10% to 20% of allo-BMT survivors, a median of 12 months after BMT [71, 77]. Glucocorticoid treatment of chronic GVHD-inducing osteoblast apoptosis is the most important risk factor. Avascular necrosis appears to be related to decreased numbers of bone marrow CFU-f colonies *in vitro*, but not to BMD [77]. Avascular necrosis may thus be facilitated by a deficit in bone marrow stromal stem cell regeneration with low osteoblast numbers post BMT [76].

Prevention and treatment

Risedronate or intravenous ZA given 12 months after BMT prevents spinal and proximal femoral bone loss [78, 79]. ZA effects may be related to improved osteoblast recovery and increased osteoblast numbers post BMT as increases in *ex vivo* growth of bone marrow CFU-f have been shown.

Two randomized trials recently assessed the effectiveness of intravenous pamidronate in preventing bone loss after BMT. The first studied 99 allogeneic BMT recipients, who were randomized to receive calcium and vitamin D daily, hormone therapy with estrogen in females or testosterone in men, or the same treatments plus intravenous 60 mg pamidronate infusions before and 1, 2, 3, 6, and 9 months after BMT [16]. In the pamidronate group, LS BMD remained stable but decreased significantly in the control group. Total hip BMD and FN BMD decreased by 5.1% and 4.2%, respectively, in the pamidronate group, and by 7.8% and 6.2%, respectively, in the control group at 12 months. Thus, pamidronate reduced bone loss more than in those treated with calcium, vitamin D, and sex steroid replacement alone.

A larger randomized, multicenter open-label 12-month prospective study compared intravenous pamidronate (90 mg/month) beginning prior to conditioning versus no pamidronate [80]. All 116 patients also received calcitriol (0.25 µg/day) and calcium, which were continued for a further year. Pamidronate significantly reduced bone loss at the spine, FN, and total hip at 12 months. However, BMD of the FN and total hip was still 2.8% and 3.5% lower than baseline, respectively, following pamidronate. Only the BMD benefit at the total hip remained significant between the two groups at 24 months. This study also showed the benefits of pamidronate therapy were restricted to patients receiving an average daily prednisolone dose greater than 10 mg and cyclosporin therapy for more than 5 months within the first 6 months of alloSCT (stem cell transplantation). Importantly, most BMD benefits were lost 12 months after stopping pamidronate.

A small uncontrolled, prospective study of a single 4 mg ZA infusion in allogeneic BMT patients with either osteoporosis or rapid bone loss post-allogeneic BMT [81] showed reduced bone loss at the spine and FN.

SUMMARY AND CONCLUSION

Pre-transplantation bone disease and immunosuppressive therapy result in a severe form of osteoporosis characterized by rapid bone loss and increased fracture rates, early after transplantation. There is increased bone resorption and decreased bone formation, suggestive of uncoupling of bone turnover. In the late post-transplant period, with weaning of glucocorticoid doses, bone formation begins to increase and underlying high bone turnover resulting in osteoporosis. Although rates of bone loss and fractures reported in recent studies are lower than those of 10 years ago, they remain too high. Transplant candidates should be assessed, and pre-transplantation bone disease should be treated. Preventive therapy initiated in the immediate post-transplantation period is indicated in patients with osteopenia or osteoporosis, since further bone loss will occur immediately after transplantation. All organ transplant recipients should be considered at risk for post-transplantation bone loss and fractures, as it is impossible to identify patients with the highest fracture risk. Long-term organ transplant recipients should also have bone mass measurement and treatment of osteoporosis.

A recent meta-analysis showed treatment with a bisphosphonate or active vitamin D metabolite during the first year after solid organ transplantation is associated with a 50% reduction in the number of subjects with fractures and 76% fewer vertebral fractures [Fig. 61.1(A)] [82]. Bisphosphonate treatment was associated with a 47% reduction in the number of subjects with fractures [Fig. 61.1(B)], but no significant reduction in vertebral

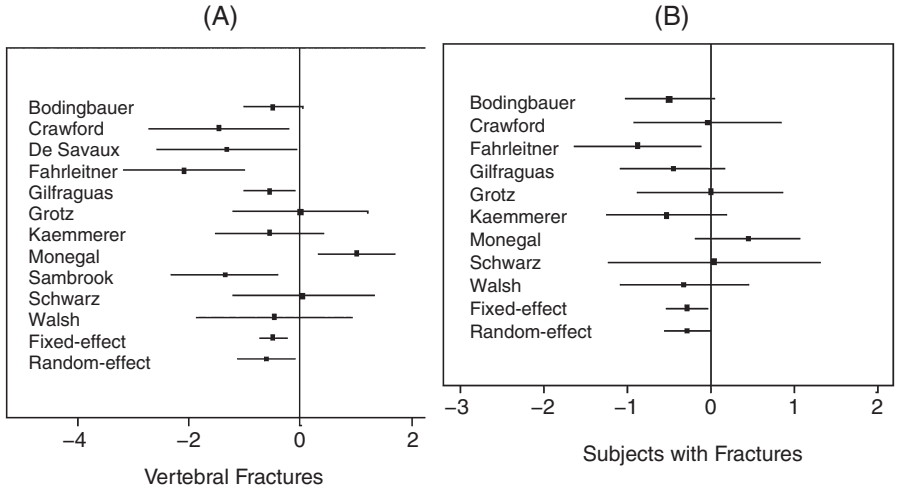

Fig. 61.1. (A) Log odds ratios (OR) and 95% confidence intervals for the effect of treatment with bisphosphonates or vitamin D analogues after organ transplantation on the number of vertebral fractures (OR 0.24, 95% CI 0.07, 0.78 by random effects model). (B) Log odds ratios (OR) and 95% confidence intervals for the effect of treatment with bisphosphonates after organ transplantation on the number of subjects with vertebral fractures (OR 0.53, 95% CI 0.30, 0.91 by fixed effect model). Reproduced with permission from Ref. 82.

fractures. Overall, bisphosphonates are the most promising approach for the prevention and treatment of transplantation osteoporosis. Active vitamin D metabolites may have additional benefits in reducing hyperparathyroidism, particularly after kidney transplantation. Potential new agents for transplantation osteoporosis include anabolic agents that stimulate bone formation, namely PTH(1-34) or teriparatide, and the anticatabolic drugs, human antibodies to RANKL (denosumab), and cathepsin K inhibitors. PTH(1-34) and other PTH1 receptor agonists may have a specific role after BMT in stimulating MSC cell differentiation into the osteoblast lineage and reducing adipogenesis [83, 84].

Several issues remain regarding the administration of bisphosphonates for transplantation bone disease, including the optimal route of administration and duration of therapy. Treatment may only need to be given for 1 year following cardiac transplantation, but its optimal duration is less clear following other transplants. It is also uncertain at what level of renal impairment oral bisphosphonates should be avoided and whether this level is the same for intravenous bisphosphonates. Another special consideration in using bisphosphonates in kidney transplant recipients is adynamic bone disease (see above). Large multicenter trials comparing treatment with oral or parenteral bisphosphonates and calcitriol, and commencing at the time of transplantation that are powered to detect differences in fracture rates are recommended here.

Despite some continuing uncertainties, much has been learned about transplantation osteoporosis. Armed with this information, it is now critical to act to prevent and treat this disabling disease.

ACKNOWLEDGMENTS

I thank Dr. Elizabeth Shane for her mentorship in this area.

INTRODUCTION

Osteoporosis in men is now recognized as an important public health problem, and there is a much greater understanding of the disorder. Effective diagnostic, preventive, and treatment strategies have been developed. Moreover, the study of osteoporosis in men has revealed male–female differences that in turn have fostered a greater understanding of bone biology in general. Nevertheless, there are important pathophysiological and clinical issues that remain unresolved and research continues to be very active.

SKELETAL DEVELOPMENT

Bone mass accumulation in males occurs gradually during childhood and accelerates dramatically during adolescence. Peak bone mass is closely tied to pubertal development, and male–female differences in the skeleton appear during adolescence [1]. The rapid increase in bone mass occurs somewhat later in boys than girls; the majority of the increase has occurred by an average age of 16 years in girls and age 18 years in boys. Moreover, whereas trabecular bone mineral density (BMD) accumulation is similar in boys and girls, boys generally develop thicker cortices and larger bones than do girls, even when adjusted for body size. These differences may provide important biomechanical advantages that could in part underlie the lower fracture risk observed in men later in life. The reasons for these sexual differences in skeletal development are unclear but could be related to differences in sex steroid action (androgens may stimulate periosteal bone formation and bone expansion), growth factor concentrations, and mechanical forces exerted on bone (e.g., by greater muscle action or activity). Sex-specific effects of a variety of genetic loci have been reported in animals and humans, suggesting that the origin of sex differences in skeletal phenotypes is complex. Finally, despite these average sex differences, there is wide variation in bone mass and structure in men after adjustment for body size, and considerable overlap with the range of similar measures in women.

EFFECTS OF AGING ON THE SKELETON IN MEN

As in women, aging is associated with large changes in bone mass and architecture in men [2]. Trabecular bone loss (e.g., in the vertebrae and proximal femur) occurs during midlife and accelerates in later life. The magnitude of these changes is similar, but probably slightly less, than those in women. In men there is more trabecu-

© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

lar thinning and less trabecular dropout than in women. Endocortical bone loss with resulting cortical thinning takes place in long bones, and cortical porosity increases with age, but these processes may be accompanied by a concomitant increase in periosteal bone expansion that tends to preserve the breaking strength of bone [3]. In general, the pattern of age-related bone loss in men is similar in men and women, but in men, there is no concomitant to the accelerated phase of loss associated with the menopause in women. In the elderly of both sexes, the rate of bone loss accelerates with increasing age.

FRACTURE EPIDEMIOLOGY

Fractures are common in men. Fracture data in men are derived primarily from the study of white populations. In them, the incidence of fracture is bimodal, with a peak incidence in adolescence and mid-adulthood, a lower incidence between ages 40 and 60, and a dramatic increase after the age of 70 (Fig 62.1) [4]. The types of fractures sustained in younger and older men are different, with long bone fractures being common in younger men, whereas vertebral and hip fractures predominate in the elderly. These differences suggest that the etiologies of fractures at these two periods of life are distinct. In younger men, trauma may play a larger role, whereas in older men skeletal fragility and fall propensity are likely to be major factors.

The exponential increase in fracture incidence as men age is as dramatic as the similar increase that occurs in women, but it begins 5–10 years later in life. This delay, combined with the longer life expectancy in women, underlies the greater burden of osteoporotic fractures in women. Nevertheless, the age-adjusted incidence of hip fracture in men is one-quarter to one-third that in women, and 20–25% of hip fractures occur in men [2]. The consequences of fracture in men are at least as great as in women, and in fact, elderly men seem to be more likely to die and to suffer disability than women after a hip fracture. Older men suffer lower rates of long bone fractures than do women [5]. There is less information concerning vertebral fracture epidemiology in men, but the age-adjusted incidence appears to be high (approximately 50% of that in women) [6]. In younger men, the prevalence of vertebral fracture is actually greater in men than in women, at least in part the result of higher rates of spinal trauma experienced by men. Although there are inadequate data, the epidemiology of fracture in men seems to be dramatically influenced by both race and geography [7, 8]. For instance, black men have a much lower likelihood of fractures than whites, and Asian men have a lower likelihood of suffering hip fracture than whites. Much more information is needed concerning these differences and their causation.

Over the past few decades, the population incidence of fractures has apparently been changing in both men and women. In Western societies the rate of hip fracture increased dramatically until about 10 years ago, but after that it began to decline, particularly in women but also in men [9, 10]. The reasons for the change are not clear but may be related to increased efforts in screening and treatment of osteoporosis, a greater prevalence of obesity, reduced smoking, etc. In contrast, recent data suggest that the rates of fracture are increasing quickly in Asian societies [11], potentially because of urbanization and other cultural changes. These divergent trends emphasize the importance of environmental influences on fracture causation. Finally, anticipated increases in the size of older populations may result in a greater number of fractures despite gradual reductions in fracture incidence.

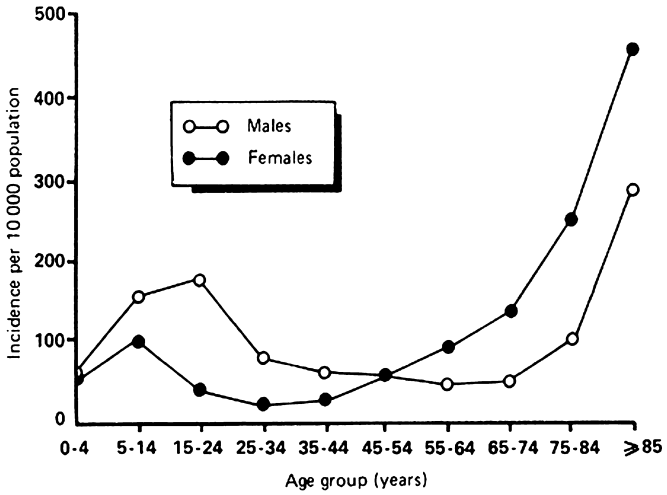

Fig. 62.1. Average annual fracture incidence rate per 10,000 population in Leicester, UK, by age group and by sex.

CAUSES OF OSTEOPOROSIS IN MEN

Fractures in men are related to a variety of risk factors. Certainly, skeletal fragility makes fracture more likely. This trait is most commonly measured as reduced BMD, but almost certainly has other components (biomechanically important alterations in bone geometry, material properties, etc.). Aging and a previous history of fracture are independently associated with a higher probability of future fracture, and men of lower weight have a higher fracture risk [2, 12]. Finally, falling becomes much more common with increasing age in men, and falls are strongly associated with increased fracture risk [13].

The causation of osteoporosis in men is commonly heterogeneous, and most osteoporotic men have several factors that contribute to the disease. One-half to two-thirds of men with osteoporosis have multiple risk factors, including other medical conditions, medications, or lifestyle issues that result in bone loss and fragility (Table 62.1). [2, 7]. The most important include alcohol abuse, glucocorticoid excess, and hypogonadism. An

Table 62.1. Causes of Osteoporosis and Bone Loss in Men

Primary
Aging
Idiopathic
Secondary
Hypogonadism

Immobilization
Osteogenesis imperfecta
Homocystinuria
Systemic mastocytosis
Neoplastic diseases and chemotherapy
Rheumatoid arthritis

important fraction of osteoporotic men, however, have idiopathic disease.

Idiopathic osteoporosis

Osteoporosis of unknown etiology can present in men of any age [14], but its presentation is most dramatic in younger men who are otherwise unlikely to be affected by osteoporosis. A low bone formation rate has been a consistent finding in these patients. Several possible etiologies have been considered. Most prominent among them are genetic factors, because BMD and the risk of fracture are highly heritable. The specific genes that may be responsible are uncertain.

Hypogonadism

Sex steroids are clearly important for skeletal health in men, both during growth and the attainment of peak bone mass as well as in the maintenance of bone strength in adults [14]. Hypogonadism is associated with low BMD; the development of hypogonadism results in increased bone remodeling and rapid bone loss (at least in the early phases of hypogonadism), and testosterone replacement increases BMD in hypogonadal men. One of the most important causes of severe hypogonadism is androgen deprivation therapy for prostate cancer; in this situation, bone loss is rapid, and the risk of fractures is clearly increased. Gonadal function and sex steroid levels decline with age in men, and it has been postulated that the decline may be an important risk factor for age-related bone loss and fracture risk. The strength of this association remains somewhat uncertain.

Although both are important, the relative roles of estrogens and androgens in skeletal physiology in men are uncertain [15–17]. Estrogen is essential for normal bone development in young men, as evidenced by immature delay in development and low bone mass in men with aromatase deficiency and their reversal with estrogen therapy. Moreover, estrogen is correlated with bone remodeling, BMD, and rate of BMD loss in older men, apparently more strongly than is testosterone. However, testosterone is independently related to indices of bone resorption and formation and may stimulate periosteal bone [18–20]. Low levels of estradiol have been clearly linked to increased fracture risk in older men [21, 22]. Testosterone levels appear less strongly related to fracture but may have an effect, particularly at very low concentrations [23]. High sex hormone-binding globulin (SHBG) concentrations have also been linked to increased fracture propensity [22]. The relative roles of estrogen, androgen, and SHBG must be better defined, and how measures of their levels can be used in clinical situations must be clarified.

EVALUATION OF OSTEOPOROSIS IN MEN

Guidelines for the evaluation of osteoporosis in men are not well validated, but there are several recommendations that can be made confidently.

BMD measurements

BMD measures are at least as effective in men as in women in predicting the risk of future fractures [24]. In light of the prevalence of osteoporosis and the high incidence of fractures in men, BMD measures are performed too infrequently. Two groups of men would benefit from BMD testing:

- Men over 50 years of age who have suffered a fracture, including those with vertebral deformity. Younger men who suffer low-trauma fractures should also be assessed.
- Men who have known secondary causes of bone loss should have their BMD determined. These include men treated with glucocorticoids or other medications associated with osteoporosis, men with hypogonadism of any cause, including those treated with androgen deprivation therapy, or men who have alcoholism. Many other risk factors may also prompt BMD measures (Table 62.1).

Screening BMD measures in older men have been recommended (e.g., older than 70 years of age) [25], and recent cost-effectiveness analysis has suggested that screening may be appropriate at that age, especially as treatment costs have declined [26, 27].

Currently, the presence of reduced BMD in men is commonly quantified with T-scores using a grading system parallel to that used in women (BMD T-score –1.0 to –2.5 = low bone mass; BMD T-score below –2.5 = osteoporosis). Whether BMD measurements in men should be interpreted using T-scores based on a male-specific reference range or using the same reference range used in women has been controversial. Analyses of large population level data suggest that the BMD-fracture risk association is the same in men and women. Some reports from carefully studied cohorts indicate there may be some sex differences [28, 29], but those differences appear to be relatively small. The use of FRAX or other fracture risk calculators may improve the estimation of fracture risk and the selection of men for therapy.

Men who have been selected for androgen deprivation therapy deserve special note because the risk of bone loss and fractures is clearly increased, especially in the first 5 years after sex steroid deficiency is induced [30, 31]. Men starting high-dose glucocorticoid therapy present the same challenges and should be similarly managed. When antiandrogen (or glucocorticoid) therapy is begun, a BMD assessment is appropriate. If it is normal, routine preventative measures are reasonable. A repeat BMD measurement should be done in 1–2 years. If BMD is reduced at the onset of therapy, more aggressive preventive measures should be considered (e.g., bisphosphonate therapy). Pharmacological approaches to prevent further bone loss or fractures are warranted in men with osteoporosis, even before antiandrogen (or glucocorticoid) therapy is begun.

Clinical evaluation

The clinical evaluation of men found to have low BMD should include a careful history and physical examination designed to identify any factors that may contribute to deficits in bone mass. Attention should be paid to lifestyle factors, nutrition (especially calcium, vitamin D, and protein nutrition), activity level, and family history. A history of previous fracture should be identified, and fall risk should be assessed. This information should be used to formulate recommendations for prevention and treatment.

Laboratory testing

In a man undergoing an evaluation for osteoporosis, laboratory testing is intended to identify correctable causes of bone loss. Appropriate tests are shown in Table 62.2.

Table 62.2. Evaluation of Osteoporosis in Men: Laboratory Tests

Serum calcium, phosphorus, creatinine, alkaline phosphatase, liver function tests
Complete blood count (protein electrophoresis in those over 50 years)
Serum 25(OH) vitamin D and parathyroid hormone
Serum testosterone and luteinizing hormone
24-hour urine calcium and creatinine
Targeted diagnostic testing in men with signs, symptoms, or other indications of secondary disorders
When an etiology is not apparent after the above, additional testing may be appropriate: thyroid function tests, 24-hour urine cortisol, biochemical indices of remodeling, immunological tests for sprue

OSTEOPOROSIS PREVENTION IN MEN

The essentials of fracture prevention in men are similar to those in women. In early life, excellent nutrition and exercise seem to have positive effects on bone mass. These principles and the avoidance of lifestyle factors known to be associated with bone loss (Table 62.1) remain important throughout life. Calcium and vitamin D probably provide beneficial effects on bone mass and fractures in men as in women. Recent Institute of Medicine recommendations for men include 1,000 mg of calcium for those 30–70 years of age and 1,200 mg for those over 70 years of age, with suggested vitamin D intakes of 600 IU/day until age 70 and 800 IU/day thereafter [32]. In those at risk for falls (e.g., with reduced strength, poor balance, previous falls), attempts to increase strength and balance may be beneficial.

TREATMENT OF OSTEOPOROSIS IN MEN

Ensuring adequate calcium and vitamin D intake and appropriate physical activity are essential foundations for preserving and enhancing bone mass in men who have osteoporosis. Secondary causes of osteoporosis should be identified and treated. In addition, there are pharmacological therapies that have been shown to enhance BMD, and in some cases, reduce fracture risk in men. Although the available data are not as extensive as in women, these therapies seem to be as effective in affecting BMD and in reducing fracture risk in men. The treatment indications for these drugs are similar in men and women.

Idiopathic and age-related osteoporosis

Alendronate, risedronate, ibandronate, zoledronate and teriparatide are effective in improving BMD [33, 34] regardless of age or gonadal function. Although the trials are relatively small, each is also apparently effective in reducing vertebral fracture risk. Zoledronate reduced the risk of recurrent fracture in men and women following

hip fracture [35], and although the independent effects in men could not be reliably ascertained, the effects sizes on fracture risk were similar in men and women.

Glucocorticoid-induced osteoporosis

Bisphosphonate therapy (e.g., alendronate, risedronate) is effective in improving BMD, and, although the data are not extensive, also probably reduces fracture [36, 37].

Hypogonadal osteoporosis

Bisphosphonate, denosumab and parathyroid hormone (PTH) therapy are effective in increasing BMD in hypogonadal men. Moreover, bisphosphonate and denosumab treatment can prevent the bone loss that is common after androgen deprivation therapy for prostate cancer, and denosumab reduces vertebral fracture risk in those men [38]. Testosterone replacement therapy results in increases in serum levels of both estradiol and testosterone and improves BMD in men with established hypogonadism [2], but whether fracture risk is reduced is unknown. In older men with less severe, age-related reductions in gonadal function, the usefulness of testosterone is less certain. Relatively high doses (200 mg of intramuscular testosterone every 2 weeks) is associated with an increase in BMD and strength in older men with low testosterone levels [39, 40], but its impact on fracture risk has not been examined. Lower doses (e.g., dermal administration of testosterone) seem to have lesser effects [41]. Once again, the effects of testosterone replacement on fracture risk are uncertain. Moreover, the long-term risks of testosterone therapy in older men are unknown. Therefore, testosterone replacement therapy is appropriate for management of the hypogonadal symptoms, but the treatment of osteoporosis in a man with low testosterone levels is most confidently undertaken with an osteoporosis drug for which there are more data concerning fracture risk reduction (e.g. a bisphosphonate or teriparatide) [42]

INTRODUCTION

In this chapter, we will discuss issues specific to the diagnosis, clinical evaluation, and management of premenopausal women who present with low trauma fracture and/or low bone mineral density (BMD).

PREMENOPAUSAL WOMEN WITH A HISTORY OF LOW-TRAUMA FRACTURE

The diagnosis of osteoporosis in premenopausal women is most secure when there is a history of low trauma fracture(s). A fracture (excluding fracture of the digits) that occurs with trauma equivalent to a fall from a standing height or less may be a sign of decreased bone strength, regardless of BMD.

Several studies have shown that fractures before menopause predict postmenopausal fractures [1–3]. In the Study of Osteoporotic Fractures (SOF), women with a history of premenopausal fracture were 35% more likely to fracture during the early postmenopausal years than women without a history of premenopausal fracture [1]. These findings suggest that certain lifelong traits, such as fall frequency, neuromuscular protective response to falls, bone mass, or various aspects of bone quality can affect lifelong fracture risk [2].

PREMENOPAUSAL WOMEN WITH LOW BONE MINERAL DENSITY

In postmenopausal women, osteoporosis may be diagnosed before a fracture has occurred by using BMD T-scores (see Chapter 49). However, in premenopausal women, the World Health Organization (WHO) criteria for diagnosis of osteoporosis and osteopenia do not apply to, and generally should not be used to categorize, BMD measurements. This is because in premenopausal women, the relationship between BMD and fracture risk is not clear. Since premenopausal women have a reported incidence and prevalence of fractures that is orders of magnitude lower than in postmenopausal women [1–4], the relationship between BMD and fracture risk is likely to be quite different in this younger age group.

The International Society for Clinical Densitometry (ISCD) recommends using Z-scores (comparison to an age-matched reference population), to categorize BMD measurements in premenopausal women. Young women with BMD Z-scores below –2.0 should be categorized as having BMD that is "below expected range for age" and those with Z-scores above –2.0 should be categorized as having BMD that is "within the expected range for age" [4]. Because Z-scores rather than T-scores are used, the diagnostic categories of "osteoporosis" and "osteopenia" based on T-scores should not be applied to premeno-

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

pausal women. An exception to these recommendations occurs in perimenopausal women, in whom use of T-scores is appropriate.

According to current guidelines, the diagnosis of "osteoporosis" should not be based solely upon BMD measurements in premenopausal women. This is because the clinical significance of low BMD in a premenopausal woman remains unclear since there are no longitudinal data that allow us to evaluate the extent to which BMD predicts fracture incidence in this population. However, several studies have shown that young women with low BMD are at higher risk for fractures than young women with normal BMD [5, 6]. Premenopausal women with Colles fractures have been found to have significantly lower BMD at the non-fractured radius [7], lumbar spine, and femoral neck [8] than controls without fractures. Stress fractures in female military recruits and athletes are associated with lower BMD than controls [6]. In addition, high-resolution imaging and transiliac bone biopsy studies have found that healthy, normally menstruating, premenopausal women with unexplained low BMD and no fractures have similar microarchitectural disruption to a comparable cohort of premenopausal women with low-trauma fractures, suggesting that very low BMD may represent a presymptomatic phase of osteoporosis in this group [9, 10a].

Additionally, the International Osteoporosis Foundation has recommended maintaining the T score cutoff of –2.5 at the spine or hip for the diagnosis of osteoporosis in those young adults who are thought to have completed growth and who suffer from a chronic disorder known to affect bone mass or to have an ongoing secondary cause of bone loss or fragility [10b].

SPECIAL ISSUES RELATED TO BONE MINERAL DENSITY INTERPRETATION IN PREMENOPAUSAL WOMEN

Although the majority of bone mass acquisition occurs during adolescence, BMD may continue to increase slightly between ages 20 and 30 [11]. Thus, very young women with low BMD measurements may not have yet achieved peak bone mass.

There are expected changes in bone mass associated with both pregnancy and lactation. At the lumbar spine, longitudinal studies document losses of 3–5% over a pregnancy and 3–10% over a 6-month period of lactation [12], with recovery of bone mass expected over 6–12 months, thereafter. Therefore, when interpreting a low BMD measurement in a premenopausal woman, the clinician must take the timing of recent pregnancy and lactation into account. Note that a young woman with fractures or low BMD diagnosed in the setting of pregnancy or lactation still requires an evaluation for potential secondary causes of osteoporosis (see below).

SECONDARY CAUSES OF OSTEOPOROSIS IN PREMENOPAUSAL WOMEN

Most premenopausal women with low-trauma fractures or low BMD have an underlying disorder or medication exposure that has interfered with bone mass accrual during adolescence and/or has caused excessive bone loss after reaching peak bone mass. In a population study from Olmstead County, Minnesota, 90% of men and women aged 20–44 with osteoporotic fractures were found to have a secondary cause [13]. In contrast, several case series of young women with osteoporosis evaluated in tertiary centers report that only 50% have secondary causes [14, 15], likely reflecting referral bias of more obscure cases to specialists.

Potential secondary causes are listed in Table 63.1. Many of these are discussed elsewhere in this *Primer*. The main goal of the evaluation of a premenopausal woman with low-trauma fractures or low BMD is to identify any secondary cause, and to institute specific treatment for that cause if it is correctable. Often this can be accomplished by a detailed history and physical examination, though an exhaustive biochemical evaluation may be necessary.

Table 63.1. Secondary Causes of Osteoporosis in Premenopausal Women

Premenopausal amenorrhea (e.g., pituitary diseases, medications)
Anorexia nervosa
Cushing's syndrome
Hyperthyroidism
Primary hyperparathyroidism
Vitamin D, calcium, and/or other nutrient deficiency
Gastrointestinal malabsorption (celiac disease, inflammatory bowel disease, cystic fibrosis, postoperative states)
Rheumatoid arthritis, systemic lupus erythematosus (SLE) SLE, other inflammatory conditions
Renal disease
Liver disease
Hypercalciuria
Alcoholism
Connective tissue diseases
Osteogeneis imperfecta
Marfan syndrome
Ehlers-Danlos Syndrome
Medications
• Glucocorticoids
• Immunosuppressants (e.g., cyclosporine)
• Antiepileptic drugs (particularly cytochrome P450 inducers such as phenytoin, carbamazepine)
• Cancer chemotherapy
• GnRH agonists (when used to suppress ovulation)
• Heparin
Idiopathic osteoporosis

Idiopathic osteoporosis

Premenopausal women with osteoporosis, in whom no definable cause can be found after a detailed evaluation, are said to have idiopathic osteoporosis (IOP). IOP is predominantly reported in Caucasians, and family history of osteoporosis is common [13–15]. Mean age at diagnosis is 35 years. Multiple vertebral and/or nonvertebral fractures may occur over 5 to 15 years; alternatively, there may be a single, major osteoporotic fracture, such as a low-trauma spine, hip, or long bone fracture [13, 15, 16]. Studies of bone microarchitecture in premenopausal women with IOP have shown that women with unexplained low BMD and those with low-trauma fractures have comparably abnormal bone microstructure, with thinner cortices and thinner, more widely spaced and heterogeneously distributed trabeculae [9, 10a]. Bone turnover, as assessed by tetracycline-labeled transiliac bone biopsies, was heterogeneous, with very low, normal, and high remodeling observed, suggesting diverse pathogeneses could account for the microarchitectural deterioration. Women with high bone turnover had a biochemical pattern resembling idiopathic hypercalciuria (mildly increased 24-hour urinary calcium and higher serum $1,25(OH)_2D$ concentrations compared to controls). In women with low bone turnover, microstructural deficits were more profound, serum insulin-like growth factor-1 (IGF-1) concentrations were higher, and osteoblasts appeared to synthesize less bone matrix per remodeling site, suggesting osteoblast resistance to IGF-1 [9, 16].

EVALUATION OF THE PREMENOPAUSAL WOMAN WITH OSTEOPOROSIS

Premenopausal women with low BMD (Z-score below –2.0), and those with a low-trauma fracture regardless of whether their BMD is frankly low, should undergo a thorough evaluation for secondary causes of bone loss. Identification of a contributing condition often helps to guide management of the affected individual.

A careful medical history is essential, including information about family history, fractures, kidney stones, oligo- or amenorrhea, or other history consistent with premenopausal estrogen deficiency, timing of recent pregnancies and lactation, dieting and exercise behavior, subtle gastrointestinal symptoms and medications, including over-the-counter supplements. During the physical examination, look for signs of Cushing's syndrome, thyrotoxicosis, or connective tissue disorders (e.g., blue sclerae in some forms of osteogenesis imperfecta, joint hypermobility in Ehlers-Danlos syndrome).

The laboratory evaluation (Table 63.2) should be aimed at identifying secondary causes such as hyperthyroidism, hyperparathyroidism, Cushing's syndrome, early menopause, renal or liver disease, celiac disease, malabsorption, and idiopathic hypercalciuria. Bone turnover markers and follow-up bone density testing may help to distinguish those with stable low BMD from those with ongoing bone loss who may be at higher short-term risk of fracture. In premenopausal women with a history of low-trauma fracture(s) and no known secondary cause, bone biopsy may be indicated. In the authors' experience, a bone biopsy may occasionally identify unsuspected causes of bone fragility, such as Gaucher's disease or mastocytosis.

Table 63.2. Laboratory Evaluation

Initial Laboratory Evaluation
- Complete blood count
- Electrolytes, renal function
- Serum calcium, phosphate
- Serum albumin, transaminases, total alkaline phosphatase
- Serum TSH
- Serum 25-hydroxyvitamin D
- 24-hour urine for calcium and creatinine

Additional Laboratory Evaluation
- Estradiol, LH, FSH, prolactin
- PTH
- 1,25-dihydroxyvitamin D
- 24-hour urine for free cortisol
- Iron/TIBC, Ferritin
- Celiac screen
- Serum/urine protein electrophoresis
- ESR or CRP
- Bone turnover markers
- Transiliac crest bone biopsy

MANAGEMENT ISSUES

General measures

For all patients, one should recommend a set of general measures that benefit bone health: adequate weight-bearing exercise [17, 18], nutrition (protein, calories, calcium, vitamin D), and lifestyle modifications (smoking cessation, avoidance of excess alcohol).

In the authors' opinion, pharmacological therapy is rarely justified for premenopausal women with isolated low BMD and no history of fractures, in whom there is no identifiable secondary cause, particularly if the Z-score is above –3.0. Low BMD in such young woman may be due to genetic low peak bone mass, or to past insults to the growing or adult skeleton (nutritional deficiency, alcohol excess, medications, estrogen deficiency) that are no longer operative. Such young women usually have low short-term risk of fracture. Moreover, Peris et al. recently reported slight BMD improvement and no further fractures in women with unexplained osteoporosis managed

with only calcium (total intake of 1,500 mg/day), vitamin D (400–800 IU/daily) and exercise [19]. Bone density should be remeasured after 1 or 2 years to confirm that it is stable and identify patients with ongoing bone loss.

In women with low BMD or low-trauma fractures and a known secondary cause, address the underlying cause if possible. Women with estrogen deficiency should receive estrogen (unless contraindicated), those with celiac disease should begin a gluten-free diet, those with primary hyperparathyroidism may benefit from parathyroidectomy (see Chapter 68), and those with idiopathic hypercalciuria may benefit from thiazide diuretics.

In some women, it is not possible to address or alleviate the secondary cause directly. Premenopausal women requiring long-term glucocorticoids and those being treated for breast cancer may require pharmacological therapy to prevent excessive bone loss or fractures. Treatment options include antiresorptive drugs such as estrogen, calcitonin, bisphosphonates, and denosumab, or anabolic agents such as teriparatide. Selective estrogen receptor modulators (SERMS), such as raloxifene, should not be used to treat bone loss in menstruating women since they block estrogen action on bone and lead to further bone loss [20].

Bisphosphonates

Bisphosphonates have been shown to prevent bone loss in premenopausal women with various conditions [21–26]. However, large randomized trials are scarce and the U.S. Food and Drug Administration has approved oral bisphosphonates only for premenopausal women on glucocorticoids. Because bisphosphonates accumulate in the maternal skeleton, cross the placenta, accumulate in the fetal skeleton [27], and cause toxic effects in pregnant rats [28], they should be used with caution in women who may become pregnant. While several reports document normal pregnancies and fetal outcomes in women receiving bisphosphonates [23, 29–31], the potential for fetal abnormalities should be considered when prescribing bisphosphonates for a premenopausal woman.

Because there are so few data regarding the long-term efficacy and safety of bisphosphonates in young women, the decision to initiate treatment must be made on a case-by-case basis with consideration of individual fracture risk and with a plan for the shortest possible duration of use. In general, bisphosphonates should be reserved for those with fragility fractures or ongoing bone loss.

Glucocorticoid-induced osteoporosis

Bisphosphonates are approved for prevention and treatment of glucocorticoid-induced osteoporosis. However, relatively few premenopausal women participated in the relevant large registration trials for bisphosphonates in glucocorticoid-induced osteoporosis and none of the premenopausal women in those trials fractured [32–34]. A few studies have demonstrated protective effects of intermittent cyclical etidronate and oral pamidronate in premenopausal women with autoimmune and connective tissue diseases [24, 25]. Guidelines from the American College of Rheumatology suggest that bisphosphonates be considered for prevention and treatment of glucocorticoid-induced osteoporosis in premenopausal women taking at least 7.5 mg of prednisone or equivalent per day for 3 months or more [35]. However, because of potential harm to the fetus in women who may become pregnant, they also urge great caution in the use of bisphosphonates in premenopausal women [35].

Bisphosphonate use for other secondary causes of osteoporosis

Intravenous and oral bisphosphonates prevent bone loss in premenopausal women experiencing ovarian failure in the setting of treatment for breast cancer [36–40]. Bisphosphonates may lower fracture risk in young individuals with osteogenesis imperfecta (see Chapter 99). Both alendronate and risedronate have been shown to significantly increase BMD in young women with anorexia [21, 22]. Bisphosphonates have also been associated with substantial increases of 11–23% in lumbar spine bone density [23] in women with pregnancy- and lactation-associated osteoporosis. Since bone density is expected to increase postpartum and after weaning in normal women, and there was no untreated control group, it is not clear to what extent bisphosphonate use provided an incremental benefit for these patients.

Human PTH(1-34)

There are even fewer data on the effects of teriparatide or PTH(1-34) in premenopausal women, but this medication has been studied in women with medication-induced amenorrhea, women with IOP, and those on glucocorticoids. In young women treated with the GnRH analog nafarelin for endometriosis, spine BMD declined by 4.9%, while those treated with PTH(1-34) 40 µg daily together with nafarelin had an increase of 2.1% ($p < 0.001$) [41]. It is not clear whether these results would apply to premenopausal women with normal gonadal status. A recent study comparing teriparatide and alendronate for glucocorticoid-induced osteoporosis included some premenopausal women. Overall, teriparatide was associated with significantly greater increases in lumbar spine and total hip BMD and resulted in significantly fewer incident vertebral fractures than alendronate [42]. The BMD responses were similar in premenopausal women as in men and postmenopausal women, but no fractures occurred in either premenopausal group.

In an observational study of teriparatide 20 µg daily in 21 premenopausal women with IOP, BMD increased by 12.2% at the lumbar spine and 6.4% at the total hip (both $p < 0.05$) after 12 months of treatment [26]. However, among this unique cohort, a small subset with very low baseline bone turnover had little or no increase in BMD on this medication [26]. Because the long-term effects of

teriparatide in young women are not known, use of this medication should be reserved for those at highest risk for fracture or those who are experiencing recurrent fractures. In young women younger than 25 years of age, documentation of fused epiphyses is recommended prior to consideration of teriparatide treatment, since continued bone growth is considered a contraindication to use of this medication.

SUMMARY AND CONCLUSIONS

Premenopausal woman with low-trauma fracture(s) or low BMD (Z-score below –2.0) should have a thorough evaluation for secondary causes of osteoporosis and bone loss. In most, a secondary cause can be found, the most common being glucocorticoid excess, anorexia nervosa, premenopausal estrogen deficiency, and celiac disease. Where possible, identification and treatment of the underlying cause should be the focus of management. Although pharmacologic therapy is rarely justified in premenopausal women, those with an ongoing cause of bone loss and those who have had or continue to have low-trauma fractures may require pharmacological intervention, such as bisphosphonates or teriparatide. Few high-quality clinical trials exist to provide guidance, and there are no data that such intervention actually reduces the risk of future fractures.

INTRODUCTION

Iatrogenic bone loss, caused by therapies for nonskeletal diseases, is a growing and important cause of osteoporosis (Table 64.1). Drugs that have been implicated include aromatase inhibitors, androgen deprivation therapy, thiazolidenediones, and proton pump inhibitors. In contrast, some interventions for nonskeleta1 diseases may be protective to the skeleton. Osteoporosis associated with glucocorticoids, progestagens, excess thyroid hormone, chemotherapy, and calcineurin inhibitors is described in other sections; this chapter focuses on the remaining drugs listed in Table 64.1. Drugs that may have protective skeletal effects are also considered.

ANTIHORMONAL DRUGS

Androgen deprivation therapy

Androgen deprivation therapy (ADT) for carcinoma of the prostate encompasses a number of options, including bilateral orchidectomy, gonadotrophin-releasing hormone (GnRH) analog therapy, and antiandrogenic agents (cyproterone acetate, flutamide, and bicalutamide). Its use has increased considerably in recent years, and osteoporosis has emerged as a common complication. ADT is associated with increased rates of bone loss at multiple skeletal sites, and increased fracture rates have also been reported [1–4]. Examination of a large database containing medical records of more than 50,000 men revealed that, in those treated with ADT for prostate cancer and surviving at least 5 years after diagnosis, 19.4% had a fracture compared with 12.6% of men not receiving ADT. In men who received at least nine doses of GnRH analogs, the relative risk was 1.45 (95% CI, 1.36–1.56) [2]. In another retrospective study, the clinical fracture rate in men treated for prostate cancer with GnRH analogs was 7.91/100 person-years compared with 6.55/100 person years in men with early prostate cancer who were not treated with GnRH analogs, translating into a relative risk (RR) of 1.23 (95% CI, 1.09–1.34); the largest increase in risk was seen for hip fractures (RR, 1.76; 95% CI, 1.33–2.33) [3]. Finally, in a retrospective population-based cohort study in 742 men with prostate cancer, overall fracture risk was increased 1.9-fold; the increase in risk in men on ADT being mainly accounted for by pathological fractures [4]. In this study, a 1.7-fold increase in fracture risk was also seen in men with prostate cancer who were not receiving ADT.

A number of interventions have been shown to have beneficial effects on bone mineral density (BMD) in men treated with ADT. These include raloxifene, toremifene, risedronate, pamidronate, zoledronic acid, alendronate and denosumab [5–9]. Reduction in vertebral fracture risk has been reported with two of these treatments, namely

toremifene (80 mg/day) and denosumab (60 mg sc every 6 months) [8, 9]. All men treated with ADT should undergo assessment of fracture risk using BMD measurement and clinical risk factors at the start of treatment, with repeat BMD measurement at 1–2 years as clinically indicated. Bone protective therapy should be started in men with a history of hip or vertebral fracture and/or a T-score at or below –2.5. Additionally, drug therapy has been recommended in men with a low T-score (–1.0 to –2.5) and a 10-year risk of 3% or higher for hip fracture or 20% or lower for major osteoporotic fracture, as assessed by FRAX (fracture risk assessment tool) [10].

Aromatase inhibitors

Aromatase inhibitors (AIs) are now regarded as front-line adjuvant therapy in women with estrogen receptor-positive breast cancer. They reduce endogenous estrogen production by 80–90% by blocking the peripheral conversion of androgens to estrogen and have largely replaced the selective estrogen receptor modulator, tamoxifen, as the preferred treatment option for postmenopausal women. The most commonly used AIs in clinical practice are exemestane, anastrozole, and letrozole; the former is steroidal, whereas the latter two are nonsteroidal [11].

In contrast to tamoxifen, which is bone protective in postmenopausal women (but has the opposite effect in premenopausal women), AIs have adverse effects on BMD and possibly also fracture risk. Interpretation of studies of the effects of AIs on bone is complicated by the use of tamoxifen as a comparator in many studies and also, in some studies, the use of tamoxifen before AI therapy. In addition, comparative data on the effects of different AIs on BMD and fracture rate are currently lacking. Nevertheless, the existing biomarker data indicate that all three AIs increase bone turnover, although some studies indicate a proportionately greater effect of exemestane on formation than resorption. Increased rates of bone loss have also been reported; for example, in the ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial, median rates of bone loss at the spine and hip were 4.1% and 3.9%, respectively, over 2 years [12], and in a study of letrozole versus placebo after 5 year of tamoxifen therapy, losses in the spine and hip over 2 years were 5.4% and 3.5%, respectively [13]. Significant increases in fracture rate have been shown in several trials of postmenopausal women with breast cancer, although interpretation of the data is again complicated by the use of tamoxifen as a comparator and treatment with tamoxifen before AI therapy in the majority of studies. In the ATAC study, the incidence of fractures after 5 years was 11% in women treated with anastrozole and 7.7% in those receiving tamoxifen ($p < 0.001$) [14]. Comparison of letrozole and tamoxifen produced similar results, with fracture rates of 8.6% and 5.8%, respectively ($p < 0.001$) at a median follow-up period of 51 months [15]. However, comparison of letrozole with a placebo in women with breast cancer after completion of 5 years of tamoxifen therapy did not show any significant difference in fracture rate (3.6% in letrozole group versus 2.9% placebo; $p = 0.24$) [16]. Finally, in the Intergroup Exemestane Study, in which women who were disease free after 2–3 years with tamoxifen were randomized to continue tamoxifen or switched to exemestane to complete a total of 5 years of therapy, a significantly higher fracture rate was seen in the women taking exemestane (7% vs 5%, $p = 0.003$). [17] Collectively, these data indicate that AI therapy is associated with a significantly higher fracture risk than tamoxifen but may not increase fracture risk above that seen in untreated women. This suggests that the difference in fracture risk between women treated with AIs and tamoxifen is at least partly caused by a protective effect of the latter.

Prevention of bone loss associated with AI therapy has been demonstrated with intravenous zoledronic acid, 4 mg every 6 months, oral risedronate 35 mg once weekly and denosumab 60 mg sc every 6 months, although data on fracture reduction are lacking [18–22]. At present, it seems reasonable to advise risk assessment, including BMD measurements, in all postmenopausal women treated with AIs and to perform repeat measurements at 1- to 2-year intervals in those at moderate risk (based on age, BMD, and other clinical risk factors). In view of the uncertainty about whether AIs are associated with increased fracture risk and the absence of data on antifracture efficacy of bone protective therapy, the indications for intervention are not clearly defined. One approach is to use guidelines similar to those for postmenopausal women not receiving AIs, while others advocate treating at a higher BMD threshold in view of the rapid bone loss that occurs in some women.

THIAZOLIDINEDIONES

Thiazolidinediones (TZDs) are ligands for peroxisome proliferator-activated receptor γ (PPARγ) and are widely used in the treatment of type 2 diabetes. Activation of PPARγ increases marrow adiposity, increases insulin sensitivity, and suppresses bone formation. In transgenic

mice models PPARγ deficiency is associated with high bone mass whereas activation of PPARγ induces bone loss [23, 24]. The mechanisms by which suppression of bone formation occurs have not been fully established but may include inhibition of the Wnt/ß-catenin signaling pathway, inhibition of osteoblast differentiation genes including Runx2 and osterix, and suppression of insulin-like growth factor production [25]. The effects of TZDs in humans are particularly relevant in view of the increased risk of fracture associated with type 2 diabetes. In an observational study, increased rates of bone loss in the lumbar spine, trochanter, and whole body were reported in older diabetic women treated with TZDs [26]. Grey et al. [27] in a randomized controlled trial in healthy postmenopausal women, showed that administration of the TZD rosiglitazone for 14 weeks resulted in significant bone loss in the hip (mean 1.9% vs 0.2% in the placebo group) and significant suppression of biochemical markers of bone formation. In the ADOPT study (A Diabetes Outcome Progression Trial), a randomized controlled trial in 4,360 patients with type 2 diabetes, the effects of treatment with rosiglitazone were compared with those of metformin and glibenclamide [28]. In women, there was a statistically significant increase in the incidence of fractures, mainly affecting the foot, hand, and upper arm (9.3% in the rosiglitazone group versus 1.54% and 1.29% in the metformin and glibenclamide groups, respectively). Subsequent studies, including a meta-analysis [29] have confirmed the increase in fracture risk associated with TZDs. This appears to be a drug class effect and is positively associated with duration of treatment; some, although not all, studies indicate that women and men are equally affected [30]. Adverse skeletal effects, therefore, have to be considered when weighing up the risk/benefit balance associated with TZDs, particularly in high-risk individuals. The contribution to fracture of factors other than reduced BMD in this population, including alteration in collagen cross-linking as a result of the formation of advanced glycation end products and increased risk of falling, merits further study.

ACID-SUPPRESSIVE MEDICATIONS

Increased risk of fracture has been reported in individuals treated with acid-suppressive medications. Grisso et al. [31] reported an association between use of the H_2 receptor blocker, cimetidine, and hip fracture in a case-control study of men with hip fracture (OR, 2.5; 95% CI, 1.4–4.6). Subsequently, in a case-control study from Denmark, proton pump inhibitor (PPI) use within the past year was shown to be associated with a small increase in overall fracture risk (adjusted OR, 1.18; 95% CI, 1.12–1.43), hip fracture risk (adjusted OR, 1.45; 95% CI, 1.28–1.65), and spine fracture risk (adjusted OR, 1.60; 95% CI, 1.25–2.04) [32]. Interestingly, in this study, the use of histamine H_2 receptor antagonists within the past year was associated with a significantly reduced risk of fracture (adjusted OR, 0.88; 95% CI, 0.82–0.95), although a significant increase in fracture risk was observed with antacid medications other than PPIs and H_2 receptor blockers. Analysis of data from the Study of Osteoporotic Fractures (SOF) showed that women taking a PPI or H_2 receptor blocker (grouped together) had a significantly increased risk of non-spine fracture (RH, 1.18; 95% CI, 1.01–1.39), but total hip BMD and rates of bone loss at this site were similar between users and nonusers of these acid-suppressive medications [33]. In a nested case control study from the General Practice Research Database in the U.K., a significant increase in hip fracture risk was found in PPI users, which increased significantly with dose and with duration of use [34]. However, in a subsequent study using the same database, use of PPIs was not associated with increased risk of hip fracture in individuals without major risk factors, suggesting that residual confounding or effect modification may have explained the increased risk reported in the original study [35]. Similar findings were recently reported by Corley et al. in a case control study of individuals taking either PPIs or H_2 receptor antagonists [36]. In a prospective analysis of women enrolled in the Women's Health Initiative (WHI) study, PPI use was associated with an increase in clinical spine, forearm or wrist, and all clinical fractures, but not hip fractures; a robust association between PPI and BMD was not demonstrated [37]. Overall, therefore, existing data support an association between acid-suppressive medication and fracture, although the limitations of observational studies, particularly the effects of potential but unmeasured confounding factors, have to be recognized, and the discrepant findings with respect to H_2 receptor blockers remain unexplained.

The mechanism by which PPIs and possibly other acid-suppressive medications increase fracture risk is unknown. Reduced intestinal calcium absorption resulting from increased gastric pH may contribute, although the relatively small reduction in absorption of calcium carbonate shown in one study of postmenopausal women taking omeprazole seems unlikely to be solely responsible for the development of increased fracture risk within 1 year of starting therapy [38]. Inhibition of the osteoclastic proton pump would be expected to have beneficial skeletal actions, although it is unknown whether such effects are associated with PPI use *in vivo*. Finally, the data from SOF and the WHI study indicate that the increase in fracture risk associated with PPIs may not be BMD driven. Nevertheless, the association has important clinical implications because PPI use is common in the elderly population and potentially might attenuate the effects of bone protective interventions.

ANTIEPILEPTIC DRUGS

An association between antiepileptic drugs (AEDs) and increased fracture risk has been reported in several

observational studies, and reduced BMD and increased rates of bone loss have also been reported [39–43]. The underlying pathogenesis is unclear; vitamin D deficiency, trauma during seizures, increased risk of falling, and co-medications including glucocorticoids may all contribute. In a few patients with severe vitamin D deficiency, osteomalacia or rickets may be present. Currently, there are insufficient data to distinguish between the skeletal effects of specific AED regimens.

Management guidelines to prevent and treat bone disease in AED users have been proposed, although at present, these lack a robust evidence base. Routine prophylaxis of vitamin D deficiency should be considered in high-risk individuals, for example, the elderly and institutionalized (higher than normal doses may be required in patients taking some AEDs), and in such cases, calcium supplements should also be given. Routine bone densitometry in all AED users cannot be justified at present, although BMD should be measured in those who present with fracture or have other clinical risk factors. Treatment of established osteoporosis in this population has not been specifically evaluated.

SELECTIVE SEROTONIN RECEPTOR UPTAKE INHIBITORS

Selective serotonin receptor uptake inhibitors (SSRIs) are widely prescribed as antidepressants and have been associated with reduced BMD in older men [44], increased rates of hip bone loss in older women [45], and increased fracture risk in men and women 50 years of age or older [46]. While depression itself may be associated with increased risk of osteoporosis [47], the regulatory role of serotonin in bone remodeling provides a plausible biological mechanism by which SSRIs may cause adverse skeletal effects [48].

HEPARIN

Long-term heparin therapy, which nowadays is virtually restricted to prophylaxis against thromboembolism in high-risk women during pregnancy, is associated with an increased risk of osteoporosis [49]. Reduced BMD, increased rates of bone loss, and increased fracture risk have all been reported during long-term heparin administration although the mechanisms responsible for bone loss have not been established [50, 51]. The use of low molecular weight heparin and of newer antithrombotic agents such as fondaparinux may be associated with fewer adverse skeletal effects. Calcium and vitamin D supplements are often advocated but, in common with other antiresorptive regimens, have not been formally evaluated in this situation.

DRUGS THAT MAY PROTECT AGAINST OSTEOPOROSIS

Beta-blockers

In some studies, a significant protective effect of β-blocker therapy on fracture risk has been reported, although this finding has not been universal [52–55]. In a case-control study, a significant decrease in hip/femur fracture risk was associated with current β-blocker use, but was only present in patients with a history of using other antihypertensive medications and was not related to cumulative exposure, suggesting that the association may not be causal [56]. In a recent large cohort study of the effect of single therapy antihypertensive medication on fracture risk no decrease in risk of fracture was seen in people receiving β-blockers, although a significant reduction was seen in those using angiotensin receptor blockers (HR 0.76; 95% CI 0.68–0.86) and thiazide diuretics (HR 0.85; 95% CI 0.76–0.97) [57].

Thiazides

Reduced fracture risk in thiazide users has been reported in several prospective observational studies, and small increases in BMD have also been shown in randomized controlled trials [53, 57–60]. Increased renal calcium reabsorption is thought to play a role in these beneficial effects, although because this is transient, other mechanisms are likely to operate.

Statins

Statins inhibit the enzyme 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase in the mevalonate pathway, thus reducing cholesterol biosynthesis but also preventing the prenylation of GTP- binding proteins and thus inhibiting osteoclast activity. Beneficial skeletal effects of statins in animals have been shown *in vitro* and *in vivo* [61], but studies in humans have produced conflicting results. Two meta-analyses have been conducted: one on BMD effects and the other on fracture [62, 63]. The former concluded that statins had small but significant benefits on BMD in the hip, whereas the latter suggested that statin use is likely to reduce hip fractures, although effects on other fracture types have not been demonstrated. However, in a double-blind randomized placebo-controlled trial, clinically relevant doses of atorvastatin that lower lipid levels had no effect on BMD or biochemical indices of bone metabolism [64].

INTRODUCTION

A broad range of fractures and associated injuries present to the orthopedic or trauma surgeon for management. The principle that fracture immobilization supports both alignment and union of the fracture, while minimizing discomfort, has been known since antiquity. The energy of the injury, associated soft tissue injury, and displacement of the fracture usually guide intervention.

The initial management of fractures consists of realignment of the broken limb segment and immobilization of the fractured extremity once the initial assessment, evaluation, and management of any life-threatening injury are completed. The aim of fracture treatment is to obtain union of the fracture in the most anatomical position compatible with maximal functional recovery of the extremity or the spine, with minimal complications. This is accomplished by obtaining and subsequently maintaining reduction of the fracture with an immobilization technique that allows the fracture to heal and, at the same time, provides the patient with functional aftercare. Either nonoperative or operative means may be used. Any surgical technique, if chosen, should minimize additional soft tissue and bone injury, which can delay fracture healing.

In open fractures, in addition to the treatment aims outlined above, the prevention of infection is vital [1]. This is achieved by urgent wound irrigation and debridement (with serial irrigations and debridements every 24–48 hours until the wounds are clean and closed), antibiotic administration and tetanus vaccination. If soft-tissue coverage over the injury is inadequate, soft-tissue transfers or free flaps are performed when the wound is clean and the fracture is definitively treated.

TREATMENT PRINCIPLES

Fracture management can be divided into nonoperative and operative techniques. Nonoperative technique consists of a closed reduction (required if the fracture is significantly displaced or angulated), achieved by applying traction to the long axis of the injured limb and then reversing the mechanism of injury. This is followed by a period of immobilization with casting. Casts are made from fiberglass or plaster of paris. Complications of casts can include the development of pressure ulcers, thermal burns during plaster hardening, and joint stiffness. Traction (skin or skeletal) is rarely used nowadays for definitive fracture management.

If the fracture cannot be reduced (e.g., due to soft tissue interposition), surgical intervention may be required. Indications for surgery include failed nonoperative management, unstable fractures that cannot be adequately maintained in a reduced position, displaced intra-articular fractures (greater than 2 mm), impending pathologic fractures, unstable or complicated open fractures, fractures in growth areas in skeletally immature individuals who

have increased risk for growth arrest, and nonunions or malunions that have failed to respond to nonoperative treatment [2]. Contraindications to internal fixation include active infection (local or systemic), soft tissues that compromise the overlying fracture or the surgical approach (e.g., burns and previous surgical scars), medical conditions that contraindicate surgery or anesthesia (e.g., recent myocardial infarction), and cases in which amputation would be more appropriate (e.g., severe neurovascular injury).

SURGICAL OPTIONS

The treatment goals for surgical fracture management, as outlined by the Association for the Study of Internal Fixation (ASIF), are anatomic reduction of the fracture fragments (for the correction of length, angulation, and rotation, and for intra-articular fractures for the restoration of the joint surface), stable internal fixation to cope with physiological biomechanical demands, preservation of blood supply, and active, pain-free mobilization of adjacent muscles and joints [3]. The objectives of open reduction and internal fixation include adequate exposure and reduction of the fracture, followed by maintenance of the reduction by stabilization using one or a combination of the methods below.

Kirschner wires

Kirschner wires, or K-wires, placed percutaneously or through a mini-open approach, are commonly used for temporary and definitive treatment of fractures. However, they have poor resistance to torque and bending forces, and rely on friction with the bone for maintenance of reductions. Therefore, when they are used as the sole form of fixation, casting or splinting is used in conjunction. K-wires are commonly used as adjunctive fixation for screws or plates and screws that involve fractures around joints.

Plates and screws

Plates and screws are commonly used in the management of articular fractures as they provide strength and stability to neutralize the forces on the injured limb for functional postoperative aftercare. Plate designs vary, depending on the anatomic region and size of the bone the plate is used for. All plates should be applied with minimal stripping of the soft tissue. Five main plate designs exist:

1. *Buttress (antiglide) plates* counteract the compression and shear forces that commonly occur with fractures that involve the metaphysis and epiphysis. These plates are commonly used with interfragmentary screw fixation and require anatomical contouring to achieve stable fixation.
2. *Compression plates* counteract bending, shear, and torsional forces by providing compression across the fracture site via the eccentrically loaded holes in the plate. Compression plates are commonly used in the long bones, especially the fibula, radius, and ulna, and in nonunion or malunion surgery.
3. *Neutralization plates* are used in combination with interfragmentary screw fixation. The interfragmentary compression (lag) screws provide compression at the fracture site. This plate function neutralizes bending, shear, and torsional forces on the lag screw fixation, as well as increases the stability of the construct. These plates are commonly used for fractures involving the fibula, radius, ulna, and humerus.
4. *Bridge plates* are useful in the management of multifragmented diaphyseal and metaphyseal fractures. Indirect reduction techniques are preferred in bridge plating without disrupting the soft-tissue attachments to the bone fragments.
5. *The tension band plate* technique converts tension forces into compressive forces, thereby providing stability, e.g., in oblique olecranon fractures.

More recently, *locking plates* have been introduced. A locking plate acts like an internal fixator. There is no need to anatomically contour the plate onto the bone, thus reducing bone necrosis and allowing for a minimally invasive technique. Locking screws directly anchor and lock onto the plate, thereby providing angular and axial stability. These screws are incapable of toggling, sliding, or becoming dislodged, thus reducing the possibility of a secondary loss of reduction, as well as eliminating the possibility of intraoperative overtightening of the screws. The locking plate is indicated for osteoporotic fractures, for short and metaphyseal segment fractures, and for bridging comminuted areas. These plates are also appropriate for metaphyseal areas where subsidence may occur or prostheses are involved.

The technique of minimally invasive percutaneous plate osteosynthesis (MIPPO) with indirect reduction is becoming increasingly popular. This involves the use of anatomically pre-shaped plates and instrumentation to safely and effectively insert the plate percutaneously or through limited incisions [4]. Advantages of MIPPO may include faster bone healing, reduced infection rate, decreased need for bone grafting, less postoperative pain, faster rehabilitation, and more aesthetic results. Some disadvantages include difficulty with indirect reduction, increased radiation exposure due to more intraoperative radiographs being utilized, malunion, pseudoarthrosis through diastases, and delayed union with flexible fixation in simple fractures.

Intramedullary nails

These nails operate like an internal splint that shares the load with the bone and can be flexible or rigid, locked or unlocked, and reamed or unreamed. Locked intramedullary nails provide relative stability to maintain bone alignment and length and to limit rotation. Ideally, the intramedullary nail allows for compressive forces at the fracture site, which stimulates bone healing.

Intramedullary nails are commonly used for femoral and tibial diaphyseal fractures, and, occasionally, humeral diaphyseal fractures. The advantages of intramedullary nails include minimally invasive procedures, early postoperative ambulation, and early range of motion being permitted in adjacent joints. Reaming may also increase union rates possibly by providing the equivalent of a bone graft to the fractured region.

External fixation

External fixation provides fracture stabilization at a distance from the fracture site, without interfering with the soft-tissue structures that are near the fracture. This technique not only provides stability for the extremity and maintains bone length, alignment, and rotation without requiring casting, but it also allows for inspection of the soft-tissue structures that are vital for fracture healing. Indications for external fixation (temporarily or as definitive care) are as follows [5]:

1. Open fractures that have significant soft-tissue disruption (e.g., type II or III open fractures)
2. Soft-tissue injury (e.g., burns)
3. Pelvic fractures
4. Severely comminuted and unstable fractures
5. Fractures associated with bony defects
6. Limb-lengthening and bone transport procedures
7. Fractures associated with infection or nonunion

Complications of external fixation include pin tract infection, pin loosening or breakage, interference with joint motion, neurovascular damage during pin placement, malalignment caused by poor placement of the fixator, delayed union, and malunion. Modern external fixators, such as the Taylor Spatial Frame, allow for postoperative adjustment to effect more anatomical reduction of the fracture in the weeks following intervention.

COMMON FRACTURES IN OSTEOPOROTIC PATIENTS

Vertebral compression fractures, Colles' (distal radius) fractures, hip fractures and other peripheral (nonvertebral) fractures all occur in patients with osteoporosis. These fractures may indicate the need for treatment of osteoporosis for secondary fracture prevention.

Osteoporotic fractures are usually low energy injuries. Some fractures such as fatigue fractures of the pelvis have no displacement. Colles' fractures and hip fractures are usually displaced and require reduction and fixation. They are sometimes held in a cast but may require wire fixation or low-profile plating to maintain reduction. Colles' fractures nearly always heal, but significant malunion can interfere with function. Intertrochanteric hip fractures are usually fixed with sliding hip screw devices that allow compression of the fracture fragments on weight bearing. Subcapital neck of femur fractures require joint arthroplasty of some form in the majority of cases because of the high incidence of nonunion and avascular necrosis. In recent times, the development of locking plate technology has improved the surgeon's ability to internally fix fractures in osteoporotic bone, but further research is needed as in many cases optimal fixation cannot be achieved. It is a principle of management for all osteoprorotic fractures to institute load bearing and functional tasks as quickly as possible to minimize loss of function or mobility.

INTERVENTION FOR VERTEBRAL FRACTURES IN OSTEOPOROTIC PATIENTS

Acute vertebral compression fractures can be painful and lead to disability, whereas multiple "silent" compression fractures lead to kyphosis and loss of height. While in many clinically apparent fractures the pain settles in a few weeks, it has been estimated that one-third of fractures can remain chronically painful. While most vertebral compression fractures are managed nonoperatively, there has been an increase in intervention for painful acute fracture to minimize morbidity. These techniques are known as vertebroplasty and kyphoplasty.

In vertebroplasty, a percutaneous approach to the vertebral body is made under fluoroscopic control, either through or adjacent to the pedicles. Bone cement, usually polymethylmethacrylate (PMMA) is injected into the fracture under pressure via a cannula while the cement is in a fluid state. This acutely stabilizes the fracture and results in an immediate reduction of pain that is significant enough in many cases to allow immediate return to activities of daily living. Pain reduction is thought to be from the stabilization of the fracture, although heat necrosis of nerve endings from the exothermic setting of the cement has also been suggested. Vertebroplasty makes little difference to the spinal alignment as the injection of cement usually does little to change the wedging deformity of the fracture.

Kyphoplasty is designed to address these limitations. In this technique, cannulae are placed usually bilaterally to allow the introduction of balloon tamps that are expanded with radio-opaque saline. Some elevation of the endplate and thus correction of deformity can be achieved by this method. The balloon expansion creates a void into which cement is injected at a slightly more viscous state than in vertebroplasty. The literature available suggests that while correction of vertebral morphology is achievable, overall spinal balance is usually not affected as alterations in shape can be accommodated by disc spaces and deformity at other levels [6].

When one considers comparisons with conservative care, both procedures appear to be effective in relieving pain in a few days in the majority of individuals. One nonrandomized study showed decreases in pain, rapid return to function, and decreased hospital stay in vertebroplasty

versus conservatively treated patients [7]. A systematic review favored a therapeutic effect and some superiority for kyphoplasty over nonoperative treatment [8]. There is a suggestion from this meta-analysis that kyphoplasty may be associated with fewer cement leakage events than vertebroplasty. Serious complications include neurological sequelae and have been reported to run at about 1%.

Recent randomized trials of vertebroplasty have placed these apparent benefits into doubt. Two separate sham-controlled vertebroplasty trials showed no benefit of active over sham treatment [9, 10]. These trials have been criticized for including patients who were not "acute"; however, a study using the data of both trials found no difference even in the acute subset [11]. Further trials are underway but as of the time of writing this chapter, these trials place the utility of these procedures in doubt.

Abnormalities in Bone and Calcium Metabolism After Burns

Gordon L. Klein

Introduction 531
The Inflammatory Response 531
The Stress Response 531
Other Possible Contributing Factors 532
Treatment 532
Applicability to Other Conditions 532
References 532

INTRODUCTION

Burn injury is an example of how the body's nonspecific adaptive response can adversely affect bone. Because humans did not evolve a specific means of protection against burn injury, the responses are nonspecific and have unintended consequences. The two major adaptive responses in question are the inflammatory response and the stress response.

THE INFLAMMATORY RESPONSE

A systemic inflammatory response occurs within 24 hours of severe burn injury and includes high circulating levels of the pro-inflammatory cytokines interleukin (IL)-1β and IL-6 [1]. Both cytokines stimulate osteoblast receptor activator of nuclear factor-κB ligand (RANKL) production with subsequent marrow stem cell differentiation into osteoclasts, thus increasing bone resorption. That this occurs early on after burns can be inferred from the success of acute administration of the bisphosphonate pamidronate within the first 10 days after a burn injury in preventing both total body and lumbar spine bone loss, both acutely [2] and for up to 2 years following this acute intervention [3]. In contrast those, who did not receive pamidronate lost approximately 3% of total body bone mineral content (BMC) in the ensuing 6 months and 7% of lumbar spine bone mineral density (BMD) in the first 6 weeks postburn [2].

Moreover, children with severe burns develop acute sustained hypocalcemia and hypoparathyroidism with urinary calcium wasting [4], suggesting cytokine-mediated upregulation of the parathyroid calcium-sensing receptor (CaSR). A 50% upregulation of the CaSR has been shown to occur within 48 hours in a sheep model of burn injury [5] and suggests that the CaSR upregulation may serve to clear the excess calcium that enters the blood following cytokine-mediated bone resorption.

THE STRESS RESPONSE

The three- to eightfold increase in urine free cortisol [1, 6] within the first 24 hours of the burn injury could well act synergistically with the inflammatory cytokines during the first 2 weeks in stimulating osteoblast RANKL production and subsequent bone resorption. However, by the second week postburn there are no visible surface osteoblasts on bone biopsy [6], markedly reduced surface uptake of tetracycline label and disappearance of double labeling (Figs. 66.1 and 66.2), as well as a failure of the marrow stromal cells cultured from the bone biopsies of burned children to exhibit normal quantities of markers of osteoblast differentiation [6]. Along with the marked reduction in bone formation, urinary deoxypyridinoline,

Fig. 66.2. Iliac crest bone biopsy from a burned subject showing patchy surface doxycycline uptake and absent double label.

as a marker of resorption, also fell [1] creating an adynamic bone despite persistent high circulating levels of resorptive cytokines.

Thus, there would appear to be two stages of postburn bone loss: a primary resorption mediated by both inflammatory cytokines and endogenous glucocorticoids, and a secondary adynamic stage mediated primarily by endogenous glucocorticoids.

Bone remodeling resumes by 12 months postburn [3] but the lumbar spine BMD Z-scores in burned children who did not receive acute bisphosphonate therapy remained significantly lower than in those who did [3].

OTHER POSSIBLE CONTRIBUTING FACTORS

Vitamin D deficiency, beginning sometime in the first year postburn, is caused by at least two factors: lack of routine supplementation [7] and failure of the skin to convert normal quantities of 7-dehydrocholesterol to vitamin D_3 [8]. The deficiency is progressive such that at 2 years, while all serum levels of 25(OH)D are low, all levels of $1,25(OH)_2D$ are normal. By 7 years postburn, not only are all serum levels of 25(OH)D low but half of all levels of $1,25(OH)_2D$ are also low [7].

Immobilization following burn injury has not been adequately studied with regard to bone loss. Between skin grafts the patient's mobility is restricted, but the effects of immobilization are mediated by the sympathetic nervous system via beta adrenergic receptors on the osteoblast [9]. By 2 weeks postburn, in the presence of osteoblast apoptosis it is unclear what kind of effect sympathetic drive can have on bone.

TREATMENT

Current treatment consists of a 1-year course of oral oxandrolone, which increases both lean body mass followed by an increase in BMC and bone area, though not BMD [10, 11]. It acts via insulin-like growth factor-1 (IGF-1) stimulation, although the remainder of the signaling pathway is unclear at present [11]. Recombinant human growth hormone had been used in burns, and at doses of 0.5–1 mg/kg per day subcutaneously for a year works in a similar way as oxandrolone, with increase in BMC and area secondary to an increase in lean body mass [12]. However, at a dose of 0.2 mg/kg per day, direct bone resorption is observed [12]. While pamidronate has been used to prevent the postburn bone loss, it is not universally used to treat patients following burn injury.

APPLICABILITY TO OTHER CONDITIONS

Acute and chronic conditions, such as sepsis, arthritis, and inflammatory bowel disease may lead to clinically silent bone loss mediated by these adaptive responses. The clinician should be aware of these possibilities. Further studies are required to determine the extent to which patients with these and other conditions lose bone in a manner similar to burns.

Approach to Parathyroid Disorders

John P. Bilezikian

Intrinsic Functional Abnormalities of the Parathyroid Gland(s) 537
Hypercalcemic and Hypocalcemic Disorders Not Due to an Intrinsic Abnormality of the Parathyroid Glands 540
Acknowledgments 541
References 541

Disorders of the parathyroid glands are an important consideration in disorders of mineral metabolism. In this section, chapters focus upon many of these disorders either due to excessive or inadequate secretion of parathyroid hormone (PTH). The section also features disorders in which the parathyroid glands overproduce or underproduce PTH as a normal physiologic adjustment to other inciting pathophysiological events that lead either to hypercalcemia or hypocalcemia. The primary parathyroid disorders, in which parathyroid glandular activity is intrinsically abnormal (e.g., primary hyperparathyroidism, hypoparathyroidism) and the secondary parathyroid disorders, in which increased or decreased parathyroid glandular activity is a normal adjustment to another pathophysiological process (e.g., vitamin D deficiency, chronic renal disease), have given us new insights into the importance of PTH not only in the regulation of the serum calcium concentration but also in terms of skeletal health. Not covered in this section, but elsewhere, is a consequence of intense interest in and investigation of PTH: namely the use of PTH as a treatment for osteoporosis. Based upon our expanded knowledge base about the parathyroids, I offer, in this chapter, an approach to the primary and secondary parathyroid disorders. More detailed information will be found in the individual chapters that follow.

INTRINSIC FUNCTIONAL ABNORMALITIES OF THE PARATHYROID GLAND(S)

Primary oversecretion of PTH: Primary hyperparathyroidism

Primary hyperparathyroidism (PHPT) is the classic endocrine disorder associated with parathyroid gland hyperfunction [1, 2]. It is most often a sporadic occurrence with only one of the four parathyroid glands involved in a benign, adenomatous process of excessive synthetic and secretory activity. Arnold provides a comprehensive discussion of the genetics of the hyperparathyroid diseases when they present in their many other manifestations such as familial hypercalciuric hypercalcemia (FHH), hyperparathyroidism-jaw tumor syndrome, and in multiple glandular syndromes such as MEN1 and MEN2 [3].

While known since the late 1920s, PHPT has undergone a rather dramatic change in its clinical phenotype from a symptomatic disorder of "bones and stones" to one that in most parts of the world is asymptomatic. It is typically discovered incidentally during the course of a calcium measurement on a routine biochemical screening test [4]. Assisted by new technologies with which the

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

skeleton can be evaluated, these and other aspects of PHPT have spawned greater interest than ever before in this disease.

Hypercalcemia is the major clinical clue to the diagnosis of PHPT. Several highly useful PTH assays expedite the diagnosis and clearly distinguish this disease from non-parathyroid etiologies of hypercalcemia [5]. Even with a PTH level that is not frankly elevated, PTH levels in the mid-range of normal establishes the diagnosis. The exquisite physiological regulation of PTH by calcium indicates that readily detectable levels of PTH in the context of hypercalcemia essentially rule out most other causes of hypercalcemia. The use of lithium, thiazide diuretics, and the exceedingly rare example of true ectopic PTH secretion are exceptions.

The skeleton, one of the major target organs in PHPT, has been a rich source of knowledge about PTH action. First shown by dual energy X-ray absorptiometry (DXA) and then followed by histomorphometric analyses of bone biopsies, the trabecular skeleton is relatively well preserved [6, 7]. DXA and bone biopsies also have established that the skeletal compartment that preferentially shows deterioration is cortical. These findings suggest that the nonvertebral skeleton, composed substantially of cortical bone, should be the greatest risk for fracture in this disease. Such expectations remain speculative because prospective epidemiology studies to address this question are lacking. Nevertheless, with successful surgery, both cortical and trabecular elements improve as shown by DXA [8] and more recently by high-resolution peripheral computed tomography [9].

While these skeletal features are noteworthy, kidney stones are the most common overt complications of PHPT, with incidence figures in the neighborhood of 20% in most series [10].

With appreciation that PHPT historically had protean manifestations, it has been exceedingly difficult to identity nontraditional target organs that are specifically affected by the hyperparathyroid process in asymptomatic PHPT. For example, several groups have attempted to discern neurocognitive and cardiovascular manifestations of asymptomatic PHPT [11–14], but it is still uncertain whether, and to what extent, such observations can be directly linked to the disease and/or whether they are reversible upon successful parathyroidectomy. The most recent guidelines for surgery in PHPT do not include these putative nontraditional aspects of PHPT, but they are acknowledged for their potential importance. Rather, the guidelines are directed to more easily measurable and traditional end points, such as bone density, kidney stones, and renal function [15].

Primary hyperparathyroidism is being increasingly recognized in subjects whose serum total and ionized calcium are consistently normal. "Normocalcemic PHPT" is associated with levels of PTH that are consistently elevated [16]. Secondary causes of an elevated PTH level must be ruled out before normocalcemic PHPT can be seriously considered. An important consideration is the 25-hydroxyvitamin D level, which is the index of body stores of vitamin D. Reduced 25-hydroxyvitamin D can account for an elevated PTH. The controversial matter of how vitamin D adequacy is defined is covered in this section of the *Primer* [17, 18]. For the purposes of establishing the diagnosis of normocalcemic PHPT, many experts require a 25-hydroxyvitamin D level that is greater than 30 ng/mL. This level helps to ensure that the patient is not demonstrating a subtle form of secondary hyperparathyroidism with levels that some people might regard as normal, such as between 20 and 30 ng/mL.

The normal serum calcium level in normocalcemic PHPT might lead one to expect weaker evidence for target organ involvement than in subjects whose PHPT is accompanied by overt hypercalcemia. However, in the experience so far with normocalcemic PHPT, many subjects demonstrate reduced BMD [16]. This may be due to the fact the most of the published literature on normocalcemic PHPT has dealt with a referral population that is being evaluated for a specific reason, such as reduced bone mineral density (BMD). Screening an unselected population for normocalcemic PHPT might lead to the identification of a normocalcemic cohort whose parathyroid disease is minimal [19].

Approach to the patient. After the patient with PHPT is evaluated, parathyroidectomy may be recommended. The recommendation for surgical intervention is based usually on meeting one or more of the criteria for parathyroid surgery as set forth by the latest International Workshop [15]. However, these guidelines are not rules. Patients who meet one or more criteria may decide against surgery; patients who do not meet any criteria might opt for the operation [20]. This latter view is acceptable if there are no medical contraindications to surgery. Virtually all parathyroid surgeons now require successful preoperative localization of the abnormal parathyroid gland. Advances in imaging with high-resolution modalities such as four-dimensional (4D) computed tomography has made it possible to identify abnormal parathyroid tissue in the vast majority of patients with PHPT [21]. With preoperative localization and a highly experienced surgeon, parathyroidectomy can be performed under local anesthesia and conscious sedation with an outstanding outcome record [22]. Successful parathyroidectomy is defined by a fall in intraoperative PTH levels by more than 50%, into the normal range, after removal of the offending adenoma. In patients who do not meet or refuse the recommendation of parathyroidectomy, observation is needed with annual serum calcium measurements and regular BMD monitoring. Pharmacological approaches to these individuals include the use of bisphosphonate [23] or the calcimimetic, cinacalcet [24].

Undersecretion of PTH: Hypoparathyroidism

In contrast to primary hypersecretion of PTH, which is relatively common, the hypoparathyroid states in which PTH is undersecreted are uncommon. In fact, hypopara-

thyroidism is defined as an orphan disease because there are fewer than 200,000 affected individuals in the United States [25]. Hypoparathyroidism presents a contrast with its more common counterpart in another way, namely in terms of symptomatology. Asymptomatic PHPT is the most common way the hypersecretion syndrome presents. The widespread use of screening biochemical panels is responsible, in large part, for this observation. In hypoparathyroidism, on the other hand, subjects generally are not asymptomatic. They are invariably discovered only when classical signs and symptoms of hypocalcemia are present [25–28]. It remains to be seen whether there is a variant of hypoparathyroidism, similar to normocalcemic PHPT, in which asymptomatic individuals can be discovered by screening an unselected cohort with calcium and PTH levels [29].

In hypoparathyroidism, the serum calcium is typically below normal limits, and the PTH level is either undetectable or inappropriately low for the hypocalcemic state. Similar to the physiology that governs suppression of PTH in hypercalcemic states not due to PHPT, the physiology of hypocalcemia indicates that the PTH should be elevated, if not due to an intrinsic functional abnormality or absence of the parathyroids. When hypocalcemia is not associated with elevated PTH levels, the diagnosis of a hypoparathyroidism is clear. Autoimmune destruction of the parathyroids and the sequelae of neck surgery are the two most common causes of hypoparathyroidism. The genetics of the autoimmune form and other much less common heredity manifestations of hypoparathyroidism, either in isolated form or involving multiple organs systems, are reviewed in this section of the *Primer* [26].

In virtually all forms of hypoparathyroidism, the condition is permanent. The one exception is the setting of severe hypomagnesemia. In this situation, the marked magnesium deficiency impairs parathyroid secretory function, mimicking a hypoparathyroidism [30]. However, with severe magnesium deficiency, the secretory abnormality is reversible, after magnesium is administered. Thus, in the evaluation of anyone who has hypocalcemia and low PTH levels, the serum magnesium should be measured.

The skeletal manifestations of hypoparathyroidism present an opportunity to address questions related to the role of PTH in skeletal metabolism and structure. The detailed knowledge of skeletal abnormalities in PHPT provides a counterpoint and permits the delineation of some of the findings to PTH itself. PHPT is a high turnover disease; hypoparathyroidism is a low turnover disease. While the two ends of the bone turnover spectrum, high and low, are not always appreciated by the measurement of circulating or urinary bone turnover markers, such as P1NP, osteocalcin, CTX, or urinary NTX, it is clear by dynamic histomorphometry of bone biopsies that the two disorders are diametrically different from each other. By double tetracycline labeling, there is very little bone turnover in hypoparathyroidism [31] while bone turnover is generally high in PHPT [1, 2]. In hypoparathyroidism, BMD is above average, using age-specific norms (Z-scores) or young normative databases (T-score). It is not unusual for individuals with hypoparathyroidism to show BMD values that are one- to threefold higher than normal (Z- and T-scores +1 to +3). By bone biopsy, there appears to be a cortical predominance in hypoparathyroidism that contrasts with the trabecular predominance of the hyperparathyroid skeleton [32]. These insights suggest a role for PTH is helping to regulate the distribution of cortical and trabecular bone at given sites. Clearly, overall site specificity to the distribution of cortical and trabecular bone is unlikely to be governed by PTH, but within a given site, (lumbar spine, hip, or forearm) PTH might be a key modulator. Improvement of the abnormalities in these skeletal compartments after parathyroidectomy in PHPT and after PTH administration in hypoparathyroidism helps to assign this modulatory role to PTH [33].

Besides skeletal abnormalities, subjects with hypoparathyroidism are prone to deposition of calcium–phosphate complexes in the kidney, basal ganglia, and other soft tissues. Similar to PHPT, in hypoparathyroidism, there is a spectrum on nonspecific observations that are not clearly related to the disease. In many nonspecific ways, individuals with hypoparathyroidism do not feel well. They complain of lack of energy, easy fatigability, arthritic symptoms (without frank arthritis) and "brain fog." To what extent these nonspecific symptoms can be reversed by PTH administration is not yet clear.

The administration of PTH represents a logical step in the definitive treatment of a disease characterized by lack of PTH [28, 33]. In fact, hypoparathyroidism is the last endocrine deficiency disease for which the missing hormone is not yet available as an approved therapy. This situation may be changing because of promising results of studies in hypoparathyroidism with the foreshortened peptide of PTH [PTH(1-34)] and the full length PTH molecule itself [PTH(1-84)] [33–35]. With PTH administration in hypoparathyroidism, bone turnover rapidly increases within the first year and then returns to more normal baseline values. Bone structure improves. Subjects require less calcium and vitamin D [33]. Anecdotal reports, which are now being substantiated, indicate that these individuals really do feel better and that their quality of life is improved.

Approach to the patient. Hypoparathyroidism usually presents as a symptomatic condition with complaints ranging from mild paresthesias to tetany and even seizures. In the patients who have not had ever had neck surgery (note, the neck surgery may have occurred decades before), it is important to consider multiglandular autoimmune endocrine deficiency syndromes [26]. It is also important to evaluate the patient for the possibility of ectopic calcifications (basal ganglia and other brain sites), renal calcifications, and if symptomatic, joint calcifications. The mainstay of treatment is calcium and vitamin D. While most patients can be controlled with calcium and vitamin D, some patients can present a challenge because of unexplained wide swings in the level of

control. In addition, many patients require very large doses of calcium and 1,25-dihydroxyvitamin D that raises additional concerns about the long term sequelae of such chronic treatment. The use of calcium and vitamin D (I prefer the judicious use of both parent vitamin D, either ergo- or cholecalciferol, and 1,25-dihydroxyvitamin D) is clearly not equivalent to replacement therapy with PTH. If PTH becomes available for the treatment of hypoparathyroidism, many patients are likely to show improved control with less need for calcium and vitamin D, thus reducing concerns of large doses of calcium and vitamin D therapy. Moreover, if quality of life is documented to improve, as appears to be the case, this would be another major benefit of treating hypoparathyroidism with PTH.

HYPERCALCEMIC AND HYPOCALCEMIC DISORDERS NOT DUE TO AN INTRINSIC ABNORMALITY OF THE PARATHYROID GLANDS

Non-parathyroid dependent hypercalcemia: Reduced PTH levels

As already noted, the differential diagnosis of hypercalcemia due to PTH or other cause is straightforward because of the PTH assay. An undetectable PTH level, the normal physiological response to hypercalcemia, argues in a compelling manner that the hypercalcemia is due to a non-PTH dependent mechanism [5]. When the hypercalcemia is associated with suppressed PTH, the next task is to establish the cause of hypercalcemia. The initial focus is usually malignancy, particularly if the patient presents with constitutional signs. If the malignancy is lung, breast, renal, or is myeloma, the diagnosis is usually readily established. If the parathyroid hormone related peptide (PTHrP) level is elevated, a squamous cell cancer becomes most suspect. Other malignancies such as pancreatic cancer or lymphoma may require extensive diagnostic testing, which is generally not recommended unless there are clinical or biochemical clues. For example, a lymphomatous or granulomatous process might be suspected if the 1,25-dihydroxyvitamin D level is elevated. If the 25-hydroxyvitamin D is elevated, on the other hand, the diagnostic possibility focuses upon exogenous ingestion of vitamin D. There are times when after an extensive search, the etiology of the non-parathyroid hormone dependent hypercalcemia is not clear. In that scenario, time usually declares the condition.

Hypocalcemia: Elevated PTH levels

The PTH assay helps to distinguish between hypocalcemia due to a hypoparathyroid state and hypocalcemic conditions associated with a normal physiological response to hypocalcemia. If the PTH level is elevated, the search begins for the cause of the hypocalcemia. Often this is readily apparent such as a malabsorption syndrome, or renal or liver failure. In these so-called secondary hyperparathyroid states, the serum calcium can be low, but it is often in the lower range of normal. The therapeutic approach depends upon adequate control of the stimulus for PTH secretion. In the secondary hyperparathyroidism of renal disease, the pathophysiology and subsequent therapeutic approaches can be complex [36, 37]. A major goal in the secondary hyperparathyroidism of renal failure is to ascertain what the PTH level is and then to control PTH so that it is unlikely to be associated with unwanted effects of the secondary hyperparathyroid state. There are various official guidelines that suggest goals for maintaining PTH levels within a range [38, 39]. All the guidelines acknowledge, however, that an acceptable PTH level in renal failure will be higher than the normal range. This point takes into account the fact that there are circulating inactive fragments of PTH that accumulate in renal failure and are detected by the commonly used intact assay for PTH.

The dictum that in primary hyperparathyroidism, the serum calcium is elevated and that in the secondary hyperparathyroidism states, such as renal failure, the serum calcium is not elevated, has to be qualified by several points. First, we are now recognizing a primary hyperparathyroidism (normocalcemic PHPT) that is characterized by normal serum calcium levels, as described above. This is the reason why secondary causes for an elevated PTH must be ruled out before considering the diagnosis of normocalcemic PHPT. Second, with prolonged stimulation of the parathyroid glands due to a renal or severe gastrointestinal disease, the serum calcium can rise to levels above normal. In this setting, the chronic stimulation of PTH secretion leads to the emergence of a semi-autonomous state due to the selection and proliferation of a clone of parathyroid cells into a single adenomatous gland. Thus, a prolonged secondary hyperparathyroidism can "morph" into a primary hyperparathyroidism. Whenever the serum calcium becomes chronically elevated in someone who has had a prolonged stimulus for PTH secretion, this possibility should be considered.

In the absence of renal disease, liver disease, and overt vitamin D deficiency, identifying the stimulus for high PTH levels can be a challenge. The phosphorus level, if elevated, can be a clue to the diagnosis of pseudohypoparathyroidism, a classic genetic disorder associated with PTH resistance [40]. If the physical signs of pseudohypoparathyroidism are present (the Type 1a variant), the diagnosis is straightforward. However, there are other forms of pseudohypoparathyroidism, in which the classical physical phenotype is not present. Such variants of pseudohypoparathyroidism can present without any physical findings.

INTRODUCTION

Primary hyperparathyroidism is a disorder resulting from excessive secretion of PTH from one or more of the four parathyroid glands. In 90% of cases, hypercalcemia can be explained by primary hyperparathyroidism or malignancy. Other potential causes of hypercalcemia are considered after the first two are ruled out or if there is reason to believe that a different cause is likely. The differential diagnosis of hypercalcemia, as well as features of hypercalcemia of malignancy, are considered elsewhere in this *Primer*. This chapter will deal exclusively with the clinical presentation, evaluation, and therapy of primary hyperparathyroidism.

Primary hyperparathyroidism is a relatively common endocrine disease, with an incidence as high as 1 in 500 to 1 in 1,000. A four- to fivefold increase in incidence in what was once a rare disorder was noted in the early 1970s, when the widespread use of the multichannel biochemistry autoanalyzer provided physicians with serum calcium levels in patients being evaluated for unrelated complaints [1]. The incidence has leveled off or even declined slightly [2, 3]. Women are affected more often than men by a ratio of 3:1. The majority of patients are postmenopausal women, often presenting within the first decade after menopause. The disease can, however, present at all ages. When diagnosed in childhood, an unusual event, it is important to consider the possibility that the disease is a harbinger of a genetic endocrinopathy, such as multiple endocrine neoplasia type (MEN) I or II.

Primary hyperparathyroidism is caused by a benign, solitary adenoma 80–85% of the time [4]. A parathyroid adenoma is a collection of chief cells surrounded by a rim of normal tissue at the outer perimeter of the gland. In the patient with a parathyroid adenoma, the remaining three parathyroid glands are usually normal. Less commonly (approximately 10–15% of cases), the disease is caused by hyperplasia of all four parathyroid glands. Four-gland hyperplasia may occur sporadically or in association with multiple endocrine neoplasia type I or II. Multiple adenomas account for the balance of benign disease, with parathyroid carcinoma, a very rare and severe form of primary hyperparathyroidism, occurring in fewer than 1% of patients [5]. Pathological examination of the malignant tissue might show mitoses, vascular or capsular invasion, and fibrous trabeculae. However, unless gross local or distant metastases are present, the diagnosis of parathyroid cancer is difficult to make histologically. Specific genetic studies and immunohistochemical analyses (*HRPT2* gene and parafibromin staining) may help to distinguish benign from malignant parathyroid tissue when standard approaches are not clear [6, 7].

The pathophysiology of primary hyperparathyroidism relates to the loss of normal feedback control of PTH by

extracellular calcium. Under virtually all other hypercalcemic conditions, there is feedback suppression of the parathyroid glands, and parathyroid hormone (PTH) levels are very low or undetectable. In adenomas, the parathyroid cell loses its normal sensitivity to calcium, whereas in primary hyperparathyroidism caused by hyperplasia of the parathyroid glands, the "set point" for calcium is not changed for a given parathyroid cell; instead, an increase in the number of cells gives rise to hypercalcemia.

The etiology of primary hyperparathyroidism is apparent in only a small minority of patients. These include those who received external neck irradiation in childhood (an average of 20–40 years before disease presentation), or through exposure during a radiation leak more than 20 years previously. A recent report on Chernobyl victims suggests a markedly increased risk of primary hyperparathyroisim (odds ratio 63, CI 36–113) [8]. Lithium, which decreases parathyroid sensitivity to calcium, can be associated with hypercalcemia and hyperparathyroidism in a small percentage of patients [9].

The molecular basis for primary hyperparathyroidism remains elusive in the vast majority of patients (see the chapter on familial hyperparathyroidism for more extensive discussion of genetic causes of primary hyperparathyroidism) [10–14]. The clonal origin of most parathyroid adenomas suggests a defect at the level of the gene controlling growth of the parathyroid cell or the expression of PTH. A gain of function mutation has been identified in 20–40% of sporadic parathyroid adenomas, in which the relocation of the cyclin D1 gene on chromosome 11 results in overexpression of this cell cycle regulator. Genes involved in MEN syndromes have also been investigated in sporadic disease. Inactivating mutations of the MEN1 gene have been reported in less than 10–15% of cases of sporadic parathyroid adenomas. The role of this tumor suppressor gene and menin, its gene product, in the pathogenesis of these sporadic adenomas is unknown. RET proto-oncogene gain-of-function mutations that are seen in MEN 2A or 2B have not been reported in sporadic primary hyperparathyroidism. Inactivating HRPT2 mutations have been described in familial hyperparathyroidism-jaw tumor syndrome (HPT-JT), in which they are associated with an increased risk of parathyroid cancer. While mutations of this gene have been reported in patients with sporadic parathyroid carcinoma, they are not a common feature in the absence of this familial hyperparathyroid syndrome. The possibility of mutations in the Wnt-β-catenin signaling pathway is also under investigation.

SIGNS AND SYMPTOMS

"Classical" primary hyperparathyroidism was a symptomatic disease associated with a typical skeletal disorder (osteitis fibrosa cystica), nephrolithiasis, and neuromuscular complaints. While this phenotype is still occasionally seen in the United States, today the overwhelming majority of patients lack these symptoms [15]. Osteitis fibrosa cystica, characterized by subperiosteal resorption of the distal phalanges, tapering of the distal clavicles, a "salt and pepper" appearance of the skull, bone cysts, and brown tumors of the long bones, is now seen in fewer than 5% of patients with primary hyperparathyroidism.

The incidence of kidney stones has also declined from 33% in the 1960s to 15–20% now. Nephrolithiasis, nevertheless, is still the most common overt complication of the hyperparathyroid process. Other renal features of primary hyperparathyroidism include diffuse deposition of calcium-phosphate complexes in the parenchyma (nephrocalcinosis). Hypercalciuria (daily calcium excretion of more than 250 mg for women or 300 mg for men) is seen in up to 30% of patients. In the absence of any other cause, primary hyperparathyroidism may be associated with a reduction in creatinine clearance.

The classic neuromuscular syndrome of primary hyperparathyroidism included a definable myopathy that has virtually disappeared [16]. In its place, however, is a less well-defined syndrome characterized by easy fatigue, a sense of weakness, and a feeling that the aging process is advancing faster than it should. This is sometimes accompanied by an intellectual weariness and a sense that cognitive faculties are less sharp. Some psychiatric complaints (depression and anxiety) are more common in these patients, and a recent study demonstrates some specific reversible areas of mild cognitive impairment (i.e., visual memory) [17]. However, the cumulative results of three randomized studies of surgery in patients with mild disease do not suggest that an individual patient can expect specific reversible changes in constitutional or neuropsychiatric complaints following parathyroidectomy [18–20]. Thus, the available data do not support surgical intervention for the purpose of improving neuropsychiatric symptoms at this time [21].

Gastrointestinal manifestations of primary hyperparathyroidism have classically included peptic ulcer disease and pancreatitis. Peptic ulcer disease is not likely to be linked in a pathophysiologic way to primary hyperparathyroidism unless type I multiple endocrine neoplasia is present. Pancreatitis is virtually never seen anymore as a complication of primary hyperparathyroidism because the hypercalcemia tends to be so mild.

In classical primary hyperparathyroidism, cardiovascular features included myocardial, valvular, and vascular calcification, with subsequent increased cardiovascular mortality. The limited available data suggest that cardiovascular mortality is not increased in mild disease [22]. Although overt cardiovascular involvement is not seen, there are data supporting increased vascular stiffness in mild disease, and reports of other subtle cardiovascular manifestations. Although there may be an increased incidence of hypertension in primary hyperparathyroidism, it is rarely corrected or improved after successful surgery [23]. Other potential organ systems that in the past were affected by the hyperparathyroid state are now relegated to being archival curiosities. These include gout and pseudogout, anemia, band keratopathy, and loose teeth.

CLINICAL FORMS OF PRIMARY HYPERPARATHYROIDISM

In the United States today, classical primary hyperparathyroidism is rarely seen [15]. Instead, the most common clinical presentation of primary hyperparathyroidism is characterized by asymptomatic hypercalcemia with serum calcium levels within 1 mg/dl above the upper limits of normal. Most patients do not have specific complaints and do not show evidence for any target organ complications. They have often been discovered in the course of a routine multichannel screening test. Rarely, a patient will show serum calcium levels in the life-threatening range, so-called acute primary hyperparathyroidism or parathyroid crisis [24]. These patients are invariably symptomatic due to their hypercalcemia. This unusual presentation of primary hyperparathyroidism should be considered in any patient who presents with acute hypercalcemia of unclear etiology. Other unusual clinical presentations of primary hyperparathyroidism include multiple endocrine neoplasia types I and II, familial primary hyperparathyroidism not associated with other endocrine disorders, familial cystic parathyroid adenomatosis, and neonatal primary hyperparathyroidism.

Normocalcemic primary hyperparathyroidism has recently been recognized as a specific phenotype of the disease [15, 25, 26]. These patients have normal serum calcium concentration with elevated PTH levels in the absence of an identifiable cause for secondary hyperparathyroidism. This diagnosis is often made in individuals who are undergoing evaluation for low bone mineral density (BMD) or who are receiving comprehensive screening tests for their skeletal health. In some patients this constellation of findings may represent the earliest manifestation of hypercalcemic primary hyperparathyroidism, when PTH alone is elevated and serum calcium is still normal. In order to make this diagnosis, both serum total and ionized calcium must be normal, and alternate causes for PTH elevation ruled out (i.e., renal failure, renal calcium loss, calcium malabsorption). It is particularly important to be sure that these individuals do not have vitamin D deficiency or insufficiency, a cause of secondary hyperparathyroidism that can also lower serum calcium levels in hypercalcemic primary hyperparathyroidism into the normal range. Little is known about the natural history of this phenotype. While some patients quickly progress to hypercalcemic disease, others do not. It is also not known whether current surgical criteria for hypercalcemic disease apply to patients with normocalcemic disease.

EVALUATION AND DIAGNOSIS OF PRIMARY HYPERPARATHYROIDISM

The history and the physical examination rarely give any clear indications of primary hyperparathyroidism but are helpful because they may suggest an alternate cause for hypercalcemia. The diagnosis of primary hyperparathyroidism is instead established by laboratory tests [27]. The biochemical hallmarks of primary hyperparathyroidism are hypercalcemia (except in patients with normocalcemic primary hyperparathyroidism) and elevated levels of PTH. In the presence of hypercalcemia, an elevated level of PTH virtually establishes the diagnosis. A PTH level in the mid or upper end of the normal range in the face of hypercalcemia is also consistent with the diagnosis of primary hyperparathyroidism. The standard assays for measurement of PTH are the second generation immunoradiometric (IRMA) or immunochemiluminometric (ICMA) assays that measures the "intact" molecule. This assay also measures large carboxyterminal fragments [PTH(7-84) is one such fragment] of PTH in addition to full-length PTH(1-84) and can therefore overestimate the amount of bioactive hormone in the serum. A third-generation assay specific for PTH(1-84) may offer somewhat increased diagnostic sensitivity in cases where the intact IRMA is within the normal range (albeit inappropriately), or in patients with renal insufficiency or failure. Most data suggest that either second- or third-generation PTH assays can be used in the diagnosis of the disease.

The clinical importance of PTH measurement in the differential diagnosis of hypercalcemia is a result of the fact that all non-parathyroid mediated causes of hypercalcemia (including malignancy) are associated with suppressed PTH levels. There is no cross reactivity between PTH and PTH-related peptide (PTHrP; the major causative factor in humoral hypercalcemia of malignancy) in the above assays for PTH. PTH concentration and serum calcium levels are also elevated in familial hypocalciuric hypercalcemia (FHH) [28, 29]. Some cases of reversible primary hyperparathyroidism are related to lithium or thiazide diuretic use [9, 30]. More commonly, thiazide diuretics unmask primary hyperparathyroidism by inhibiting calcium excretion. Ultimately, the only secure way to make the diagnosis of drug-related primary hyperparathyroidism is to withdraw the medication (if it is safe to do so) and confirm persistent hypercalcemia and elevated PTH levels 2–3 months later.

In addition to calcium and PTH abnormalities, serum phosphorus tends to be in the lower range of normal and is frankly low in approximately one-third of patients. Both total serum alkaline phosphatase activity and more specific markers of bone turnover (bone formation markers: bone-specific alkaline phosphatase, osteocalcin and bone resorption markers: urinary deoxypyridinoline and N-telopeptide of collagen) are elevated when there is active bone involvement but otherwise tend to be in the upper range of normal. The actions of PTH to alter acid–base handling in the kidney can lead to a small increase in the serum chloride concentration and a concomitant decrease in the serum bicarbonate concentration. Only 30% of patients are hypercalciuric. The circulating 1,25-dihydroxy-vitamin D concentration is elevated in 25% of patients while 25-hydroxyvitamin D levels tend

to be in the lower end of the normal range. Although the definition of vitamin D deficiency remains controversial, most patients with primary hyperparathyroidism have levels that are below 30 ng/ml and many are below 20 ng/ml [31, 32]. New guidelines suggest that 25-hydroxyvitamin D be measured in all patients with primary hyperparathyroidism, and that those with levels under 20 ng/ml be treated with vitamin D, although guidelines for repletion are lacking [21].

Although osteitis fibrosa cystica is rarely seen in the United States today, the skeleton remains an important target organ in primary hyperparathyroidism [33–35]. Plain X-rays are generally unrevealing and are not recommended. On the other hand, bone mineral densitometry has proven to be an essential component of the evaluation because of its great sensitivity in detecting early changes in bone mass. Patients with primary hyperparathyroidism tend to show a pattern of bone involvement that preferentially affects the cortical, as opposed to the cancellous, skeleton (Fig. 68.1) [33]. Typically, BMD of the distal third of the forearm, a site enriched in cortical bone, is reduced while the lumbar spine, a site enriched in cancellous bone, is relative preserved. The hip region (femoral neck) tends to show values intermediate between the distal radius and the lumbar spine because its composition is a more equal mixture of cortical and cancellous elements. The preferential reduction of bone density at the distal forearm underscores the importance of measuring BMD at that site in primary hyperparathyroidism. A small subset of patients (15%) present with an atypical BMD profile, characterized by vertebral osteopenia or osteoporosis, while occasionally patients may show reductions in BMD at all sites [34]. Bone densitometry gives an accurate assessment of the degree of skeletal involvement in primary hyperparathyroidism, information that is used to make recommendations for parathyroid surgery (see Table 68.1) [21]. As useful as bone density measurement is, it remains a proxy for the end point of fracture in primary hyperparathyroidism. Although case-control and cohort studies suggest that there may be an increase risk of fracture, questions of ascertainment bias exist, and this question remains unresolved [36–39].

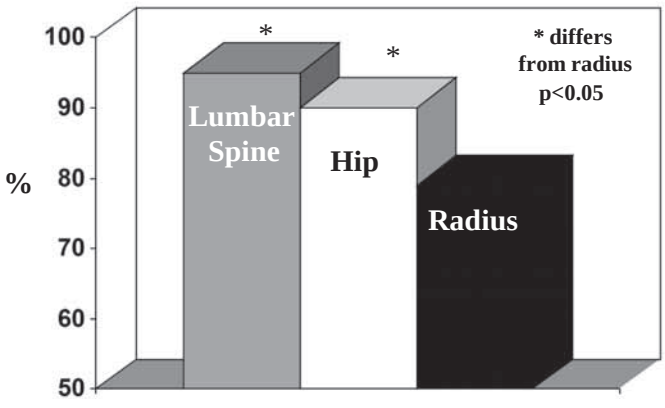

Fig. 68.1. Bone mineral density in primary hyperparathyroidism. Data are shown as percent of expected by site (adapted from Ref. 33).

TREATMENT OF PRIMARY HYPERPARATHYROIDISM

Parathyroid surgery

Surgery provides the only option for cure of primary hyperparathyroidism [4]. While surgery is indicated in all patients with classical symptoms of primary hyperparathyroidism (overt bone disease or kidney stones, or if they have survived an episode of acute primary hyperparathyroidism with life-threatening hypercalcemia), there is considerable controversy concerning the need for intervention in patients who have no clear signs or symptoms of their disease. To date, three national and international conferences (1990, 2002, 2008) have updated guidelines for surgical intervention (Table 68.1) [21, 40, 41].

Surgical guidelines (Table 68.1) [21]. Asymptomatic patients are now advised to have surgery if they have: (1) serum calcium greater than 1 mg/dl above the upper limit of normal; (2) significantly reduced creatinine clearance (less than 60 cc/min) (for the first time marked hypercalciuria is not an indication for surgery); (3) bone density more than 2.5 SD below young normal control subjects at any site (T-score: –2.5 or below) or fragility fracture; (4) younger than 50 years of age. These patients are at

Table 68.1. Guidelines for Use in Patients with Asymptomatic Primary Hyperparathyroidism

Measure	Surgical Criteria	Guidelines for Follow-Up of Nonsurgical Patients
Serum calcium	>1 mg/dl above normal	Annually
Urinary calcium	Do not measure	Do not measure
Renal function: Creatinine clearance	< 60 cc/min	Do not measure
Serum creatinine		Measure annually
BMD	T-score < –2.5 any site or fragility fracture	Every 1–2 years at spine, hip and forearm
Age	<50 years	

Guidelines describe patients for whom surgical intervention is desirable and criteria for follow-up of nonsurgical patients. It is recommended that all symptomatic patients be sent for parathyroidectomy. [Adapted from the 2008 International Workshop on Asymptomatic Primary Hyperparathyroidism (Ref. 21).]

greater risk for disease progression than older patients. Because surgery is an acceptable approach even in patients who do not meet surgical guidelines, some physicians will recommend surgery for all patients with primary hyperparathyroidism; others will not recommend surgery unless clear-cut complications of primary hyperparathyroidism are present. Similarly, some patients do not want to live with a curable disease while others may be unwilling to face the risks of surgery, although surgical indications are present. Finally, advances in surgical techniques may also shift the balance in favor of intervention in the eyes of some patients and their physicians [4].

Preoperative localization was initially used to identify the location of an ectopic parathyroid gland. Today it is used to identify candidates for minimally invasive parathyroidectomy (MIP) as well as in disease that is recurrent or persistent after surgery [42–45]. These techniques should not be used to make the diagnosis; rather, they should guide the surgeon once a diagnosis is made. The most widely used localization modalities are technetium-99m-sestamibi [with or without single photon emission computed tomography (SPECT)] or ultrasound. The former is excellent in single gland disease but is often inaccurate in multigland disease. Other localization techniques include four-dimensional (4D) CT scanning, magnetic resonance imaging (MRI), and the invasive modalities of selective venous sampling or arteriography. Radioisotopic imaging and ultrasound are best for parathyroid tissue that is located in proximity to the thyroid, whereas CT and MRI approaches are better for ectopically located parathyroid tissue. Arteriography and selective venous studies are reserved for those individuals in whom the noninvasive studies have not been successful. In patients who have undergone prior unsuccessful surgery, localization by two different modalities is suggested.

Surgery. Even without localization, an experienced parathyroid surgeon will find the abnormal parathyroid gland(s) 95% of the time in the patient who has not had previous neck surgery. The glands are notoriously variable in location, requiring the surgeon's knowledge of typical ectopic sites such as intrathyroidal, retroesophageal, the lateral neck, and the mediastinum. Four-gland exploration was long considered the gold standard surgical approach. It remains the procedure of choice in patients with no suggestive localization studies and those with hereditary disease or lithium-induced disease, in whom multigland involvement is common. Today, focused MIP is rapidly becoming the procedure of choice in patients in whom preoperative localization has localized single gland disease [4, 45]. MIP or unilateral exploration require the capability to measure intraoperative PTH levels. Taking advantage of the short half-life of PTH (3–5 minutes), an intraoperative PTH level is drawn shortly after resection [46]. If the PTH level falls by 50% and is within the normal range, the adenoma that has been removed is considered to be the only source of abnormal glandular activity, and the operation is terminated. There is some concern about the 50% decline rule, because if the PTH level falls by more than 50% but remains frankly elevated, other glandular sources of PTH may remain. In the case of multiglandular disease, the approach is to remove all tissue except for a fragment of parathyroid tissue that is left *in situ* or autotransplanted into the nondominant forearm. Potential complications of surgery include damage to the recurrent laryngeal nerve, which can lead to hoarseness and reduced voice volume, and permanent hypoparathyroidism in those who have had previous neck surgery or who undergo subtotal parathyroidectomy (for multiglandular disease).

Postoperatively, the patient may experience a brief period of transient hypocalcemia, during which time the normal but suppressed parathyroid glands regain their sensitivity to calcium. This happens within the first few days after surgery but can be prevented in most cases by providing patients with several grams of calcium on a daily basis during the first postoperative week. Prolonged postoperative symptomatic hypocalcemia as a result of rapid deposition of calcium and phosphate into bone ("hungry bone syndrome") is rare today. Such patients may require parenteral calcium for symptomatic hypocalcemia.

After successful surgery, the patient is cured. Serum biochemistries and PTH levels normalize. Long-term observational data confirm short-term randomized trial findings showing that bone density improves in the first several years after surgery [18–20, 47, 48]. The cumulative increase in bone mass at the lumbar spine and femoral neck can be as high as 12%, an increase that is sustained for years after parathyroidectomy (Fig. 68.2). It is noteworthy that substantial improvement is seen at the lumbar spine, a site where PTH seems to protect from age-related and estrogen-deficiency bone loss. Because patients who have vertebral osteopenia or osteoporosis sustain an even more impressive improvement in spine BMD after cure, they should be routinely referred for surgery, regardless of the severity of their hypercalcemia.

Nonsurgical management

Most patients who are not surgical candidates for parathyroidectomy do well when they are managed conservatively. In most such patients, biochemical indices (serum calcium, PTH, 1,25-dihydroxyvitamin D, and urinary calcium excretion) and BMD remain stable over the first decade of observation [47]. However, those patients followed for longer than that period begin to show evidence of bone loss, particularly at the more cortical sites (hip and radius; Fig. 68.2) [48]. In a 15-year observational cohort, 37% of patients with asymptomatic primary hyperparathyroidism had biochemical or bone densitometric evidence of disease progression. Those under the age of 50 years have a far higher incidence of progressive disease than do older patients (65% vs 23%), supporting the notion that younger patients should be referred for parathyroidectomy [49]. Finally, today, as in the day of classical primary hyperparathyroidism, patients with symptomatic disease do poorly

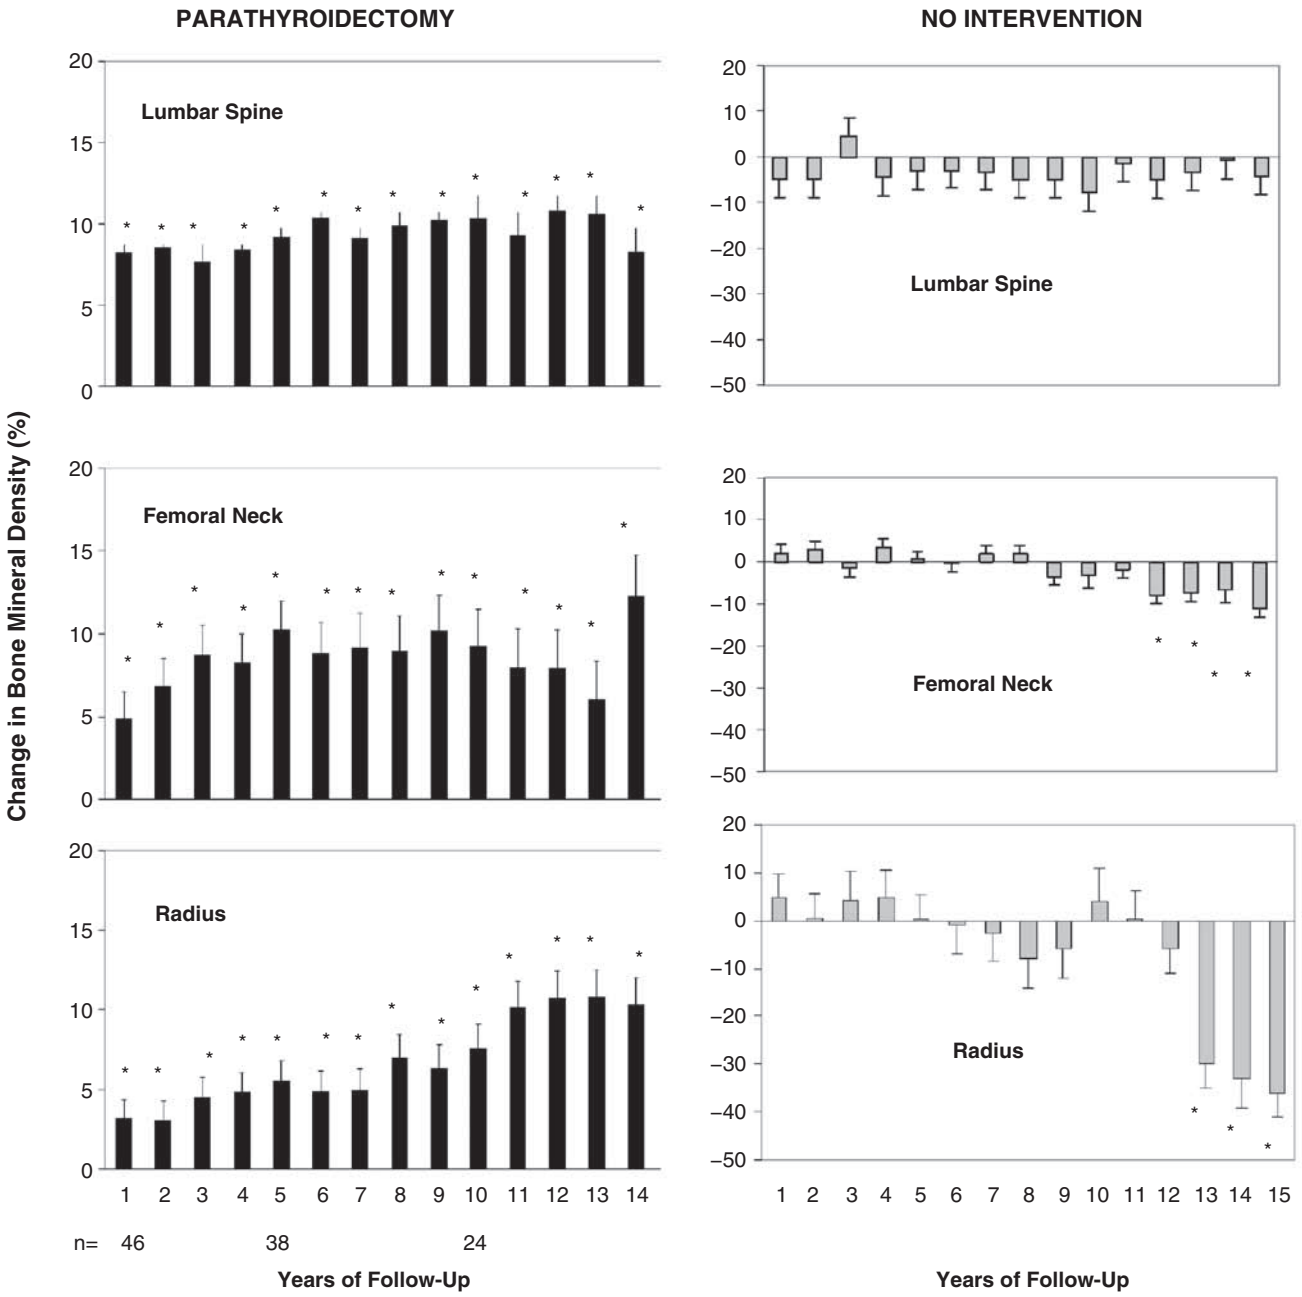

Fig. 68.2. Long-term effect of surgery (left panel) versus nonintervention (right panel) in patients with mild primary hyperparathyroidism (adapted from Ref. 48).

when observed without surgery. Thus, the data support the safety of observation without surgery only in selected patients with asymptomatic primary hyperparathyroidism, and even in those, indefinite observation is not clearly desirable.

A set of general medical guidelines is recommended for patients who do not undergo surgery (Table 68.1) [21]. Serum calcium levels should be measured once to twice yearly with annual assessment of serum creatinine and annual or biannual bone densitometry at the spine, hip, and distal one-third site of the forearm. Adequate hydration and ambulation are always encouraged. Thiazide diuretics and lithium should be avoided if possible, because they may worsen hypercalcemia. There is no good evidence that patients with primary hyperparathyroidism show significant fluctuations of their serum calcium as a function of dietary calcium intake. Dietary calcium intake should therefore be moderate, as low

calcium diets could theoretically lead to further stimulation of PTH secretion. High calcium intake (more than 1 g/day) should be avoided in patients whose 1,25-dihydroxyvitamin D levels are elevated.

We still lack an effective and safe therapeutic agent approved for the medical management of primary hyperparathyroidism in most patients [50]. **Oral phosphate** will lower the serum calcium in patients with primary hyperparathyroidism by 0.5–1 mg/dl. Phosphate seems to act by three mechanisms: (1) interference with absorption of dietary calcium, (2) inhibition of bone resorption, and (3) inhibition of renal production of 1,25-dihydroxyvitamin D. Phosphate, however, is not recommended as an approach to management, because of concerns related to ectopic calcification in soft tissues as a result of increasing the calcium–phosphate product. Moreover, oral phosphate may lead to an undesirable further elevation of PTH levels. Gastrointestinal intolerance is another limiting feature of this approach. In postmenopausal women, **estrogen therapy** remains an option in those women desiring hormone replacement for treatment of symptoms of menopause [51, 52]. The rationale for estrogen use in primary hyperparathyroidism is based on the known antagonism by estrogen of PTH-mediated bone resorption. Although the serum calcium concentration does tend to decline after estrogen administration (by 0.5 mg/dl), PTH levels and the serum phosphorous concentration do not change. Estrogen replacement may improve BMD in these patients as well. Preliminary data suggest that the **selective estrogen receptor modulator**, raloxifene, may have a similar effect on serum calcium levels in postmenopausal women with primary hyperparathyroidism [53]. **Bisphosphonates** have been investigated as a possible medical approach to primary hyperparathyroidism [54, 55]. Alendronate improves vertebral BMD in patients with primary hyperparathyroidism who choose not to have surgery but does not affect the underlying disorder. While most of the agents listed above (except for phosphate) act by inhibiting bone resorption, calcimimetics target the excess PTH secretion that underlies the disease. **Calcimimetic** agents alter the function of the extracellular calcium-sensing receptor, increasing the affinity of the parathyroid cell calcium receptor for extracellular calcium, leading to increased intracellular calcium, a subsequent reduction in PTH synthesis and secretion, and ultimately a fall in the serum calcium. Clinical trials of one such agent, cinacalcet HCl, have shown normalization of serum calcium for up to 5.5 years and sustained decreases in serum calcium levels across a wide range of disease severity [56–58]. However, this agent does not provide the equivalent of a "medical parathyroidectomy" because it does not improve bone density. There are no data on the effect of calcimimetics on constitutional or neuropsychological symptoms or fracture. Cinacalcet is approved for use in parathyroid cancer and was recently FDA approved for the treatment of severe hypercalcemia in patients with primary hyperparathyroidism who are unable to undergo parathyroidectomy. However, it is not currently recommended for general use in patients who are candidates for parathyroidectomy.

Primary hyperparathyroidism in pregnancy

Although rare, primary hyperparathyroidism does occur during pregnancy. Severe hypercalcemia can have deleterious effects on both mother and fetus. The fetal parathyroid gland is suppressed, which can lead to hypocalcemia, tetany, and even fetal demise. Preconception surgery is optimal if the diagnosis is known. Otherwise, surgery is recommended during the second trimester for patients with symptoms or significant hypercalcemia. Observation through pregnancy may be appropriate in the case of asymptomatic patients with mild hypercalcemia, although in these cases it is imperative that the neonatologists be aware of possible hypocalcemia in the neonate [59, 60].

INTRODUCTION

Persons with familial primary hyperparathyroidism (1°HPT), defined by the combination of hypercalcemia and elevated or nonsuppressed serum PTH, are a small and important subgroup of all cases with 1°HPT (about 5%). Their familial syndromes include multiple endocrine neoplasia (MEN) [types 1, 2A, and 4], familial (benign) hypocalciuric hypercalcemia (FHH), neonatal severe primary hyperparathyroidism (NSHPT), hyperparathyroidism-jaw tumor syndrome (HPT-JT), and familial isolated primary hyperparathyroidism (FIHPT). These syndromes exhibit Mendelian inheritance patterns, and the four main genes that can cause the syndromes in most families have been identified (Table 69.1). As more knowledge accumulates on genetic contributions to complex phenotypes, contributions are being identified from additional genes, including some for less penetrant and more subtle predispositions to 1°HPT.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA

Familial benign hypocalciuric hypercalcemia (FHH) (OMIM 145980) is an autosomal dominant syndrome. The prevalence of FHH is similar to MEN1; either accounts for about 2% of 1°HPT cases.

Clinical expressions

Persons with FHH usually have mild or no symptoms. Easy fatigue, weakness, thought disturbance, or polydipsia are less common and less severe than in typical 1°HPT. Nephrolithiasis or hypercalciuria are as uncommon as in normals. Bone radiographs are usually normal. Either chondrocalcinosis or premature vascular calcification can be present but are generally silent clinically. Bone mass and susceptibility to fracture are normal. Hypercalcemia has virtually 100% penetrance at all ages. Onset of 1°HPT is otherwise rare in infancy and thus can be useful for diagnosis.

The range of serum calcium levels is similar to that in typical 1°HPT with a normal ratio of free to bound calcium in serum. Serum magnesium is typically in the high range of normal or modestly elevated, and serum phosphate is modestly depressed. Urinary excretion of calcium is normal, with hypercalcemic and unaffected family members showing a similar distribution of values. Normal urine calcium with high serum calcium explains the concept of relative hypocalciuria in FHH.

Parathyroid function, including serum parathyroid hormone (PTH) and $1,25(OH)_2D$, is usually normal, with modest elevations of either index in 5–10% of cases. Such "normal" parathyroid function indices in the presence of lifelong hypercalcemia are inappropriate, diagnostically useful, and reflect the primary role for the parathyroids in causing this hypercalcemia.

Table 69.1. Outline of Syndromes of Familial Primary Hyperparathyroidism with Emphasis on Major Features That Distinguish among the Syndromes

Syndrome	Main Genes and Mutation Types[a]	Parathyroid Gland Aspects	Aspects Outside of the Parathyroids
FHH	*CASR* –[b]	Hypercalcemia begins at birth Increased secretion not growth Persist after subtotal PTX Avoid PTX	Relative hypocalciuria
NSHPT	*CASR* =	Hypercalcemia begins at birth Ca above 16 mg % Four very large PT glands Needs urgent total PTX	Relative hypocalciuria
MEN1	*MEN1* –	Begins at average age 20 yr Asymmetric adenomas Recur 12 yr after successful subtotal PTX	Tumors among more than 20 tissues (Pituitary, pancreaticoduodenal, foregut, carcinoid, dermis, etc.)
MEN2A	*RET* +	Like MEN1 but later, less intense, and less symmetrical	C-cell cancer that is preventable Find and treat pheochromocytoma(s) before thyroid or parathyroid surgery
HPT-JT	*HRPT2* –	Hypercalcemia can occur by age 10, often later Parathyroid cancer in 15% Benign or malignant Microcystic histology sometimes	Benign jaw tumors, renal cysts, and/or uterine tumors
F1HPT	Occult expression of *MEN1*-, *CASR*-, or *HRPT2*- in 30%. Other gene(s) not identified.	No specific features	None by definition. Another occult syndrome may emerge later.

FHH: familial hypocalciuric hypercalcemia; NSHPT: neonatal severe primary hyperparathyroidism; MEN: multiple endocrine neoplasia (can be type 1, 2A, or 4); HPT-JT: hyperparathyroidism jaw tumor syndrome; FIHPT: familial isolated primary hyperparathyroidism; PTX: parathyroidectomy.
[a]Mutation types in germline: – heterozygous inactivating; = homozygous inactivating; + heterozygous activating.
[b]Other genes identified for similar or identical syndromes are: FHH from *AP2S1*- and *GA11*-; MEN1 from a cyclin-dependent kinase inhibitor (CDKI) mutation (*p27*-, *p15*-, *p18*-, or *p21*-). MEN1 from *p27*- mutation was termed MEN4 by OMIM [Online Mendelian Inheritance in Man].

FHH cases often have mild enlargement of the parathyroid glands that may not be recognized at surgery and that may be evident only by careful measurement. Standard subtotal parathyroidectomy in FHH results in only a very transient lowering of serum calcium, followed by persistence of the hypercalcemia within a few days after surgery.

Pathogenesis/Genetics

Most cases result from heterozygous inactivating mutation of the *CASR* gene, which encodes a calcium-sensing receptor (CaSR). From the surface of the parathyroid cell, this CaSR "reports" the level of ionized calcium in serum. About 30% of probands and kindreds with FHH lack mutation in *CASR*. Some of these express mutation in *AP2S1* or *GA11*, but others do not have mutation in an identified gene. One rare case had homozygous *CASR* mutation despite only a mild form of FHH; the parents and other relatives with heterozygous *CASR* mutation were normocalcemic, pointing to a milder part of the spectrum of heterozygous (and homozygous) mutation.

The parathyroid cell in FHH shows decreased sensitivity to elevations of extracellular calcium, due to the inactivating mutation in its CaSR. This results in impaired calcium suppression of PTH secretion, usually with little or no increase of parathyroid cell proliferation.

There also is a disturbed calcium-sensing function intrinsic to the kidneys in FHH. Normally, the CaSR functions in the kidney to maintain tubular calcium reabsorption in the direction that would correct for changes in the serum calcium. The tubular reabsorption of calcium is also increased by rises of PTH; in FHH, it is high and remains high even after an intended or unintended total parathyroidectomy. CaSRs are normally expressed in additional tissues outside of the parathyroids and kidneys, but clinical dysfunction there has not been reported in FHH or even in NSHPT.

The usual distinctions between typical 1°HPT and the 1°HPT of *CASR* mutation can be blurred in some cases

or, rarely, in all carriers in an entire kindred. In particular, affected members in one large kindred with a germline missense mutation in the *CASR* had a typical 1°HPT syndrome, unlike the atypical 1°HPT of FHH. Several other small families with *CASR* loss-of-function mutations have contained some members with one or more features resembling typical 1°HPT. Hypocalciuric hypercalcemia can also be caused by antibodies against the CaSR and can then be associated with other autoimmune features, but this is without *CASR* mutation; this is rare and generally not familial.

Diagnosis of the family and the carrier

In the presence of hypercalcemia, a normal PTH just like a relatively low urine calcium warns about possible FHH. The family diagnosis usually is made from typical clinical features in one or more members of a family such as hypercalcemia, relative hypocalciuria, and failed parathyroidectomy. Recognition of hypercalcemia before age 10 is almost specific for the diagnosis of FHH in that kindred.

Family screening for FHH traits can be important to establish the syndrome in a proband, in an entire family, and eventually to diagnose additional relatives. Because of high penetrance for hypercalcemia in all FHH carriers, an accurate assignment for each relative at risk can usually be made from one determination of serum calcium (preferably ionized or albumin-adjusted).

Because urinary calcium excretion in a fixed interval depends heavily on glomerular filtration rate (GFR) and collection interval, total calcium excretion is not a valid index to distinguish a case of FHH from typical 1°HPT. The ratio of renal calcium clearance to creatinine clearance,

$$Ca_{Cl}/Cr_{Cl} = [Ca_u \times V/Ca_s] / [Cr_u \times V/Cr_s]$$
$$= [Ca_u \times Cr_s] / [Cr_u \times Ca_s]$$

is an empirical and useful index for this specific comparison. In hypercalcemic cases with FHH, this clearance ratio averages one-third of that in typical 1°HPT, and values below 0.01 (valid units will all cancel out) are suggestive of FHH.

CASR mutation analysis has an occasional role in the diagnosis of the syndrome, particularly with an inconclusive clinical evaluation of the family. *CASR* mutation may be undetectable if located outside the tested coding exons; this may account for much of the 30% lack of identified *CASR* mutation in typical families with FHH.

Management

Despite lifelong hypercalcemia, FHH can be compatible with survival into the ninth decade. Chronic hypercalcemia in FHH should rarely be treated, and it has been resistant to several types of drugs (diuretics, bisphosphonates, phosphates, or estrogens). Calcimimetics are a type of drug that acts like Ca^{2+} to stimulate the normal or even the mutated CaSR on the parathyroid cell and, thereby, decrease release of PTH. They might be effective (if used off-label) in rare cases of FHH for which treatment is appropriately contemplated. This potential for efficacy would be expected to depend on the domain of the mutated residues within the CaSR.

Because of their generally benign course and lack of response to subtotal parathyroidectomy, very few cases should undergo parathyroidectomy. In rare situations, such as relapsing pancreatitis, very high PTH, or very high serum calcium (persistently higher than 14 mg/dl), debulking parathyroidectomy and even total parathyroidectomy may be indicated.

Sporadic hypocalciuric hypercalcemia

Without a positive family history or *CASR* mutation, the management of sporadic hypocalciuric hypercalcemia is challenging. This should generally be managed as if it is typical FHH, unless the features of another 1°HPT syndrome become more prominent.

NEONATAL SEVERE PRIMARY HYPERPARATHYROIDISM

Clinical expressions

Neonatal severe primary hyperparathyroidism (NSHPT) (OMIM 239200) is an extremely rare neonatal state of life-threatening, severe hypercalcemia, very high PTH, rib fractures, hypotonia, respiratory distress, and massive enlargement of all parathyroid glands. The rare case to survive without early surgery is likely to show general impairments to development. The main relevance of NSHPT here is toward understanding some severe ways that *CASR* mutation can disrupt the parathyroids selectively.

Pathogenesis/Genetics

This disorder typically results from homozygous or compound heterozygous *CASR* inactivating mutation. It is uncertain if the hypercellular parathyroids are polyclonal or are overgrown by a monoclonal component.

Diagnosis

Diagnosis is usually based on the unique clinical features, often combined with parental consanguinity and/or FHH in first-degree relatives.

Management

Urgent total parathyroidectomy for severe symptoms and signs can be lifesaving. This may allow the patient

to have a normal life, with treated hypoparathyroidism. Persistence of the intrinsic renal defect makes treatment of this hypoparathyroidism simpler.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

MEN1 (OMIM 131100) is a rare and often heritable disorder with an estimated prevalence of 2–3 per 100,000 in unselected persons. Approximately 2% of all cases of 1°HPT are caused by MEN1. It is defined by consensus as tumors in two of its three main tissues (parathyroids, pituitary, and pancreaticoduodenal endocrine); affected persons are also predisposed to tumors in many other hormonal and nonhormonal tissues. By extension, familial MEN1 is defined as MEN1 with a first-degree relative showing tumor in at least one of the three main tissues.

Clinical expressions

1°HPT is the most penetrant hormonal component of MEN1 and is the initial clinical manifestation of the disorder in most cases. In MEN1, 1°HPT has several features different from the common sporadic (nonfamilial) forms of 1°HPT. The female-to-male ratio is about 1.0 in MEN1, in contrast to about threefold female predominance in sporadic 1°HPT. 1°HPT presents about 30 years earlier in MEN1, typically in the second to fourth decade of life and has been found as early as 8 years of age. Much earlier onset of primary hyperparathyroidism is likely to explain the much earlier onset of osteoporosis in MEN1.

Multiple parathyroid tumors are typical in MEN1; these tumors may vary widely in size, with an average 10:1 ratio between the largest and smallest tumor. A powerful drive to parathyroid tumorigenesis exists in MEN1, reflected by an impressively high rate of recurrent 1°HPT; this averages about 50% at 12 years after parathyroidectomy, which had been clearly successful for this patient in the earlier years postoperatively. Because of tumors in multiple parathyroid glands, an ectopic location is more likely in MEN1 than in common adenoma.

Some of the other tumors associated with MEN1 include duodenal gastrinomas, insulinoma, nonhormonal islet tumors, bronchial or thymic carcinoids, gastric enterochromaffin-like tumors, adrenocortical adenomas, lipomas, facial angiofibromas, and truncal collagenomas. In a family with few and/or mainly young affected members, tumors of MEN1 may be expressed in only the parathyroids, or in the parathyroids plus only in one additional tissue. Such families should be followed for development of other tumors of MEN1.

Pathogenesis/Genetics

Familial MEN1 shows an autosomal dominant inheritance pattern, and the main genetic basis is an inactivating germline mutation of the *MEN1* tumor suppressor gene. *MEN1* encodes menin, whose molecular pathways and detailed functions remain under study. *MEN1* mutations are distributed across the translated parts of the gene without any apparent pattern, other than the majority predicting truncation or absence of menin. Individuals with MEN1 have typically inherited one inactivated copy of the *MEN1* gene from an affected parent, but up to 10% may have a spontaneous or new germline mutation.

The outgrowth of a tumor follows from the subsequent somatic (i.e., acquired) inactivation of the normal, remaining copy of the *MEN1* gene in one cell. Such a cell, for example in the parathyroid gland, would have become devoid of *MEN1's* tumor suppressor function, contributing to a selective growth advantage over its neighbors and leading to its clonal proliferation. This process of mutational loss of function is analogous to that for many tumor suppressor genes such as *HRPT2*, *p53*, *BRCA1*, and *APC*.

MEN1 mutation is not identified in 30% of probands and families with MEN1. Several cases among this group have MEN1 from mutation in *CDKN1B*, encoding the p27KIP1 cyclin-dependent kinase inhibitor (CDKI). This combination has been termed MEN4. Few among the remainder have mutation in *p15*, *p18*, or *p21*, three other CDKI genes. These CDKI defects suggest that menin and CDKIs share a molecular pathway, important in endocrine tumorigenesis.

Diagnosis of carriers

Direct sequencing for germline *MEN1* mutations is commercially available, albeit costly, and the indications for such testing remain under discussion. Gene analyses, typically limited to the coding region and near to it, fail to detect *MEN1* mutation in about 30% of typical MEN1 kindreds. Some of these kindreds may have unrecognized *MEN1* defects, such as large deletions or small noncoding mutations, that cannot be detected by the current testing methods. The yield of detectable *MEN1* or CDKI mutation in cases with a sporadic but true MEN1 phenotype, limited to parathyroid plus pituitary tumor, is much lower (about 7%); this suggests the existence of other predisposing gene(s) in this subgroup. Still undetermined gene(s) may contribute.

In contrast to the importance of testing for *RET* mutations for prevention or cure of a cancer, presymptomatic gene diagnosis has not been established to broadly improve morbidity or mortality in MEN1. Periodic screening with serum calcium, PTH, etc., provides a non-DNA-based alternative for carrier ascertainment. *MEN1* gene testing can be helpful for diagnosis or rarely for intervention in an MEN1-like proband, when the clinical diagnosis is inconclusive but a suspicion of MEN1 exists: for example, in a young adult with sporadic or familial isolated multigland 1°HPT, or in Zollinger Ellison Syn-

drome (ZES). In the latter, *MEN1* mutation occurs in one-quarter of cases, and identifying it can lead to avoidance of abdominal surgery that would otherwise be indicated.

When *MEN1* mutation is not identified in a proband or family, classical ascertainment testing with physical or biochemical traits is the back-up method. Facial angiofibromas or hypercalcemia are rather robust traits for this.

Diagnosis of other tumors

For MEN1-like probands or for established MEN1 carriers or other family members at risk for developing manifestations of MEN1, screening for tumor indices at baseline or at follow-up for the emergence of tumors is recommended, because a benefit seems likely. Tumor screening and other management of the pituitary, pancreaticoduodenal, and other MEN1 tumors outside of the parathyroids is mostly beyond the scope of this chapter.

Management

Once the biochemical diagnosis is established, the indications for referral to surgery are similar to those in sporadic 1°HPT. Osteoporosis is a surgical indication that is frequent in women with MEN1 by 35 years of age.

An age of under 50, though a criterion for referral to surgery in sporadic 1°HPT, should not be accepted as a sufficient criterion for referral to surgery in 1°HPT of MEN1. Because direct evidence is lacking, opinions differ about the optimal timing of surgery for 1°HPT in MEN1. Early and presymptomatic surgery might, on one hand, lead to better long-term bone health. On the other hand, the parathyroids may be smaller and harder to identify. Furthermore, with the high rate of recurrent 1°HPT after surgery in MEN1, a policy of early surgery might increase a person's total number of operations and, thereby, increase the risk of intraoperative morbidity.

It should be emphasized that MEN1-associated cancers in nonparathyroid tissues cause fully one-third of the deaths in MEN1 cases. For most of these cancers, no effective prevention or cure currently exists, partly because of their problematic locations. New drugs and other promising treatments, including some drugs already FDA approved for common islet tumors, still need more evaluation in similar tumors of MEN1.

Parathyroid surgery in MEN1

Preoperative imaging for tumor localization is useful before reoperation in MEN1 cases with recurrent or persistent 1°HPT. The usefulness of preoperative imaging is lower in unoperated cases due to multiplicity of parathyroid tumors in MEN1, the efforts to identify all abnormal parathyroid glands particularly at initial surgery, and the inability to image reliably all parathyroid tumors in any one case. For the same reasons, a suspected or firm preoperative diagnosis of MEN1 argues against performing minimally invasive parathyroidectomy. Even at initial surgery for multiple parathyroid tumors, intraoperative PTH measurement can be helpful.

The initial operation most frequently performed in MEN1 is 3.5 gland subtotal parathyroidectomy with transcervical near-total thymectomy. A parathyroid remnant is usually left on its native vascular pedicle in the neck and may be marked with a clip. Alternately, the remnant can be immediately autotransplanted to the forearm during an intended complete parathyroidectomy (see below). Transcervical thymectomy in MEN1 has an unproven benefit but is widely used, because it may prevent or cure thymic carcinoids (mainly in males); in addition, the thymus is a common site for parathyroid tumors in MEN1 patients with recurrent 1°HPT. Involvement of an experienced parathyroid surgical team is crucial to optimal outcome.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2A

MEN2 is subclassified into three clinical syndromes with mutations in the same gene, *RET*. These are MEN2A, MEN2B, and familial medullary thyroid cancer (FMTC). Of these three syndromes, MEN2A (OMIM 171400) is the most common and the only one that manifests 1°HPT. Even further subdivision of MEN2 according to family expression or mutated codon is likely in the future.

Clinical expressions

MEN2A is a heritable predisposition to medullary thyroid or C-cell cancer (MTC), pheochromocytoma, and 1°HPT. The frequencies of these tumors in an adult carrier of MEN2A are above 90% for MTC, 40–50% for pheochromocytoma, and 20% for 1°HPT.

This intermediate penetrance of 1°HPT in MEN2A contrasts with the higher penetrance found in every other familial 1°HPT syndrome. Similarly, the 1°HPT in MEN2A is generally milder, more asymmetrical, and later in onset than in MEN1. Unlike in MEN1, late recurrence 1°HPT is infrequent after an apparently successful parathyroidectomy in MEN2A. This is similar to the presumably excellent long-term outcome of surgery with nonfamilial multiple primary parathyroid tumors.

MTC, a potentially lethal manifestation of MEN2A, evolves from preexisting parafollicular C-cell hyperplasia, and its calcitonin release can give a useful marker for recognizing the emergence of early tumors or for monitoring a large tumor burden. Despite the pharmacologic

properties of calcitonin, mineral metabolism is generally normal in the setting of impressive hypercalcitoninemia. Pheochromocytomas in MEN2A can be unilateral or bilateral.

Pathogenesis/genetics

MEN2A is inherited in an autosomal dominant pattern, with both genders affected in equal proportions; the gene defect is germline gain of function mutation of the *RET* proto-oncogene. Germline *RET* mutation is detectable in above 95% of MEN2A families. *RET* mutation at codon 634 accounts for 85% of MEN2A and is more highly associated with the expression of 1°HPT.

There are both differences and much overlap in the specific *RET* gene mutations underlying MEN2A and FMTC; in contrast, MEN2B is caused by one of two entirely distinct *RET* mutations. Why parathyroid disease fails to develop in the latter two MEN2 syndromes remains unclear. Unlike the numerous and seemingly random different inactivated codons of *MEN1* that are typical of a tumor suppressor mechanism, the mutated *RET* codons in MEN2A are limited in number, reflecting the need for highly specific changes in selected domains of the RET protein to activate this oncoprotein.

The RET protein is a plasma membrane spanning tyrosine kinase that normally transduces growth and differentiation signals in developing tissues, including around the neural crest. Knowledge of its molecular pathway and of bioassays is promoting new drugs and ongoing clinical trials, directed at MTC and other *RET*-related thyroid cancers.

Diagnosis of a kindred, of carriers, and of parathyroid tumors

For diagnosis of MEN2A, *RET* sequence testing is superior to immunoassay of basal or stimulated calcitonin, excepting, of course, in the very rare MEN2 family without detectable *RET* mutation. Gene sequencing for germline *RET* mutations is central to clinical management of MEN2A, particularly to guide thyroidectomy in management/prevention of MTC.

1°HPT in MEN2A is often asymptomatic and diagnosed and treated incidentally to thyroid surgery. Otherwise, its biochemical diagnosis, as well as indications for surgery, parallel those in sporadic 1°HPT.

Management

1°HPT is a less urgent expression of MEN2A than MTC or pheochromocytoma. Conceptually consistent with its genetics, 1°HPT in MEN2A is multiglandular, but less than four overtly enlarged glands may be present at one time. Thus, bilateral neck exploration to identify all abnormal parathyroid glands is advisable in known or suspected MEN2A; resection of enlarged parathyroid glands (up to 3.5 glands) is the most common operation. Issues of preoperative tumor localization in unoperated MEN2A patients expressing 1°HPT are similar to MEN1.

RET testing during childhood can secure a preventive or curative thyroidectomy (i.e., sufficiently early in childhood as to minimize the likelihood that extracapsular metastases of C-cell cancer will have already occurred).

If MEN2A is a possibility, evidence of pheochromocytoma should be sought before parathyroidectomy or thyroidectomy. If evident, pheochromocytoma(s) must be treated before thyroid or parathyroid surgery. Laparoscopic adrenalectomy has greatly improved the management of pheochromocytoma in MEN2A. Incompletely treated postoperative chronic hypocortisolism remains a major cause of morbidity, and even death after bilateral adrenalectomy in MEN2A.

HYPERPARATHYROIDISM-JAW TUMOR SYNDROME

Clinical expressions

Hyperparathyroidism-jaw tumor syndrome (HPT-JT) (OMIM 145001) is a rare, autosomal dominant combination of 1°HPT, ossifying or cementifying fibromas of the mandible and maxilla, renal manifestations including cysts, hamartomas, or Wilms tumors, and uterine tumors. Among adults of "classical" HPT-JT kindreds, 1°HPT is the most highly penetrant manifestation at 80%, next to ossifying fibromas of the maxilla or mandible at 30%, and a renal lesion slightly less frequently. A wide range of penetrance values occurs for uterine tumors.

1°HPT in HPT-JT may develop as early as during the first decade of life. Although all parathyroids are at risk, surgical exploration can show a solitary parathyroid tumor (even solitary atypical adenoma or solitary cancer) rather than multigland disease. Parathyroid neoplasms can be macro- or microcystic, and, whereas most tumors are classified as adenomas, parathyroid carcinoma (15–20% of 1°HPT) is markedly overrepresented in HPT-JT cases. In contrast, parathyroid cancer almost never occurs in MEN1, MEN2, or FHH. Dissemination of parathyroid cancer to the lungs can occur in the early 20s in HPT-JT. After a period of euparathyroidism, operated cases may manifest recurrent 1°HPT, and a solitary tumor asynchronously originating in a different parathyroid gland may prove responsible.

Ossifying fibromas in HPT-JT are generally benign but still may be large and destructive. More often they are small, asymptomatic, and identified incidentally on dental radiographs. They are clearly distinct from the classic, osteoclast-rich "brown tumors" of the jaws.

Pathogenesis/genetics

Germline mutation of the *HRPT2* gene (also called *CDC73)* causes HPT-JT. The yield of *HRPT2* mutation in HPT-JT kindreds is about 60–70%; the remaining kindreds may have *HRPT2* mutations that evade detection because they are not amplified by polymerase chain reaction (PCR) prior to sequencing. Mutations of *HRPT2* cause tumors, including parathyroid cancer, by inactivating or eliminating its protein product, parafibromin, consistent with a classical "two-hit" tumor suppressor mechanism. Both parafibromin's normal cellular roles and its influence (via loss of function) in tumorigenesis are under study.

Importantly, many cases with seemingly sporadic presentations of parathyroid carcinoma (OMIM 608266) also harbor a germline mutation in *HRPT2*, thus representing newly ascertained HPT-JT, occult HPT-JT, or another variant syndrome.

Diagnosis of carriers and cancers

The biochemical diagnosis of 1°HPT in HPT-JT parallels that in sporadic 1°HPT. Recognition of germline *HRPT2* mutation in classic or variant HPT-JT has opened the door to DNA-based diagnosis in probands or individuals with apparently sporadic parathyroid carcinoma, and for carrier identification in at-risk family members, aimed at preventing or curing parathyroid malignancy.

Prior to parathyroid surgery of a known or likely carrier of HPT-JT, the surgeon should be alerted to the possibility of parathyroid cancer.

Management

Management in HPT-JT centers around monitoring and surgery to address the high risk for current or future parathyroid malignancy. The finding of biochemical 1°HPT should lead promptly to surgery. All parathyroids should be identified at operation, signs of malignancy sought, and resection of abnormal glands performed. Because of the potential for malignancy, the consideration of prophylactic total parathyroidectomy (perhaps even for euparathyroid carriers) has been raised as an alternative approach. This is not favored in view of the difficulty in removing all parathyroid tissue, difficulties with lifelong hypoparathyroidism, the incomplete penetrance of parathyroid cancer in the syndrome, and the preliminary belief that close biochemical monitoring for recurrent 1°HPT will promote successful management of cancer.

Any case of apparently sporadic parathyroid cancer without identified *HRPT2* mutation should be monitored for potential HPT-JT, including consideration of screening the serum calcium periodically in first degree relatives.

FAMILIAL ISOLATED HYPERPARATHYROIDISM

Clinical expressions and diagnosis

Familial isolated primary hyperparathyroidism (FIHPT) (OMIM 145000) is clinically defined as familial 1°HPT without the extraparathyroid manifestations of another syndromal category. The diagnosis of FIHPT should therefore be changed, if features of another 1°HPT syndrome develop. Partly because this category is likely to encompass several occult or even totally unknown causes, the spectrum of its 1°HPT is broad.

Pathogenesis/Genetics

FIHPT is genetically heterogeneous and can be caused by incomplete expression from germline mutation in *MEN1, HRPT2*, or *CASR*; however, the majority of families do not have a detectable mutation in any of these three genes. One unidentified gene may be on the short arm of chromosome 2 (OMIM 610071); one or more other genes likely accounts for other families.

Mutation testing should be considered (e.g., when results might impact on the advisability of, or approach to, management of parathyroid and other tumors or to more gene testing in relatives). However, in FIHPT the low yield of mutations in the three known genes must be considered.

Management

Management is very similar to that in common 1°HPT. Monitoring and management must recognize that additional features of a genetically defined 1°HPT syndrome or a previously unidentified 1°HPT syndrome could become detectable. For example, the heightened risk of parathyroid carcinoma must be borne in mind in FIHPT, when occult HPT-JT is possible.

OVERLAPPING CONSIDERATIONS AMONG ALL FORMS OF FAMILIAL 1°HPT

Multifocal parathyroid gland hyperfunction

For three hereditary 1°HPT syndromes (MEN1, MEN2A, and HPT-JT), the germline mutation in the parathyroid cell causes susceptibility to postnatal and gradual overgrowth of mono- or oligoclonal parathyroid tumor. For two others (FHH and NSHPT), the phenotype is fully expressed around birth (i.e., with no postnatal delay). Stated differently, an underlying feature of these five multiorgan syndromes is that every parathyroid cell carries the same syndromal germline mutation; this is either sufficient to cause the overfunction phenotype in

all parathyroid cells immediately or to put each parathyroid cell at risk to yield clonal proliferation many years later.

Detection of asymptomatic carriers

Once a 1°HPT syndrome has been diagnosed, testing for carriers among asymptomatic relatives should be considered. The concept of the carrier must include disease predisposition in a relative, even without an identifiable syndromal mutation in that family. Testing of germline DNA is often the gold standard for detection of carriers; however, carrier testing by use of traits that are expressed early and with high penetrance (such as hypercalcemia for the early carrier in FHH) or lower penetrance (such as hypercalcemia for delayed parathyroid cancer in HPT-JT) is sometimes a useful alternative.

The possible benefits of germline mutation testing include providing information to the subject, family, and physician.

Among all 1°HPT syndromes, carrier testing only for MEN2 can lead to a major intervention of almost certain efficacy in reducing mortality (from medullary thyroid carcinoma). Testing for HPT-JT can lead to management that may lessen mortality associated with parathyroid malignancy. Testing in other 1°HPT syndromes is mainly for information to the physician and patient and is less urgent. Such information about silent or even affected carriers is widely used to plan screening for tumors at baseline and during follow-up.

Monitoring for tumors

Tumor monitoring is best done with a syndrome-specific protocol; it should be followed in each carrier of a syndrome of 1°HPT. Monitoring for parathyroid and other tumors should address tumors present at the time of initial ascertainment of the carrier and the tumors that emerge during periodic follow-up. The plan for monitoring must deal with issues of cost and effectiveness.

Special approaches in surgery for familial parathyroid tumors

Many aspects of surgery for parathyroid adenoma require modification, when multiple parathyroid glands have the potential to be overactive. Efforts are made intraoperatively to know when sufficient pathologic tissue has been removed. Traditionally, the identification of all four parathyroid glands has been pursued for this reason. Rapid measurement of PTH intraoperatively to see a major drop from high values also can be useful immediately to judge if any overactive parathyroid tissue remains *in vivo*.

Efforts to identify all four parathyroid glands and remove several glands result in increased frequency of postoperative hypoparathyroidism. To minimize permanent hypoparathyroidism, in some centers, small fragments of the most normal-appearing parathyroid tumor are autografted immediately to the nondominant forearm. In other centers, because of difficulty in establishing such grafts, the surgeon leaves a small remnant of parathyroid in the neck, attached to its own vascular pedicle. In either case, one may cryopreserve fragments of the most normal-appearing tissue for possible delayed autograft for late postoperative hypoparathyroidism. However, such cryopreservation is not permitted in many centers due to concerns about legal liabilities. A normal-sized gland is not sufficiently large to give a satisfactory fresh or cryopreserved autograft; thus, tumor tissue is used. Fortunately, it can sustain euparathyroidism for many years. The potential for malignancy of any parathyroid tissue in HPT-JT argues against the autografting option there.

Beyond hypoparathyroidism, other complications are also more frequent after surgery for multigland 1°HPT, including familial 1°HPT, than after surgery for adenoma. These include complications to surrounding tissues (such as a recurrent laryngeal nerve) and postoperative persistent 1°HPT. The most obvious reason for the latter is an incomplete exploration for multigland disease.

True recurrent 1°HPT is a late complication that is much more frequent in MEN1 and other familial 1°HPT, than in common adenoma. True recurrence is defined for convenience as 1°HPT after a 3- to 6-month postoperative period of documented euparathyroidism. It could arise when a small tumorous remnant becomes overactive or when a previously normal parathyroid cell progresses into a tumor clone.

PATHOPHYSIOLOGY OF HYPERCALCEMIA

As discussed elsewhere in the *Primer*, the normal total serum calcium concentration of 9.5 mg/dl can be divided into three components: ionized serum calcium (approximately 4.2 mg/dl); serum calcium complexed to anions such as phosphate, sulfate, carbonate, etc., (approximately 0.3 mg/dl); and calcium bound to serum proteins, principally albumin (approximately 4.5 mg/dl). Hypercalcemia is defined as a serum calcium greater than 2 SD above the normal mean in a given laboratory, commonly 10.6 mg/dl for total serum calcium, and 1.25 mmol/L for ionized serum calcium. There is no formal grading system for defining the severity of hypercalcemia. In general, however, serum calcium concentrations less than 12 mg/dl can be considered mild, those between 12 and 14 mg/dl moderate, and those greater than 14 mg/dl severe.

The serum calcium concentration is tightly regulated by the flux of serum ionized calcium to and from four physiologic compartments: the skeleton, the intestine, the kidney, and serum binding proteins. Hypercalcemia, therefore, always results from an abnormality in calcium flux between the extracellular fluid (ECF) and one or a combination these compartments. Said another way, hypercalcemia can result only from one of four mechanisms: abnormal binding of calcium to serum proteins, or abnormal flux of calcium into extracellular fluid from the gastrointestinal (GI) tract, the skeleton, or the kidney. Combinations of the above three mechanisms are common. Understanding hypercalcemia in this kind of mechanistic construct is critical for accurate diagnosis and is essential for effective treatment of hypercalcemia. For example, hypercalcemia from vitamin D intoxication or milk-alkali syndrome commonly arises from increased GI absorption of calcium and would not be expected to respond to antiresorptive agents such as bisphosphonates. Conversely, humoral hypercalcemia of malignancy results principally from increased skeletal resorption and renal calcium reabsorption, and therefore is not influenced by restricting dietary calcium intake.

CLINICAL SIGNS AND SYMPTOMS OF HYPERCALCEMIA

Hypercalcemia raises the electrical potential difference across cell membranes and increases the depolarization threshold. Clinically, this is manifested as a spectrum of neurological symptoms ranging from mild tiredness to obtundation to coma. There is no precise serum calcium level that leads to impaired neurologic function. Instead, the presence or absence and degree of neurologic symptoms depends on the abruptness of onset of hypercalcemia, the age and underlying neurological status of the patient, and comorbidities and medications such as narcotics and neuroleptics.

Hypercalcemia acts directly at the nephron to prevent normal reabsorption of water, leading to a functional form of nephrogenic diabetes and polyuria. This may lead to thirst, prerenal azotemia, and significant dehydration, which are common clinical features of hypercalcemia. Hypercalcemia may also cause precipitation of calcium phosphate salts in the renal interstitium (nephrocalcinosis), vasculature, cardiac conduction system, the cornea (visible as so-called band keratopathy), and the gastric mucosa. Hypercalcemia may lead to renal failure from obstructive uropathy, from nephrolithiasis, from nephrocalcinosis, and from prerenal causes, including dehydration and a reversible component of hypercalcemia-induced afferent arteriolar vasoconstriction.

Hypercalcemia can also lead to electrocardiographic abnormalities, the most specific of which is a prolonged Q-Tc interval. Hypercalcemia increases the depolarization threshold of skeletal and smooth muscle, making them more refractory to neuronal activation. Resulting decreases in muscle contraction manifest clinically as skeletal muscle weakness and as constipation. Nausea, anorexia, vomiting, and flushing are also common. Finally, hypercalcemia may lead to abdominal pain and pancreatitis.

DISORDERS THAT LEAD TO HYPERCALCEMIA

The complete differential diagnosis of hypercalcemia is shown in Table 70.1. In this chapter, we consider non-parathyroid causes of hypercalcemia. The parathyroid hormone (PTH)-dependent family of hypercalcemic disorders, including primary and tertiary hyperparathyroidism, their inherited variants, and familial hypocalciuric hypercalcemia, also known as familial benign hypercalcemia, are discussed elsewhere in the *Primer*.

Cancer

Malignancy-associated hypercalcemia (MAHC) accounts for approximately 90% of hypercalcemia encountered among hospitalized patients and is a negative prognostic factor. The first patient with MAHC was reported in 1921, immediately following the development of clinical methods to measure serum calcium. MAHC can be subdivided into four mechanistic subtypes: (1) humoral hypercalcemia of malignancy (HHM); (2) local osteolytic hypercalcemia (LOH); (3) $1,25(OH)_2$-vitamin D-induced hypercalcemia; and, (4) authentic ectopic hyperparathyroidism.

HHM

HHM is the most common form of MAHC, accounting for about 80% of subjects in large series of unselected patients with MAHC. HHM results from the secretion of parathyroid hormone-related protein (PTHrP) (discussed elsewhere in the *Primer*) by HHM-associated tumors. Whereas almost any kind of tumor may cause HHM, the most common types are squamous carcinomas of any origin (lung, esophagus, skin, cervix are common sites), and breast and renal carcinomas.

HHM was first described in the 1940s and '50s in patients in whom hypercalcemia associated with cancer was corrected following successful removal of the responsible tumor. Investigators deduced the humoral nature of the syndrome from these events, but the responsible "humor" was not identified until 1987, when PTHrP was purified, sequenced, and its cDNA and gene were cloned. We now understand that continuous secretion of PTHrP by tumors leads to a dramatic uncoupling of bone resorption from formation, by activating osteoclastic bone resorption and suppressing osteoblastic bone formation (Fig. 70.1). As a result, enormous net quantities of calcium of up to 700–1,000 mg/day leave the skeleton, causing marked hypercalcemia. In addition, the anti-calciuric effects of PTHrP prevent or restrict effective renal calcium clearance. Finally, HHM is associated with reductions in circulating $1,25(OH)_2D$ levels, which in turn limit intestinal calcium absorption. Thus, in pathophysiologic

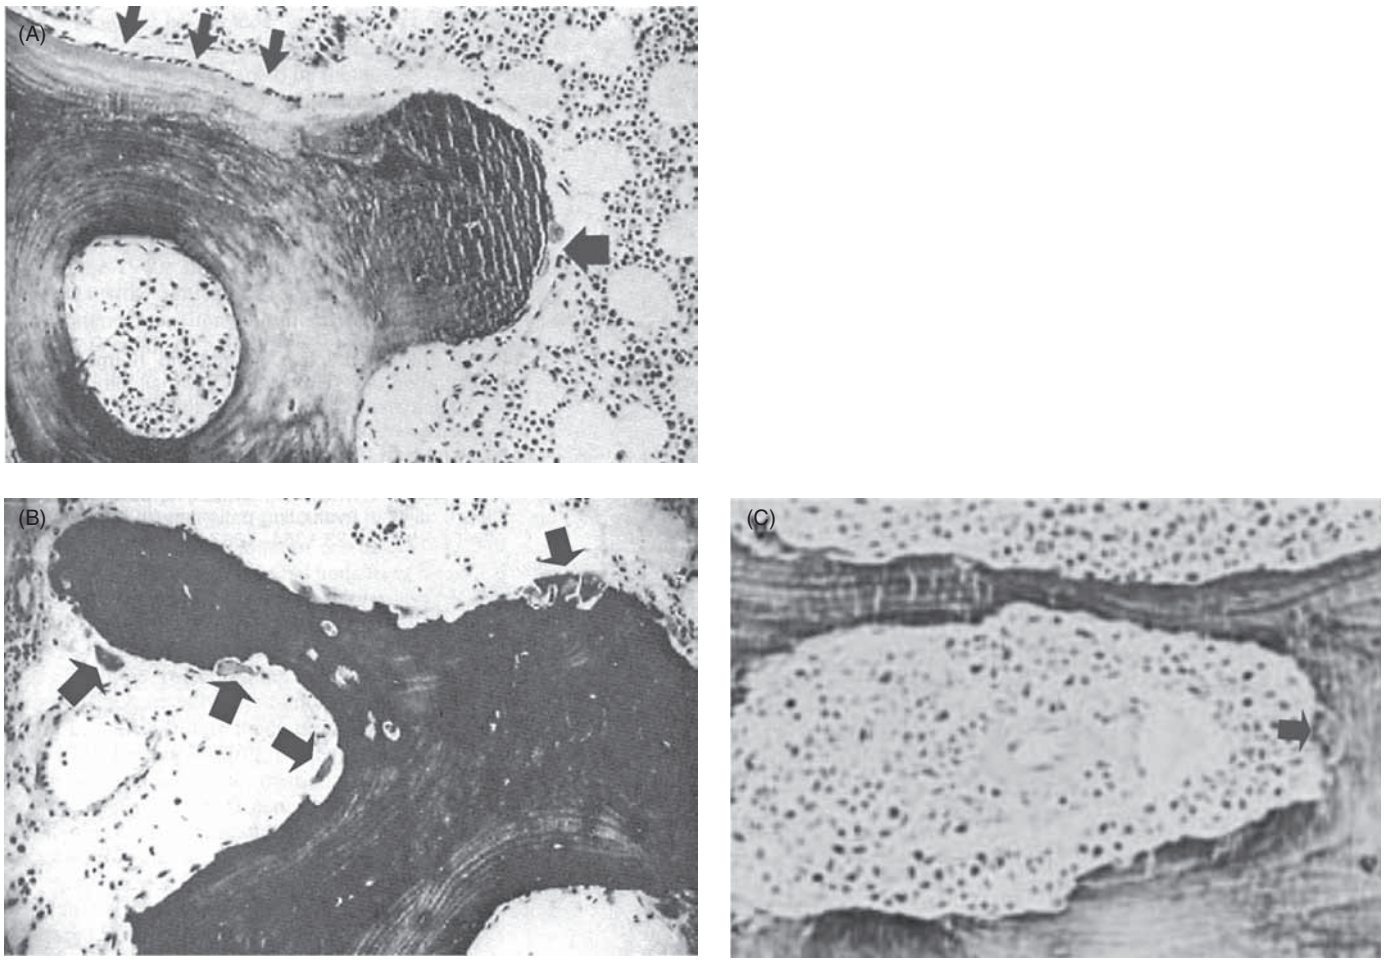

Fig. 70.1. Comparison of bone histology in a patient with hyperparathyroidism (HPT) (Panel A), humoral hypercalcemia of malignancy (HHM) (Panel B), and local osteolytic hypercalcemia due to leukemia (LOH) (Panel C). In HPT, HHM, and LOH osteoclastic activity is accelerated (large, thick arrows), although it is higher in HHM than in HPT. In HPT, osteoblastic activity (thin arrows) and osteoid are increased, but both are markedly decreased in HHM and LOH. This uncoupling of formation from resorption in HHM and LOH plays the major role in causing hypercalcemia. (From Stewart AF, Vignery A, Silvergate A, Ravin ND, LiVolsi V, Broadus AE, Baron R. 1982. Quantitative bone histomorphometry in humoral hypercalcemia of malignancy: Uncoupling of bone cell activity. *J Clin Endo Metab* 55: 219–227. Copyright 1982 The Endocrine Society. Used with permission.)

terms, HHM results from enhanced skeletal resorption coupled with an inability to clear calcium through the kidney.

HHM is also associated with a reduction in the renal phosphorus threshold, which results in phosphaturia and hypophosphatemia. The HHM syndrome is also characterized by a marked increase in cyclic adenosine monophosphate (AMP) excretion by the kidney, termed "nephrogenous cyclic AMP" or "NcAMP." The bone resorption, increased renal tubular calcium resorption, phosphaturia, and increase in NcAMP excretion that characterize HHM reflect interaction of circulating PTHrP with the common PTH/PTHrP receptor in the skeleton and the renal tubule. Surprisingly, HHM syndrome is also associated with paradoxical reductions in $1,25(OH)_2D$ and osteoblastic bone formation [Fig. 70.1(B)]. These observations stand in striking contrast to primary hyperparathyroidism (HPT), in which $1,25(OH)_2D$ is increased, and both osteoblast and osteoclast activity are increased but remain coupled [Fig. 70.1(A)]. Why PTH and PTHrP, which act through the identical receptor, should produce directionally opposite physiologic effects was unexplained until the recent demonstration by Dean et al. that PTHrP dissociates far more rapidly from the PTH1 receptor than PTH, thereby limiting its potency.

Bone scans, bone biopsies, and autopsy reveal few or no skeletal metastases in patients with HHM. This finding emphasizes the humoral nature of the syndrome and stands in contrast to patients with LOH, described below.

In an interesting turn of events, it is now also clear that systemic overproduction of PTHrP by tumors does not inevitably indicate the presence of cancer. Thus, it has been reported that in very rare instances, benign

neoplastic lesions also may lead to hypercalcemia by systemic overproduction of PTHrP, a condition that has been referred to as "humoral hypercalcemia of benignancy." For example, benign uterine fibroids, benign ovarian tumors, insulinomas, pheochromocytomas, and massive mammary hyperplasia have all been documented to secrete PTHrP and thereby cause hypercalcemia that reverses on tumor excision or reduction mammoplasty.

LOH

The tumors that most commonly produce LOH are breast cancer and hematological neoplasms (myeloma, lymphoma, leukemia) in subjects with widespread skeletal involvement. By the 1940s, series of patients with hypercalcemia associated with these malignancies were reported, all of which documented extensive marrow invasion by the tumor. In the 1960s and '70s, these malignancies were shown to be associated with marked activation of osteoclasts adjacent to the sites of marrow infiltration by the malignancy. In this era, it was widely believed that hypercalcemia in the majority of patients with MAHC resulted from LOH. However, today, large series have shown that LOH accounts for only about 20% of patients with MAHC. Indeed, evidence suggests that the frequency of MAHC due to LOH may be declining with the widespread use of bisphosphonates to prevent skeletal fractures, metastases, and pain in patients with myeloma and breast cancer.

In the 1970s, several authors began to search for the osteoclast-activating factors (OAFs) responsible for LOH. Locally produced osteoclast-activating cytokines are now known to include interleukins-1 and -6, PTHrP, and macrophage inflammatory protein-1α, among others. This area has been reviewed elsewhere in the *Primer*.

Patients with LOH are characterized at bone biopsy or autopsy by extensive skeletal metastases or marrow infiltration [Fig. 70.1(C)]. Bone scintigraphic scans are generally intensely and widely positive in patients with metastatic disease from solid tumors but may be completely negative despite extensive marrow involvement in patients with multiple myeloma, reflecting a reduction on bone formation.

In mechanistic terms, LOH can be thought of as primarily a resorptive (skeletally derived) form of hypercalcemia in which massive removal of calcium from the skeleton exceeds the normal ability of the kidney to clear calcium. As the dehydration associated with such marked hypercalcemia occurs, the hypercalcemia is exacerbated by a typical decline in renal function as well.

$1,25(OH)_2D$-induced hypercalcemia

In the 1980s, reports began to appear describing patients with lymphomas in whom hypercalcemia occurred as a result of increased production of $1,25(OH)_2D$. There have been about 60 patients described to date with this syndrome. There is no particular histopathological correlation: all types of lymphomas have been reported to cause this syndrome. In the past several years, the same syndrome has been reported in patients with ovarian dysgerminomas.

The primary pathophysiological abnormality in this syndrome is that the malignant cells or adjacent normal cells overexpress the enzyme 1-α-hydroxylase, which converts normal circulating quantities of the precursor 25(OH)D to abnormally elevated circulating concentrations of the active form of vitamin D, $1,25(OH)_2D$. This pathophysiology can be viewed as the malignant counterpart of events that occur in sarcoidosis (see section on granulomatous diseases below). Since $1,25(OH)_2D$ activates intestinal calcium absorption, this syndrome is principally an absorptive form of hypercalcemia, although decreased renal clearance of calcium may also develop as a consequence of the dehydration caused by the hypercalcemia. In addition, there is emerging evidence that $1,25(OH)_2D$ may increase osteoclast mediated bone resorption by directly activating the receptor activator of nuclear factor-κB ligand (RANK-L) pathway, and therefore worsening hypercalcemia. It is of note that circulating levels of $1,25(OH)_2D$ may not always reflect the high local concentrations seen in patients with marrow tumor involvement.

Authentic ectopic hyperparathyroidism

From the 1950s through the 1980s, when HHM syndrome was finally shown to be caused by PTHrP, the hypercalcemia of HHM was widely ascribed to "ectopic secretion of PTH" by offending neoplasms. With the demonstration in the 1980s that the responsible factor in HHM was PTHrP, not PTH, authentic ectopic secretion of PTH by cancers was believed not to occur. This changed in the 1990s with the description of rare cases in which production of authentic PTH, and not PTHrP, by tumors was shown to cause MAHC. At the time of this writing, approximately 10 cases have been reported in which convincing evidence exists for hypercalcemia resulting from authentic ectopic secretion of PTH from malignant tumors. Thus, authentic ectopic secretion of PTH does exist, but it is very rare.

Other mechanisms for MAHC

The four categories described above account for more than 99% of patients with MAHC. Occasionally, however, patients who do not fit any of these categories have been described. For example, there are rare case reports in which none of the above scenarios could be invoked, and in which elevated circulating concentrations of prostaglandin E2 may have been responsible. This is thought to result from the ability of PGE2 to induce RANK-L expression via the EP4 receptor that in turn activates osteoclastic activity.

Granulomatous diseases

Almost every single disease associated with granuloma formation has been reported to cause hypercalcemia. The

most common is sarcoidosis, but tuberculosis (both from *M. bovis* and *M. avium*), berylliosis, histoplasmosis, coccidoimycosis, *Pneumocystis*, inflammatory bowel disease, histocytosis X, foreign body granulomas, and granulomatous leprosy have all been associated with the syndrome. In the case of sarcoidosis, approximately 10% of patients become hypercalcemic, and 20% hypercalciuric, during the course of their disease.

The mechanism in sarcoidosis and tuberculosis is inappropriate production of $1,25(OH)_2D$ by the granulomas, as a result of increased activity of 1-α-hydroxylase, the enzyme that converts 25(OH)D to its active form, $1,25(OH)_2D$. The reasons for this are unknown, but this results in elevated circulating concentrations of $1,25(OH)_2D$, which in turn lead to intestinal hyperabsorption of calcium, hypercalciuria, and ultimately hypercalcemia.

The syndrome reverses with the eradication of granulomas, (e.g., by glucocorticoids or antituberculosis medications), and by oral or intravenous hydration coupled with lowering dietary intake of vitamin D and calcium. Since sunlight is a source of vitamin D, sunlight exposure should be reduced.

Other endocrine disorders

Hyperparathyroidism is the classical endocrine disorder associated with hypercalcemia, but there are four other endocrine disorders that may cause hypercalcemia as well.

Hyperthyroidism

Hyperthyroidism has been reported to cause increases in ionized or total serum calcium in up to 50% of affected patients. In general, the hypercalcemia is mild (in the 10.7–11.0 mg/dl range), but it has been reported to be as high as 13 mg/dl in rare cases. It is believed to result from increases in osteoclastic bone resorption due to thyroid hormone induced increases in RANK-L, a key regulator of osteoclast function.

Addisonian crisis

Addisonian crisis has also been reported to cause hypercalcemia with increases in both ionized as well as total calcium. In general, hypercalcemia is mild and responds to standard therapy for hypoadrenalism (fluid resuscitation and intravenous glucocorticoids). The cause is not known, but, at least in some cases, it may be due to the underlying disorder, such as tuberculosis, that led to the hypoadrenalism. In others, it is possible that the associated volume contraction may have led to factitious increases in total serum calcium through relative hyperalbuminemia. In such cases, though the measured concentration of total serum calcium is elevated, ionized serum calcium remains normal. However, at least in some cases, ionized serum calcium has been reported to have been elevated.

Pheochromocytoma

Pheochromocytoma has been associated with hypercalcemia. In some cases, the hypercalcemia is due to primary hyperparathyroidism in the setting of multiple endocrine neoplasia type 2, and hypercalcemia corrects with parathyroid surgery. In some patients, however, hypercalcemia reverses with removal of the pheochromocytoma, and some of these tumors have been shown to secrete PTHrP. In other cases, it has been suggested that catecholamine secretion by the pheochromocytoma is sufficient to activate bone resorption.

VIPoma syndrome

VIPoma syndrome is caused by vasoactive intestinal polypeptide (VIP) secretion by the pancreatic islet or other neuroendocrine tumors, and is associated with severe watery diarrhea ("pancreatic cholera"), hypokalemia, and achlorhydria (the WDHA syndrome). Interestingly, 90% of patients with this rare syndrome have been reported to be hypercalcemic, although the mechanism is unknown. VIP has been demonstrated to stimulate osteoclastic bone resorption *in vitro*, suggesting at least one potential mechanism.

Immobilization

Immobilization in association with another cause of high bone turnover (such as the high turnover associated with youth, hyperparathyroidism, myeloma or breast cancer with bone metastases, and Paget's disease) may cause hypercalcemia. The classic examples are the hypercalcemia that was prevalent in the polio epidemics and that still regularly accompanies paraplegia and quadriplegia. The age dependence of this phenomenon is evident from the observation that hypercalcemia never occurs in elderly subjects with strokes that result in complete immobilization, yet regularly occurs in children and young adults with similar degrees of immobilization from spinal cord injury, or other causes of complete immobilization.

Immobilization suppresses osteoblastic bone formation and markedly increases osteoclastic bone resorption, leading to complete uncoupling of these two normally tightly coupled processes. The result is massive loss of calcium from the skeleton, with resultant hypercalcemia and reductions in bone mineral density (BMD). It has been suggested that this process is mediated by sclerostin, which is elevated in patients who are immobilized and appears to inhibit bone formation. The process is most effectively reversed by restoration of normal weight bearing. Alternate options are bisphosphonates and measures to increase renal calcium clearance (hydration and loop diuretics).

Milk-alkali syndrome

Originally reported in 1949, this syndrome initially described patients who developed moderate or severe

hypercalcemia when treated with large amounts of milk (several quarts or gallons per day) and absorbable antacids (e.g., baking soda or sodium bicarbonate) for peptide ulcer disease. Additional features of the syndrome were a metabolic alkalosis due to antacid ingestion and renal failure due to hypercalcemia.

Contemporary reports occur primarily in patients taking large amounts of calcium carbonate for peptic ulcer or esophageal reflux symptoms. Since calcium is absorbed with only moderate efficiency, normal dietary intake (800–2,000 mg/day) does not cause hypercalcemia. In contrast, daily doses in excess of 4,000 mg/day can induce hypercalciuria and hypercalcemia in normal adults. Indeed, in many case reports, the daily intake has been in the range of 10–20 gm of elemental calcium per day. Since one standard antacid tablet contains approximately 120–200 mg of elemental calcium, and each packet or roll contains some 10 tablets, it is clear that subjects must consume multiple packages of antacids per day for this syndrome to develop. The hypercalcemia reverses with hydration and correction of excessive calcium ingestion. Renal damage, however, may be permanent.

Total parenteral nutrition

Patients with short bowel syndrome or otherwise unable to eat normally by mouth who receive chronic total parenteral nutrition (TPN) have been reported to develop hypercalcemia. In some cases, it was a result of the inclusion of excessive amounts of calcium or vitamin D supplements in early TPN solutions. In other early cases, it appears to have been associated with the use of collagen lysates contaminated with aluminum. Case reports have been rare in recent years, but the etiology of recent cases is uncertain.

Abnormal protein binding

Hypercalcemia may be "artifactual" or "factitious" in some settings. In general, this refers to situations in which the total serum calcium is elevated, but the ionized serum calcium is normal. In one example, severe dehydration may lead to increases in serum albumin concentration and in the albumin-bound component of total serum calcium. This results in an increase in total, but not ionized, serum calcium. This can be suspected in the setting of volume contraction with hyperalbuminemia and confirmed by measurement of ionized serum calcium.

An analogous situation has been reported in subjects with multiple myeloma or Waldenstrom's macroglobulinemia whose monoclonal immunoglobulin specifically recognizes calcium ion. In these cases, patients have displayed severe increases in total serum calcium, in the absence of neurologic or EKG abnormalities, and in the absence of symptoms or signs of hypercalcemia. In these cases, the ionized serum calcium was found to be normal, as was the urinary calcium excretion, and the patients' immunoglobulins were shown to have an abnormal affinity for serum calcium. Treatment with agents to lower serum calcium such as mithramycin precipitated hypocalcemic seizures, despite a total serum calcium that remained in or above the normal range.

Medications

A number of medications may cause hypercalcemia. Calcium containing antacids are included above in the section on milk-alkali syndrome.

Vitamin D intoxication from standard vitamin D preparations has been reported in association with inappropriate addition by dairies or manufacturers of vitamin D to milk or to infant formula. Vitamin D intoxication may also occur with use of doses of vitamin D in excess of 50,000 units two or three times per week as a treatment for hypoparathyroidism or metabolic bone diseases such as osteoporosis. Vitamin D analogs such as calcitriol [$1,25(OH)_2D$] used in the treatment of hypoparathyroidism, chronic renal failure, and metabolic bone disease may also cause hypercalcemia. The mechanism in all of the above is a combination of increased intestinal calcium absorption and bone resorption induced by vitamin D, together with reductions in renal ability to clear calcium as a result of dehydration.

Vitamin A intoxication can cause hypercalcemia. This may occur through the excessive use of vitamin supplements, or, in Antarctic explorers, as a result of eating sled dog livers. More recently, the use of retinoic acid derivatives for the treatment of dermatologic disorders or as chemotherapy agents has also been associated with induction of hypercalcemia.

Thiazide diuretics such as hydrochlorthiazide or chlorthalidone commonly cause mild hypercalcemia. This has been ascribed to their ability to induce distal renal tubular calcium reabsorption, although it has been reported to occur in anephric subjects on dialysis, suggesting additional mechanisms.

Lithium has been reported to cause hypercalcemia in as many as 5% of patients. It has been suggested that lithium may actually induce parathyroid hyperplasia or induce parathyroid adenomas, but it is also possible that the coincidence of lithium use with hyperparathyroidism may represent the simultaneous occurrence of two common clinical syndromes. There are also well-documented patients treated with lithium whose hypercalcemia reversed with cessation of lithium therapy, and in whom hypercalcemia therefore was clearly lithium induced. Proposed mechanisms include lithium-induced activation of PTH secretion and lithium-induced stimulation of renal calcium reabsorption, both of which have been documented *in vitro* or in animals. Whether these are responsible for the hypercalcemia that occurs in humans is not certain.

Parathyroid hormone, both the PTH(1-34) and PTH(1-84) forms used for treatment of osteoporosis, are associated with hypercalcemia in a substantial minority of patients so treated. In general, it is mild and requires little or no treatment, or a reduction in the dose of PTH or supplemental calcium, but it can be severe and require discontinuation of PTH therapy.

Other medications that are known to cause hypercalcemia with no known mechanism include: estrogens and the selective estrogen receptor modifier (SERM) tamoxifen in women with breast cancer and extensive skeletal metastatic disease; aminophylline and theophylline when used in large, supratherapeutic doses in subjects with bronchospastic disease; Foscarnet, an antiviral agent used in HIV/AIDS; growth hormone treatment in subjects with severe burns and also in subjects with HIV/AIDS; and 8-chloro-cyclic AMP employed as an anticancer agent.

Acute and chronic renal failure

The recovery phase from acute renal failure caused by rhabdomyolysis has been associated with hypercalcemia. Typically, this follows an episode of severe hyperphosphatemia and hypocalcemia in the acute, oliguric phase, accompanied by severe secondary hyperparathyroidism. It has been ascribed to residual effects of PTH on bone turnover, as well as release of calcium phosphate precipitated into soft tissues such as skeletal muscle during the early hypocalcemic, hyperphosphatemic phase.

Chronic renal failure and dialysis are associated with hypercalcemia. Frequently, it is associated with the use of calcitriol or other vitamin D analogs used to prevent secondary hyperparathyroidism, or with the use of oral calcium binding agents and supplements. Hypercalcemia in this population may also result from tertiary hyperparathyroidism, as discussed elsewhere in the *Primer*. Hypercalcemia has also been observed after kidney transplant, particularly in cases of moderate to severe secondary hyperparathyroidism.

Hypophosphatemia

Severe dietary phosphate deprivation in rats causes hypophosphatemia associated with hypercalcemia. This has not been documented in humans but merits attention when considering the management of patients with hypercalcemia, since moderate to severe hypophosphatemia so commonly accompanies hyperparathyroidism, cancer hypercalcemia, and other disorders that cause hypercalcemia. It is the authors' anecdotal experience that hypercalcemia may be refractory to treatment in the presence of severe hypophosphatemia, but responds nicely to appropriate measures once the hypophosphatemia has been corrected.

Miscellaneous

Several other diseases and syndromes associated with hypercalcemia include: end-stage liver disease in patients awaiting liver transplantation; manganese intoxication in people exposed to well water contaminated with manganese derived from improperly disposed batteries; fibrin glue when used to treat refractory recurrent pneumothorax in children; idiopathic infantile hypercalcemia due to decreased 24-hydroxylase activity by a CYP24A1 mutation and other pediatric syndromes, which are covered in more detail elsewhere in the *Primer*.

APPROACH TO DIAGNOSIS

Although space precludes a detailed description of the specific approach to the differential diagnosis of each of the causes of hypercalcemia in Table 70.1, it is helpful to consider several broad guidelines. First, the causes of hypercalcemia can be divided into two broad categories: those associated with elevated PTH values (for example, primary and tertiary hyperparathyroidism, ectopic hyperparathyroidism, familial hypocalciuric hypercalcemia (FHH), and occasionally lithium treatment) and those in which PTH is low normal or frankly suppressed. This algorithm requires that the PTH samples be collected properly and performed in a state-of-the-art two site PTH-immunoassay as described elsewhere in the *Primer*.

Second, common diseases are common. Thus, the most common cause of hypercalcemia among outpatients is primary hyperparathyroidism, and the most common cause among inpatients is cancer. Thus, it is reasonable to begin a diagnostic strategy with these two disorders in mind.

Third, most patients with MAHC have large, bulky tumors that are obvious on initial screening exams and CT scans; thus, if no tumor is apparent after a careful physical exam and appropriate imaging procedures, attention should be focused on the less common items in Table 70.1. Exceptions to this guideline include small neuroendocrine tumors such as pheochromocytomas, bronchial carcinoids, and pancreatic islet tumors that may be small and difficult to find.

Fourth, although it is tempting to initially select what seems an obvious diagnosis and manage the patient with this diagnosis in mind, many of the less common items in Table 70.1 are overlooked unless specifically considered. Because so many of these are easily treatable, it is critical to consider every diagnosis in Table 70.1 in every patient. For example, a patient with breast cancer can also have primary hyperparathyroidism, which is easily treated and may change the overall prognostic perception. Similarly, patients with lung cancer may also have tuberculosis, and hypercalcemia in this setting may reverse with appropriate antitubercular treatment, again, altering the overall prognostic perception. Another

common example is milk-alkali syndrome that occurs in a patient whose hypercalcemia has inappropriately been attributed to a coexisting cancer.

Fifth, carefully documenting the duration of hypercalcemia is helpful. Most hypercalcemia syndromes are unstable, and rapidly become more severe if left untreated (MAHC, immobilization, and vitamin D intoxication are examples), whereas long-term (longer than 6 months) stable hypercalcemia has a relatively short differential diagnosis that includes largely primary and tertiary hyperparathyroidism, FHH, thiazide, and lithium use, and occasional cases of sarcoid.

And sixth, it is useful to consider the principal underlying pathophysiologic mechanism responsible for hypercalcemia before completely committing to a diagnosis or therapeutic plan. Is the hypercalcemia mainly postprandial (i.e., GI in origin) as might occur in sarcoid or vitamin D intoxication? Or is it equally apparent in fasting conditions, which may suggest inability of the kidney to clear calcium (as in FHH or thiazide use) or excessive bone resorption (as in MAHC)? And between these two, is the urinary calcium/creatinine ratio very high [suggesting GI causes (such as sarcoid, milk-alkali syndrome, or vitamin D intoxication) or bone resorption (from cancer, immobilization, etc.)], or is it normal? Is the patient taking oral calcium supplements or antacids? These considerations help to narrow the diagnostic possibilities and suggest specific laboratory tests, such as PTH, PTHrP measurements, vitamin D metabolites, thyroid indices, serum angiotensin converting enzyme (ACE), serum/urine protein electrophoresis, lithium levels, bone marrow biopsy, liver biopsy, etc.

Considering these tenets while considering each of the items in Table 70.1 will facilitate and accelerate accurate diagnosis.

MANAGEMENT

Management of hypercalcemia optimally targets the underlying pathophysiology. For example, removal of a parathyroid adenoma, discontinuing or reducing the dose of an offending medication such as vitamin D or PTH, or eradication of a tumor responsible for hypercalcemia with chemotherapy or surgery would be optimal management strategies. Of course, sometimes these are not possible, or therapy must begin before a definitive diagnosis is made. In these cases, targeting the underlying pathophysiology is most appropriate. Thus, in patients whose hypercalcemia is primarily based on accelerated bone resorption (e.g., LOH, HHM, immobilization), therapy should include agents that block bone resorption, such as intravenous bisphosphonates, zoledronate, or pamidronate. In patients whose hypercalcemia is principally GI in origin [e.g., sarcoidosis, milk-alkali syndrome, vitamin D intoxication, 1,25(OH)2D-secreting lymphomas], reducing or eliminating oral calcium and vitamin D intake and sunlight exposure may be most appropriate. For those with important renal contributions to hypercalcemia (e.g., dehydration), increasing renal calcium clearance by increasing the glomerular filtration rate (GFR) using saline infusions, and blocking renal calcium absorption using loop diuretics such as furosemide are appropriate. Of course, many patients have contributions from several sources (e.g., dehydration plus increased bone resorption in LOH, or increased GI calcium absorption plus dehydration in patients with sarcoidosis, or a combination of PTHrP-induced bone resorption plus PTHrP-induced renal calcium retention in HHM), and optimal therapy targets each of these components.

For hyperparathyroidism and its variants, specific therapy is discussed elsewhere in the *Primer*. For patients with cancer, the most effective long-term therapy is tumor eradication. If that is not possible, or while waiting for a response to chemotherapy, aggressive hydration with saline, keeping a careful watch for signs of congestive heart failure, accompanied by a loop diuretic such as furosemide are appropriate. Limiting oral calcium intake (e.g., milkshakes, ice cream) is not important in HHM and LOH, since intestinal calcium absorption is already low as a result of the low $1,25(OH)_2D$ concentrations in these patients, and because cachexia is a common feature of these patients. On the other hand, in patients with $1,25(OH)_2D$-induced hypercalcemia from lymphoma or dysgerminoma, reducing oral calcium and vitamin D intake is important. While some physicians wait to see the magnitude of the decline in serum calcium induced by hydration and diuresis, the authors' practice, when the serum calcium exceeds 12.0 mg/dl, is to institute antiresorptive therapy with an intravenous bisphosphonate such as zoledronate or pamidronate soon after the discovery of hypercalcemia. Specific doses and regimens have been reviewed in detail recently.

For the granulomatous diseases, correcting the underlying cause is critical, where possible (e.g., tuberculosis). In sarcoid, limiting calcium and vitamin D intake and sun exposure are important, together with oral or parenteral hydration. Glucocorticoid therapy may be necessary to treat the granulomas, to lower intestinal calcium absorption, and to lower $1,25(OH)_2D$ concentrations.

For immobilization-induced hypercalcemia, weight-bearing ambulation is the mainstay of therapy. Often, however, this is not possible because of spinal cord injury or pain. Here, aggressive hydration and intravenous bisphosphonates are effective and important.

For the remainder of the diagnoses in Table 70.1, correcting the underlying disorder or withdrawing or reducing the dose of the offending medication corrects the serum calcium.

INTRODUCTION

Hypocalcemia, defined as an ionized calcium (Ca^{2+}) concentration that falls below the lower limit of the normal range, is a commonly encountered clinical problem with multiple causes. A normal level of ionized Ca^{2+} (usually 1.00 to 1.25 mM) is critical for many vital cellular functions including hormonal secretion, skeletal and cardiac muscle contraction, cardiac conduction, blood clotting, and neurotransmission. Approximately 50% of the total serum Ca^{2+} is in the ionized fraction, with the remainder being protein-bound (45–50%, predominantly to albumin), or complexed to circulating anions such as phosphate. Total serum Ca^{2+} is usually the only value a clinician has when making an initial determination of the state of serum Ca^{2+} homeostasis in a patient, because ionized Ca^{2+} determinations are not routine measurements in most clinical settings. Therefore, the clinician must make the first assessment based on total serum Ca^{2+} levels.

The total serum Ca^{2+} concentration is a reliable indicator of the serum ionized Ca^{2+} concentration under most, but not all, circumstances. One important common situation where total serum Ca^{2+} poorly reflects the ionized Ca^{2+} concentration is when hypoalbuminemia is present. When serum albumin is depressed, total serum Ca^{2+} often falls to subnormal levels. This can be mistaken for hypocalcemia. Many recommend that a bedside estimation of the corrected serum total Ca^{2+} be done in the hypoalbuminemic patient to determine whether there is real concern for hypocalcemia. This estimation is often done using the following formula: adjusted total Ca^{2+} = measured total Ca^{2+} + [0.8 × (4.0-measured serum albumin)]. It is far better, however, when there is any question, to establish that the ionized Ca^{2+} is truly low by making a direct measurement. Estimates of the ionized Ca^{2+} are poor surrogates for actual measurements because, in addition to albumin, disturbances in pH and other circulating substances (e.g., citrate, phosphate, paraproteins) can influence the serum total Ca^{2+}, and these confounding factors are not considered in this estimation. It is imperative that the clinician establishes that the ionized Ca^{2+} concentration is indeed reduced, before an exhaustive search for an etiology of hypocalcemia is undertaken. Full evaluation may be costly and is unjustified if there is only weak evidence that the serum ionized Ca^{2+} level is subnormal.

ETIOLOGY AND PATHOGENESIS

There are numerous etiologies of low ionized Ca^{2+}. The disorders can be classified broadly as ones in which there is inadequate parathyroid hormone (PTH) or vitamin D production, PTH or vitamin D resistance, or a miscellaneous cause (Table 71.1). The last category encompasses a large and diverse spectrum of conditions that the endocrine clinician encounters in the course of practice.

Table 71.1. Etiologies for Hypocalcemia

Inadequate PTH production
- PTH gene mutations
  - Autosomal recessive (168450.0002)
  - Autosomal dominant (168450.0001)
- X-linked hypoparathyroidism
- Parathyroid gland agenesis
  - GCMB mutations (603716)
- Postsurgical
- Autoimmune
  - Isolated
  - Polyglandular failure syndrome type 1 (240300_and 607358)
  - Acquired antibodies that activate the CaSR
- Postradiation therapy
- Secondary to infiltrative processes
  - Iron overload: hemochromatosis, thalassemia after transfusions
  - Wilson's disease
  - Metastatic tumor
- Constitutively active CaSR mutations (145980)
- Magnesium excess
- Magnesium deficiency

Syndromes with component of hypoparathyroidism
- DiGeorge syndrome (188400)
- HDR (hypoparathyroidism, deafness, renal anomalies) syndrome (146255 and 256340)
- Blomstrand lethal chondrodysplasia (215045)
- Kenney-Caffey syndrome (244460)
- Sanjad-Sakati syndrome (241410)
- Kearns-Sayre syndrome (530000)

Inadequate vitamin D production
- Vitamin D deficiency
  - Nutritional deficiency
  - Lack of sunlight exposure
  - Malabsorption
  - Post-gastric bypass surgery
  - End-stage liver disease and cirrhosis
  - Chronic kidney disease

PTH resistance
- Pseudohypoparathyroidism
- Magnesium depletion

Vitamin D resistance
- Pseudovitamin D deficiency rickets (vitamin D-dependent rickets type 1)
- Vitamin D-resistant rickets (vitamin D-dependent rickets type 2)

Miscellaneous
- Substances interfering with the laboratory assay for total Ca^{2+}—certain gadolinium salts in contrast agents given during MRI/MRA, particularly in patients with chronic renal failure
- Hyperphosphatemia
  - Phosphate retention caused by acute or chronic renal failure
  - Excess phosphate absorption caused by enemas, oral supplements
  - Massive phosphate release caused by tumor lysis or crush injury
- Drugs
  - Intravenous bisphosphonate therapy—especially in patients with vitamin D insufficiency or deficiency
  - Foscarnet
  - Imatinib mesylate—lowers both calcium and phosphate
- Rapid transfusion of large volumes of citrate-containing blood
- Acute critical illness—multiple contributing etiologies
- "Hungry bone syndrome" or recalcification tetany
  - Post-thyroidectomy for Grave's disease
  - Post-parathyroidectomy
- Osteoblastic metastases
- Acute pancreatitis
- Rhadomyolysis

It is incumbent on the clinician to be aware of the etiologies, the pathogenic mechanisms, the intricacies of diagnostic testing including sequencing for mutations and other genetic analysis, and the best approaches to therapies in patients with hypocalcemia.

Hypoparathyroidism is a rare diagnosis. It is most commonly the sequela of parathyroid or thyroid surgery during which most or all functioning parathyroid tissues are damaged, devitalized, and/or inadvertently removed. Perhaps next in frequency is the mild hypocalcemia and hypoparathyroidism caused by constitutively activating mutations of the Ca^{2+}-sensing receptor (CaSR). These mutations lead to the inappropriate suppression of PTH secretion at subnormal serum Ca^{2+} levels. The disorder presents as autosomal dominant hypocalcemia (ADH) in families and may go unrecognized because the hypocalcemia is often mild. The biochemical hallmark of ADH is often impressive hypercalciuria, which worsens with attempts to treat the hypocalcemia with Ca^{2+} salts and vitamin D metabolites. Exacerbation of hypercalciuria with nephrocalcinosis and renal failure can result from these efforts. Such renal complications occur because the constitutively active CaSRs in the kidney misperceive prevailing serum Ca^{2+} concentrations as higher than they are, and this enhances renal excretion of Ca^{2+}. It has recently been appreciated that patients can develop antibodies that activate parathyroid and renal CaSRs. This produces an acquired form of hypocalcemia with low PTH and elevated urinary Ca^{2+} levels, thus mimicking the genetic disorder. These rare individuals often have other autoimmune disorders. Destruction of the parathyroid glands on an immune basis can occur in isolation or as part of the type 1 autoimmune polyglandular syndrome (APS1). This is an autosomal recessive disorder caused by mutations in the autoimmune regulator (AIRE-I) gene. APSl includes mucocutaneous candidiasis and adrenal insufficiency most commonly, as well as other autoimmune manifestations, and typically presents in childhood and adolescence. The parathyroid autoantigen in approximately 50% of patients with APSl appears to be the NACHT leucine rich-repeat protein 5 (NALP5), a putative signaling molecule, whose role as yet in parathyroid physiology is unknown. Patients with APSl and with isolated autoimmune hypoparathyroidism also often generate antibodies against the CaSR, although it is unclear what the role, if any, the CaSR plays in the pathogenesis of the tissue destruction.

As noted above, there are multiple modes of inheritance of hypoparathyroidism, depending on the molecule involved. Autosomal recessive mutations in the gene encoding the transcription factor glial cell missing B (GCMB) are a rare cause of hypoparathyroidism. GCMB is essential for the development of the parathyroid glands. Mutations in a gene near SOX3 on the X chromosome underlie the pathogenesis of X-linked hypoparathyroidism. Another syndrome, HDR (hypoparathyroidism, deafness, renal anomalies), is caused by mutations in the transcription factor GATA3. Variable penetrance of the renal anomalies and hearing deficits has been observed. The well-known DiGeorge syndrome, a result of multiple developmental anomalies of the third and fourth branchial pouches, includes a spectrum of hypoparathyroidism, thymic aplasia and immunodeficiency, cardiac defects, cleft palate, and abnormal facies. A variety of other very rare genetic syndromes is worth considering when a patient presents with a constellation of features that includes hypoparathyroidism (e.g., Kenney-Caffey, Kearns-Sayre, Sanjad-Sakati, and other syndromes; Table 71.1). The different forms of PTH resistance, or pseudohypoparathyroidism, are described elsewhere in the *Primer*.

In contrast to the rarity of hypoparathyroidism, vitamin D deficiency and disordered vitamin D metabolism are more common causes of hypocalcemia. Resistance to vitamin D, like resistance to PTH, remains very rare. Whereas vitamin D deficiency and insufficiency occur in multiple clinical settings (elderly patients, postmenopausal women with fractures, nursing home residents, and so forth), it is much less common to see frankly low ionized Ca^{2+} values in such patients, particularly when 25-hydroxyvitamin D [25(OH)D] levels are just mildly depressed. Generally, low ionized Ca^{2+} values result from longstanding severe vitamin D deficiency, and chronically low 25(OH)D levels and are accompanied by a significant degree of secondary hyperparathyroidism. Nevertheless, it is essential in the evaluation of patients with low ionized Ca^{2+} values that one carefully considers vitamin D inadequacy, disorders of vitamin D activation by the kidney, and reduced vitamin D-mediated signaling as possible contributors to the etiology of the hypocalcemia.

Disorders of magnesium (Mg^{2+}) homeostasis bear mentioning because both Mg^{2+} excess and deficiency can produce hypocalcemia that is generally mild and caused by functional (and reversible) hypoparathyroidism. Hypomagnesemia, often of a transient and correctable nature, accompanies a vast number of clinical situations particularly in ill and hospitalized patients (e.g., malnutrition, pancreatitis, chronic alcohol abuse, diarrhea, diuretic and antibiotic therapy, and chemotherapeutic agents such as cisplatin derivatives). Low serum Mg^{2+} levels seen in conjunction with these clinical entities require evaluation and often at least short-term therapy. Primary renal Mg^{2+} wasting states such as Gitelman's syndrome, caused by mutations in the renal thiazide-sensitive NaCl cotransporter, are more persistent and require long-term Mg^{2+} and other electrolyte replacement therapy to correct the biochemical parameters and clinical symptoms. Other rare entities that involve primary renal Mg^{2+} wasting include autosomal recessive disorders caused by mutations in the paracellin-1 gene or in the Na-K ATPase subunit (FXYDZ gene). Hypomagnesemia also interferes with PTH action at its target organs, bone and kidney, particularly the PTH receptor-mediated activation of adenylate cyclase through the stimulatory G protein alpha subunit (Gsα). Mg^{2+} is a cofactor for the adenylate cyclase enzyme complex. Hence, chronic hypomagnesemia produces a functional state of PTH resistance. More

importantly, the normal physiologic response to hypocalcemia is lacking in the patient with Mg^{2+} depletion. Intact PTH levels are inappropriately low or normal in the presence of hypomagnesemia. Once the Mg^{2+} depletion is corrected, parathyroid function returns to normal. Hypermagnesemia, in contrast, activates parathyroid CaSRs, thereby suppressing PTH secretion directly. Mg^{2+} levels high enough to stimulate the CaSR tend to occur only in patients with chronic kidney disease or in the rare instance when Mg^{2+} is used for tocolytic therapy for preterm labor.

The experienced clinician will recognize that hypocalcemia occurs in the heterogeneous conditions listed in the category "Miscellaneous" (Table 71.1). In terms of frequency, pancreatitis is the most common disorder and is often associated with a low serum Ca^{2+}. This has been ascribed to the precipitation of Ca^{2+}-containing salts in the inflamed pancreatic tissue and the presence of excess free fatty acids in the circulation. In many patients, pancreatitis may progress rapidly with hemorrhage, hypotension, and sepsis as complicating features. Thus, hypocalcemia in patients with pancreatitis often correlates with illness severity.

Acute and chronic hyperphosphatemia can cause low total serum Ca^{2+}. The most common cause for chronic hyperphosphatemia is chronic kidney disease (CKD). Hypocalcemia in CKD has many contributing factors, including poor nutrition, low 1,25-dihydroxyvitamin D production, and malabsorption. Acute changes in phosphate balance can also lower serum Ca^{2+}. In any situation where large amounts of phosphate are rapidly absorbed into the intravascular compartment, there is the potential for the serum ionized Ca^{2+} to fall, even to symptomatic levels. This can be seen with phosphate-containing enemas and supplements, especially when the latter are given intravenously for the treatment of hypophosphatemia. Also, in the setting of acute tumor lysis caused by cytolytic therapy for high-grade lymphomas, sarcomas, leukemias, and solid tumors, cell breakdown with the rapid release of phosphate from intracellular nucleotides can quickly depress serum ionized Ca^{2+}.

Treating patients who are normocalcemic with intravenous aminobisphosphonates (e.g., zoledronic acid, pamidronate), which block bone resorption dramatically, has the potential to cause a low ionized Ca^{2+}. However, this is relatively infrequent unless concomitant vitamin D deficiency/insufficiency has gone unaddressed. The drug foscarnet, used to treat immunocompromised patients with refractory cytomegalovirus or herpes infections, can lower both serum Ca^{2+} and Mg^{2+} to symptomatic levels. Recent reports indicate that the tyrosine kinase inhibitor imatinib mesylate, used to treat chronic myeloid leukemia and gastrointestinal stromal tumors, can cause both hypocalcemia and hypophosphatemia, likely due to its direct skeletal effects.

The "hungry bone syndrome," or recalcification tetany, can occur after parathyroidectomy for any form of hyperparathyroidism or after thyroidectomy for hyperthyroidism. Skeletal uptake of Ca^{2+} and phosphate is intense because of the presence of a mineral-depleted bone matrix and the sudden removal by surgery of the stimulus for maintaining high rates of bone resorption (either PTH or the thyroid hormones). Depending on the severity of the bone hunger, hypocalcemia and hypophosphatemia can persist for weeks and require large doses of Ca^{2+} and vitamin D metabolites to control. If there has been no permanent damage to the parathyroid glands, intact PTH levels should eventually rise appropriately to supranormal levels. In some cases, however, the viability of the remaining parathyroid glands or the suppression of function of the remaining glands by a previously dominant adenoma may confuse the picture. Careful management and repeated mineral and PTH analyses will usually allow the diagnosis to become clear over time.

The entity of pseudohypocalcemia caused by gadolinium (Gd^{3+})-containing magnetic resonance imaging (MRI) agents has received considerable attention lately because of the frequency of performing MR angiography in general and the use of the procedure in patients with CKD. The clearance of Gd^{3+} in such patients is very prolonged. Total serum Ca^{2+} levels, as measured by standard arsenazo III reagents, will appear to be low in patients with Gd^{3+}–containing contrast agents in the circulation. This is because Gd^{3+} complexes with this Ca^{2+}-sensitive dye and blocks the colorimetric detection of Ca^{2+}. Because ionized Ca^{2+} is measured in a completely different manner, ionized Ca^{2+} levels will be normal in these individuals, and there are no symptoms of hypocalcemia.

Acute and critical illness, often in the intensive care unit setting, is frequently accompanied by hypocalcemia, including frankly low ionized Ca^{2+} values. This entity is typically multifactorial with poor nutrition, vitamin D insufficiency, renal dysfunction, acid–base disturbances, cytokines, and other factors contributing. It is prudent to follow the ionized Ca^{2+} values and treat as deemed appropriate based on clinical circumstances.

SIGNS AND SYMPTOMS

Patients with low ionized Ca^{2+} values can present with no symptoms or with significant morbidity (Table 71.2). Their presentation depends on the severity and chronicity of the disturbance. Chronic hypocalcemia, despite even very low levels of ionized Ca^{2+}, can be asymptomatic, and the only clue is the presence of the positive Chvostek's sign. Neuromuscular irritability is the most frequent cause of symptoms that include tetany, carpopedal spasms, muscle twitching and cramping, circumoral tingling, abdominal cramps, and in severe cases laryngospasm, bronchospasm, seizures, and even coma. Basal ganglia and other intracerebral calcifications can be seen on imaging studies. Ocular findings include cataracts, particularly when there are longstanding elevations in the Ca^{2+}-phosphate product, and pseudotumor cerebri may be present. Longstanding hypocalcemia can also cause cardiomyopathy and congestive heart failure,

Table 71.2. Signs and Symptoms of Hypocalcemia

Symptoms
- Paresthesias
  - Circumoral and acral tingling
- Increased neuromuscular irritability
  - Tetany
  - Muscle cramping and twitching
  - Muscle weakness
  - Abdominal cramping
- Laryngospasm
- Bronchospasm
- Altered central nervous system function
  - Seizures of all types: grand mal, petit mal, focal
  - Altered mental status and sensorium
  - Papilledema, pseudotumor cerebri
  - Choreoathetoid movements
  - Depression
  - Coma
- Generalized fatigue
- Cataracts
- Congestive heart failure

Signs
- Chvostek's sign
- Trousseau's sign
- Prolongation of the QTc interval
- Basal ganglia and other intracerebral calcifications

which reverses with management of the usually very low ionized Ca^{2+} levels. Hypocalcemia is well known for its effects on cardiac conduction; the effects are manifested on the ECG as prolongation of the QTc interval. In addition, the patient often feels a sense of generalized weakness, fatigue, and depression that often lifts as the mineral disturbances (and vitamin D deficiency, if present) are successfully treated.

DIAGNOSIS: TESTS AND INTERPRETATION

The mainstays of diagnostic testing are determination of the serum ionized Ca^{2+}, total Mg^{2+}, phosphate, intact PTH, and 25(OH)D values. Measuring the 25(OH)D level is the best way to exclude vitamin D deficiency or insufficiency. Considerable attention has been directed to the reliability of contemporary 25(OH)D assays and clinically relevant cut points for diagnosing vitamin D deficiency/insufficiency. These important clinical issues are discussed elsewhere in the *Primer*. Intact PTH measured in a reliable two-site assay will readily disclose inappropriately low, low normal, or even undetectable values in hypoparathyroid states and generally normal levels (but inappropriately so) in patients with Mg^{2+} depletion. In marked contrast, patients with vitamin D deficiency and pseudohypoparathyroidism have elevated levels of PTH or secondary hyperparathyroidism. Phosphate levels are low in vitamin D deficiency and are elevated (or at the high end of the normal range) in patients with hypoparathyroidism and pseudohypoparathyroidism, an important distinguishing measurement to make. Accurate determination of 24-hour urinary Ca^{2+} or Mg^{2+} excretion, depending on the primary disturbance (hypocalcemia versus hypomagnesemia), can be extremely helpful. Strikingly elevated urinary Ca^{2+} levels in the asymptomatic mildly hypocalcemic patient suggest ADH. Milder elevations are expected in hypoparathyroid states. In contrast, vitamin D deficiency with secondary hyperparathyroidism classically produces hypocalciuria, in an effort by the kidney, under the influence of PTH, to conserve Ca^{2+} for systemic needs. The presence of significant Mg^{2+} in the urine in a hypomagnesemic patient strongly suggests primary renal Mg^{2+} wasting and not gastrointestinal losses.

MANAGEMENT OF HYPOCALCEMIA: ACUTE AND CHRONIC

The goals of treatment are to alleviate symptoms, heal demineralized bones when osteomalacia is present, maintain an acceptable ionized Ca^{2+} or total serum Ca^{2+}, and avoid hypercalciuria. Avoiding hypercalciuria (urine Ca^{2+}>300 mg/24 hours) is critical for the prevention of renal dysfunction, stones, and nephrocalcinosis. When clinical circumstances dictate urgent treatment, intravenous Ca^{2+} salts are used. Seizures, severe tetany, laryngospasm, bronchospasm, or altered mental status are strong indicators for intravenous therapy. In contrast, if the patient is minimally symptomatic despite low numbers, the oral regimen outlined below can be used. The preferred intravenous salt is Ca gluconate (1 gm = 1 amp = 10 mL 10% solution = 4.65 mEq = 90 mg elemental Ca^{2+}). Two grams (20 mL 10% solution, or 2 ampules) may be infused slowly over 10 min to address symptoms. Generally, an infusion is begun. One infusion method is to prepare 11 g Ca gluconate in D5W to provide a final volume of 1000 mL (~1 mg elemental Ca^{2+}/mL), and to infuse it at a rate of 0.5–2.0 mg elemental Ca^{2+}/kg/hour. The goals are to control symptoms, to restore the ionized Ca^{2+} to the lower end of the normal range (~1.0 mM), and to normalize the QTc interval. Higher rates (up to 2.0 mg/kg/h) may sometimes be needed to stabilize the patient. Ionized Ca^{2+} level should be monitored closely (e.g., after 1 hour and then every 4 hours). Once the serum ionized Ca^{2+} is stabilized, a chronic oral regimen is begun. Infusion rates are tapered down as serum ionized Ca^{2+} reaches the target, symptoms resolve, and oral medications are tolerated.

Chronic management of hypocalcemia uses oral Ca^{2+} supplements, vitamin D metabolites, and sometimes thiazide diuretics. When Mg^{2+} depletion is the source of hypocalcemia, Mg^{2+} deficits are generally large and poorly reflected by the serum Mg^{2+} level, because Mg^{2+} is predominantly an intracellular cation. Supplementation

with Mg^{2+} salts over an extended period of time will usually be needed to replenish total body Mg^{2+} stores. Serum Ca^{2+} and PTH secretory capacity will return to normal in nearly all cases unless there are ongoing and unaddressed losses.

Ca^{2+} supplements of all types work to treat hypocalcemia. A few general principles are worth emphasizing. It is best to divide up the supplements throughout the day and to time their administration to coincide with meals, because this will enhance absorption (especially of Ca carbonate, which requires the acidic environment of the gastrointestinal tract for full absorption). The most efficient means of supplementation is in the form of Ca carbonate or citrate salts. The former is approximately 40% and the latter approximately 21% elemental Ca^{2+} by weight. Generally, 500–1,000 mg elemental Ca^{2+} two or three times a day is a reasonable starting dose and can be escalated upward. This is done based on patient tolerance, compliance, and clinical goals. When Ca^{2+} supplements are insufficient to reach the target serum Ca^{2+}, vitamin D metabolites are prescribed. When renal function is intact and some PTH is present for vitamin D activation, ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) may be used. Doses in the range of 25,000–50,000 IU daily (occasionally even more) may be needed to treat hypoparathyroidism, pseudohypoparathyroidism, or vitamin D deficiency in patients with malabsorption. Care must be exercised, because these forms of vitamin D have a long tissue half-life (weeks to months) due to long-term storage in fat, and toxicity may be difficult to predict and to treat. Calcitriol (1,25-dihydroxyvitamin D; 0.25 to 1.0 mcg once or twice daily) is necessary in patients with inadequate 1-α hydroxylase activity and preferred by many clinicians because of its rapid onset and offset of action (1–3 days), and ease of titration, despite its greater costs. Other vitamin D metabolites are alternatives for treatment, including alfacalcidiol and dihydrotachysterol. In patients who develop hypercalciuria on these regimens and/or have difficulty achieving the serum Ca^{2+} goal safely, one can take advantage of the Ca^{2+}-retaining actions of thiazide diuretics. Effective doses of hydrochlorthiazide typically range from 50–100 mg/day, although lower doses can be tried. Serum Ca^{2+}, phosphorus, and creatinine levels should be monitored regularly along with 25(OH)D levels if vitamin D therapy is used, to avoid toxicity.

For the treatment of hypoparathyroidism, replacement therapy with PTH has been investigated in both adults and children. In one randomized trial of PTH(1-34) versus oral calcitriol and calcium in 27 adults with hypoparathyroidism, twice daily PTH(1-34) maintained serum calcium levels at or just below normal range over 3 years, with normal urinary calcium levels. Similar findings were reported from a 3-year randomized trial in 12 children (aged 5–14 years) with hypoparathyroidism. In an open-label study of PTH(1-84) in adults with hypoparathyroidism, PTH(1-84) reduced supplemental calcium and calcitriol requirements without changing serum and urinary calcium levels meaningfully, and other trials of PTH(1-84) are underway. Currently, no form of PTH is approved by the U.S. Food and Drug Administration for this indication.

INTRODUCTION

The term "functional hypoparathyroidism" refers to a group of metabolic disorders in which hypocalcemia and hyperphosphatemia occur either from a failure of the parathyroid glands to secrete adequate amounts of biologically active parathyroid hormone (PTH) or, less commonly, from an inability of PTH to elicit appropriate biological responses in its target tissues. Plasma concentrations of PTH are low or absent in patients with true hypoparathyroidism (HP). By contrast, plasma concentrations of PTH are elevated in patients with pseudohypoparathyroidism (PHP), and reflect the failure of target tissues to respond appropriately to the biological actions of PTH.

There are several important features that distinguish PHP from HP. First, circulating levels of PTH are elevated in patients with PHP (i.e., secondary or adaptive hyperparathyroidism) and low in patients with HP. Second, the fractional excretion of urinary calcium is elevated in HP and low in PHP. In the absence of PTH, active transport of calcium from the glomerular filtrate in the distal renal tubule is decreased. Urinary excretion of calcium is low or normal in HP patients who are hypocalcemic, but as treatment restores the serum calcium level to normal the renal filtered load of calcium increases, and urinary calcium excretion increases *pari passu*. By contrast, the distal renal tubule is responsive to PTH in patients with PHP, so that urinary calcium excretion remains low relative to the filtered load of calcium (unless PTH levels are suppressed by overtreatment). Second, skeletal responsiveness to PTH is intact in patients with PHP, and thus PTH can also induce release of calcium (and phosphate) from skeletal storage pools when circulating levels of $1,25(OH)_2D$ are normal. And third, HP is associated with low bone turnover and reduced biochemical markers of bone resorption and formation whereas bone turnover is normal or increased in PHP, particularly in patients who have elevated levels of circulating PTH. Protracted low bone turnover in HP leads to bone mass that is greater than age- and sex-matched controls, especially at the lumbar spine. Bone histomorphometry shows that subjects with HP have significantly increased cancellous bone volume, trabecular width and cortical width, as well as suppressed dynamic skeletal indices (Fig. 72.1). These changes may be associated with increased expression of the *SOST* gene encoding sclerostin in osteocytes. Sclerostin is an antagonist of the Wnt signaling pathway, and is suppressed by PTH.

CLINICAL MANIFESTATIONS OF FUNCTIONAL HYPOPARATHYROIDISM

The signs and symptoms of functional hypoparathyroidism are principally manifestations of a reduced concentration of ionized extracellular calcium. It remains

uncertain whether PTH deficiency *per se* has any clinical characteristics. Hypocalcemia causes increased neuromuscular irritability, a condition termed "tetany." Patients may complain of paresthesias, particularly in the distal extremities and face, as well as muscle cramps. When hypocalcemia is severe, patients may experience laryngospasm, seizures, or reversible heart failure. Clinical signs of latent tetany include the Chvostek sign and Trousseau sign. Other clinical features of chronic hypocalcemia include pseudopapilledema, increased intracranial pressure, and dry, rough skin. Prolonged hypocalcemia and hyperphosphatemia, with an elevated calcium–phosphate product, will lead to posterior subcapsular cataracts and calcification of intracranial structures, which can be detected by computed tomography (CT) or magnetic resonance imaging (MRI). Rarely, calcification of the basal ganglia can cause extrapyramidal neurological dysfunction. Spondyloarthopathy has also been described. Hypocalcemia can cause prolongation of the corrected QT interval on an EKG and reversible heart failure. Patients can adapt to chronic hypocalcemia, and occasionally asymptomatic patients will be diagnosed only after a low serum calcium is detected after routine blood screening. Occasional patients with postsurgical HP report neuromuscular symptoms of hypocalcemia and reduced quality of life despite normal serum calcium levels.

DIFFERENTIAL DIAGNOSIS OF FUNCTIONAL HYPOPARATHYROIDISM

The response to exogenous PTH can distinguish between HP and the several variants of PHP (Fig. 72.2). Patients

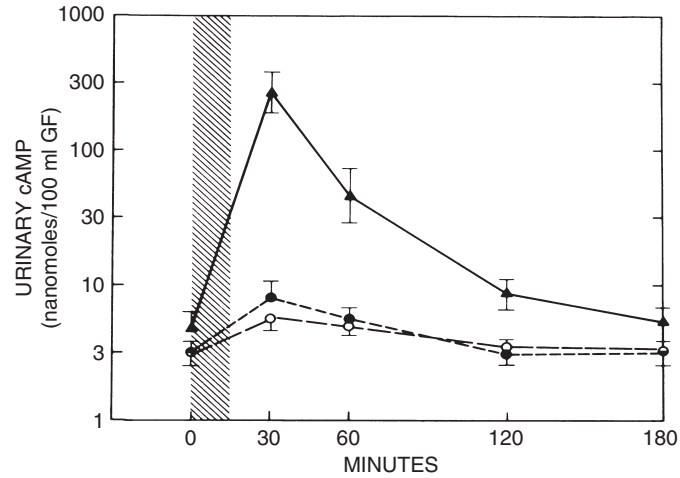

Fig. 72.2. PTH infusion. cAMP excretion in urine in response to the intravenous administration of bovine parathyroid extract (300 USP units) from 9–9:15 a.m. The peak response in normals (▲) is 50- to 100-fold times basal; patients with PHP type Ia (•) or PHP type Ib (o) show only a 2- to 5-fold response.

with HP show a robust increase in urinary excretion of nephrogenous cyclic adenosine monophosphate (cAMP) and phosphate. By contrast, patients with PHP type 1 fail to show an appropriate increase in plasma cAMP or urinary excretion of both cAMP and phosphate, while subjects with the less common type 2 form show normal increases in plasma and urinary cAMP but do not manifest a phosphaturic response (see below). The causes of PHP and HP are presented in Table 72.1.

Table 72.1. Classification of Hypoparathyroidism

Disorders of Parathyroid Gland Formation	MIM	Genetic Defect
DiGeorge sequence	188400	22q11; *TBX1* mutation 10p; intrauterine exposure to alcohol, diabetes, isotretinoin
Hypoparathyroidism, sensorineural deafness, and renal dysplasia syndrome (HDR)	146255	*GATA3*

Syndromes of PTH resistance

Pseudohypoparathyroidism (PHP) type 1

The blunted nephrogenous cAMP response to PTH in subjects with PHP type 1 is caused by a deficiency of the alpha subunit of Gs ($G\alpha_s$), the signaling protein that couples PTH1R to stimulation of adenylyl cyclase. Molecular and biochemical studies have provided a basis for distinguishing between two forms of PHP type 1: patients with generalized deficiency of $G\alpha_s$, due to mutations within exons 1-13 of the *GNAS* gene, are classified as PHP type 1a (PHP 1a; OMIM 103580), whereas patients with more restricted deficiency of $G\alpha_s$, due to mutations that affect imprinting of *GNAS*, are classified as PHP type 1b (PHP 1b; OMIM 603233). In most cases, patients with PHP 1a can be distinguished from patients with PHP 1b on the basis of the pattern of hormone resistance and the presence of additional somatic features. PHP type 1c is likely a variant of PHP 1a (see below).

Pseudohypoparathyroidism 1a

PHP 1a (MIM 103580) is the most common variant and most readily recognized form of PHP. Subjects have a constellation of features termed "Albright hereditary osteodystrophy (AHO)" that include short stature, round faces, brachydactyly of hands and/or feet, mild to moderate mental retardation, and subcutaneous ossifications plus in most cases obesity (Fig. 72.3). PHP 1a results from heterozygous mutations on the maternal allele of the imprinted *GNAS* gene (20q13.2-q13.3) that reduce expression or function of the $G\alpha_s$ protein (Fig. 72.4). As $G\alpha_s$ is required for normal transmembrane signal transduction by many hormones and neurotransmitters, subjects with PHP 1a also have resistance to other hormones (e.g, thyroid stimulating hormone, gonadotropins, calcitonin, and growth hormone releasing hormone) whose target tissues show predominant expression of the maternal *GNAS* allele. Primary hypothyroidism, without goiter, and growth hormone deficiency are common associated endocrinopathies. Obesity is common, and based on studies of a mouse model, PHP 1a is due to a loss of $G\alpha_s$ expression in imprinted regions of the hypothalamus. Obesity appears to be the result of reduced energy expenditure rather than increased calorie intake.

Responsiveness to other hormones (e.g., ACTH, vasopressin) is normal in tissues in which *GNAS* is not imprinted and both parental alleles are expressed. Subjects with paternally inherited *GNAS* mutations have phenotypic features of AHO without hormonal resistance, a condition termed "pseudopseudohypoparathyroidism (pseudoPHP)." Subjects with pseudoPHP have

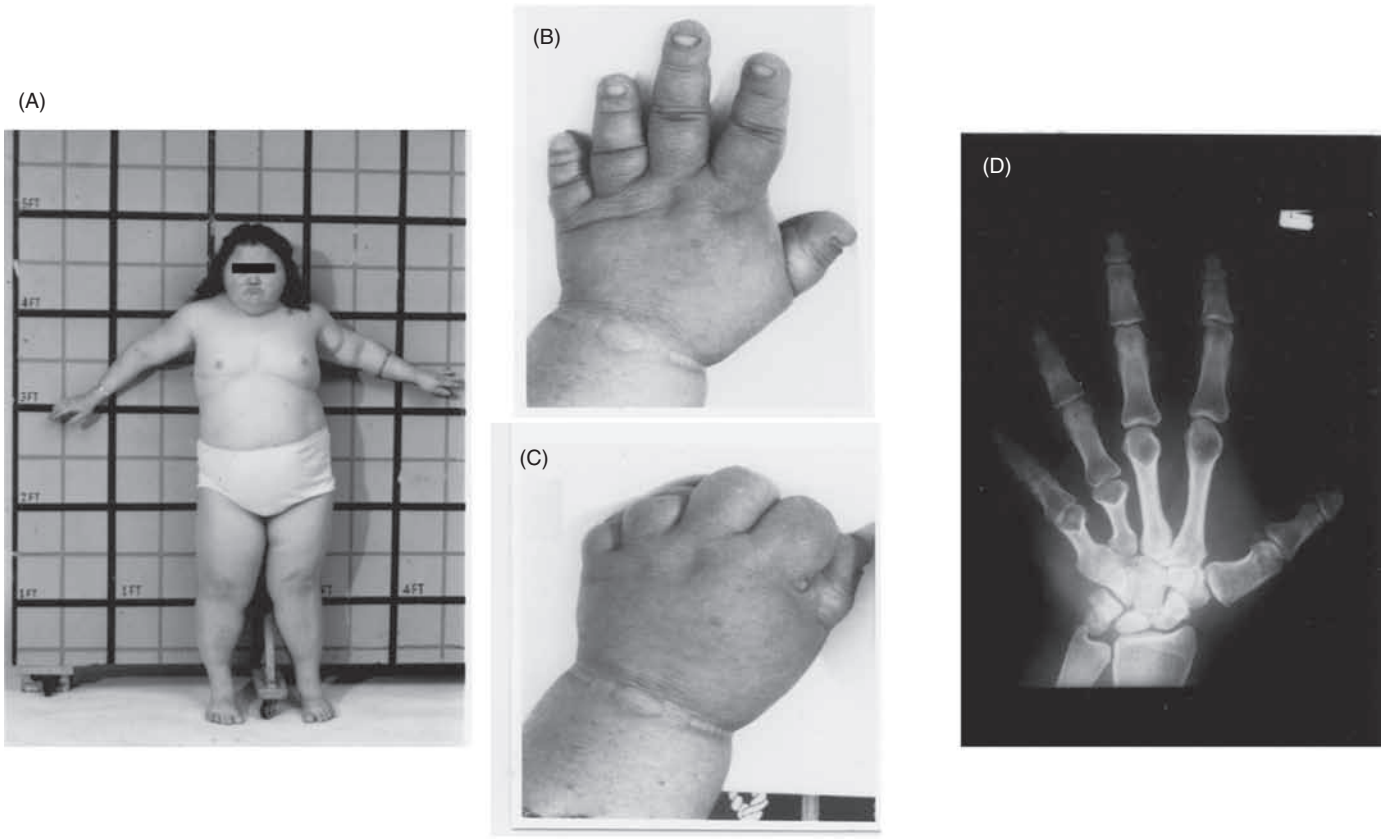

Fig. 72.3. Typical features of Albright hereditary osteodystrophy. The female in the picture demonstrates (A) short stature, sexual immaturity, and (B) brachydactyly. Note the extreme shortening of digit IV and distal phalanx of digit I (width greater than length) in (B) and (D), and the replacement of knuckles by dimples (Archibald sign) in (C).

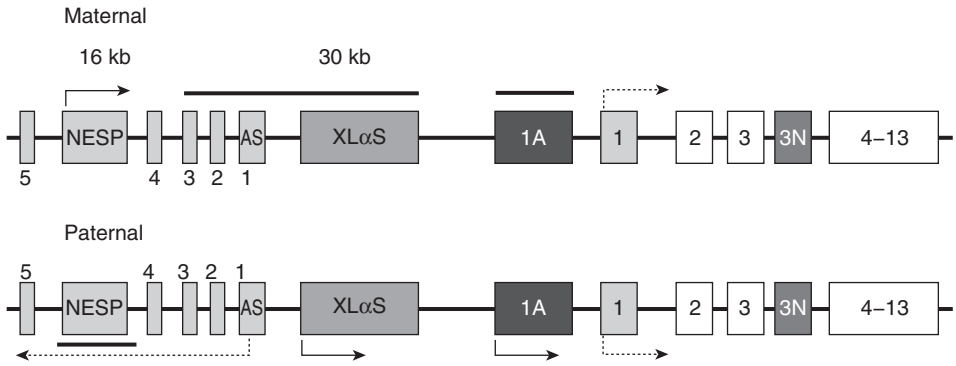

Fig. 72.4. *GNAS* gene. General organization of the *GNAS* gene complex. The *GNAS* gene complex consists of 13 exons that encode the signaling protein $G\alpha_s$. Upstream of exon 1 are three alternative first exons that are labeled exon 1A, XLαs, and Nesp55; exons 1-5 for the NESP antisense transcript (AS) are also depicted. The three alternative exons are spliced to exons 2-13 to produce unique transcripts (see text). The DMRs are denoted above the respective promoters, and arrows denote the direction of transcription. Nesp55 is transcribed exclusively from the maternal allele; XLαs and exon 1A are transcribed exclusively from the paternal allele. Nesp AS (anti-sense) and exon 1a transcripts produce noncoding RNAs. $G\alpha_s$ transcripts are biallelically expressed except in a small number of tissues, such as the renal proximal tubules, thyroid, gonads, and pituitary somatotrophs, where expression is preferentially from the maternal allele.

normal renal responsiveness to PTH, which distinguishes them from occasional patients with PHP 1a who maintain normal serum calcium levels without treatment. It is not unusual to find extended families in which some members will have only AHO (i.e., pseudoPHP) while others will have hormone resistance as well (i.e., PHP 1a), based on the parental origin of the identical *GNAS* mutation.

The *GNAS* gene is a complex transcriptional unit that derives considerable plasticity through use of alternative first exons, alternative splicing of downstream exons, antisense transcripts, and reciprocal imprinting (Fig. 72.4). $G\alpha_s$ is encoded by exons 1-13, and is synthesized as a 52- or 45-kDa protein based on the inclusion or exclusion of exon 3, respectively. There seems to be little difference in the signal transducing properties of the two $G\alpha_s$ isoforms. Upstream of exon 1 are three alternative first exons that each splice onto exons 2-13 to create novel transcripts (Fig. 72.4). These include XL, which is expressed only from the paternal allele and which generates a transcript with overlapping open reading frames that encodes $XL\alpha_s$ and ALEX. The two proteins are interacting cofactors, and are specifically expressed in neuroendocrine cells. XLαs is a much larger signaling protein than $G\alpha_s$ (≈78 kDa vs 45–52 kDa) and can interact with receptors for PTH and a variety of other hormones *in vitro*, but the native receptors that interact with XLαs *in vivo* are presently unknown. A second alternative promoter encodes the secretory protein Nesp55, which is expressed only from the maternal allele and shares no protein homology with $G\alpha_s$. The third alternative first exon, termed exon 1A or A/B (associated first exon) is transcribed only from the paternal allele. These transcripts may be translated from an initiator codon in the second exon and encode an amino-terminal truncated protein that functions as a competitive inhibitor of $G\alpha_s$. These alternative first exons are associated with promoters that contain differentially methylated regions (DMRs) that are methylated on the non-expressed allele (Fig. 72.4). In contrast, the promoter for exon 1 is within a CpG island but is unmethylated on both alleles in all tissues. The cis-acting elements that control tissue-specific paternal imprinting of $G\alpha_s$ appear to be located within the primary imprint region in exon 1A, as paternal deletion of the exon 1A DMR in mice is associated with increased $G\alpha_s$ expression.

Private mutations have been found in nearly all of the AHO kindreds studied, although a 4-base deletion in exon 7 has been detected in multiple families and an unusual missense mutation in exon 13 (A366S; see below) has been identified in two unrelated young boys, suggesting that these two regions may be genetic "hot spots." Small deletions or point mutations can be identified in approximately 80% of AHO patients using polymerase chain reaction (PCR)-based techniques, and larger genomic rearrangements or uniparental disomy may account for AHO in other patients.

Post-zygotic somatic mutations in the *GNAS* gene that enhance activity of the protein are found in many autonomous endocrine tumors and affected tissues of patients with the McCune-Albright syndrome (MIM 174800). These mutations lead to constitutive activation of adenylyl cyclase, and result in proliferation and autonomous hyperfunction of hormonally responsive cells. Clinically significant effects are more likely to ensue when *GNAS* activating mutations occur on the maternally derived allele, which is preferentially expressed in imprinted tissues. The clinical significance of $G\alpha_s$ activity as a determinant of hormone action is further emphasized by the description by of two unrelated males with both precocious puberty and PHP 1a. These two subjects had identical *GNAS* mutations in exon 13 (A366S) that resulted in a temperature-sensitive form of $G\alpha_s$. This $G\alpha_s$ is constitutively active in the cooler environment of the testis, while being rapidly degraded in other tissues at normal body temperature. Thus, different tissues in these two individuals could show hormone resistance [to PTH and thyroid stimulating hormone (TSH)], hormone responsiveness [to adrenocorticotropic hormone (ACTH)], or hormone independent activation (to LH).

Pseudohypoparathyroidism 1b

Subjects with PHP 1b (MIM 603233) lack typical features of AHO but may have mild brachydactyly. Levels of $G\alpha_s$ are normal in accessible tissues. PTH resistance is the principal manifestation of hormone resistance, but some patients have slightly elevated serum levels of TSH and normal serum concentrations of thyroid hormones as evidence of associated TSH resistance.

An epigenetic defect that results in switching of the maternal *GNAS* allele to a paternal pattern of methylation (i.e., paternal epigenotype) is a consistent finding in sporadic and familial PHP 1b. Causative mutations have been identified in most cases of familial PHP 1b, including two microdeletions in the *STX16* gene located approximately 220 kb centromeric of *GNAS* exon 1A, and deletions that remove the DMR encompassing exon NESP55 and exons 3 and 4 of the antisense transcript (Fig. 72.4). In each case, inheritance of a mutation from a female (or spontaneous mutation of a maternally derived allele) abolishes the maternal *GNAS* epigenotype. Small mutations have not been identified in sporadic PHP 1b, but some patients have uniparenal isodisomy, where both *GNAS* alleles have been inherited from the father. It is likely that the conversion of the maternal *GNAS* allele to a "paternal" epigenotype, or inheritiance of two paternal alleles, leads to biallelic transcriptional silencing of the Gαs promoter in imprinted tissues, with the result that little or no $G\alpha_s$ is expressed in these tissues.

Pseudohypoparathyroidism type 1c

In rare instances, patients with PHP type 1 and features of AHO show resistance to multiple hormones in the absence of a demonstrable biochemical defect in G_s or G_i. Molecular studies suggest that these patients have *GNAS*

mutations that result in functional defects of $G\alpha_s$ that are not apparent in conventional *in vitro* assays.

Albright hereditary osteodystrophy

Haploinsufficiency of *GNAS* is associated with an unusual constellation of skeletal anomalies that are collectively termed AHO, and which include short stature, round faces, brachydactyly, dental defects, and heterotopic ossification of the skin and subcutaneous tissues (Fig. 72.3). Additional features had been associated with AHO, such as obesity and sensory-neural abnormalities, but these defects appear limited to patients with PHP 1a who have maternal *GNAS* mutations that cause abnormal Gs_α signaling in the central nervous system. Patients who manifest AHO and have normal hormonal responsiveness due to inactivating mutations on the paternal *GNAS* allele are considered to have the genetically related disorder pseudoPHP (see above). Short stature and brachydactyly may be due in part to premature fusion of epiphyses in tubular and long bones, which implies a requirement of two functional copies of *GNAS* for normal growth plate maturation.

The heterotopic ossifications are the most unique feature of AHO and distinguish true AHO from a variety of clinical phenocopies. The ossifications are not calcifications, and are unrelated to the serum levels of calcium and phosphorus. Rather, the ossifications are islands of true intramembranous bone. These bone islands occur in the absence of a preexisting or associated lesion, as opposed to secondary types of cutaneous ossification that occur by metaplastic reaction to inflammatory, traumatic, and neoplastic processes. Recent studies suggest that Gs_α deficiency can induce ectopic expression of Cbfa1/Runx2 in mesenchymal stem cells with consequent differentiation of these cells into osteoblasts.

AHO is a unifying feature of PHP 1a and pseudoPHP, and based on the parental origin of the *GNAS* mutation, within a given kindred affected members of one generation can have only AHO (i.e., pseudoPHP) or can have hormone resistance as well (i.e., PHP 1a).

Osteoma cutis and progressive osseous heteroplasia

Osteoma cutis and progressive osseous heteroplasia (POH) represent alternative manifestations of AHO in which only heterotopic ossification occurs. In osteoma cutis ectopic ossification is limited to the superficial skin, whereas in POH heterotopic ossification involves the skin, subcutaneous tissue, muscles, tendons, and ligaments. POH can be disabling as extensive dermal ossification occurs during childhood, followed by widespread ossification of skeletal muscle and deep connective tissue. Nodules and lace-like webs of heterotopic bone extend from the skin into the subcutaneous fat and deep connective tissues, and may cross joints, thus leading to stiffness, joint locking, and permanent immobility.

Heterozygous inactivating *GNAS* mutations have been identified in most patients with osteoma cutis and POH, and in each case the defective allele was paternally inherited. Although patients with POH lack other features of AHO or PHP, maternal transmission of the defective *GNAS* allele leads to the complete PHP 1a phenotype in affected children.

Pseudohypoparathyroidism type 2

In subjects with PHP type 2, PTH resistance is characterized by a reduced phosphaturic response to administration of PTH, despite a normal increase in urinary cAMP excretion. These observations suggest that the PTH receptor–adenylyl cyclase complex functions normally to increase nephrogenous cAMP in response to PTH, but that intracellular cAMP is unable to act upon downstream targets such as the sodium phosphate transporter. PHP type 2 lacks a clear genetic or familial basis, and a similar clinical and biochemical picture occurs in patients with severe deficiency of vitamin D. Taken together, it is likely that most, if not all, cases of PHP type 2 are actually examples of unsuspected vitamin D deficiency.

Transient pseudohypoparathyroidism of the newborn

Although most newborns with late onset hypocalcemia (i.e., onset of hypocalcemia after days 5–7 of life) have low levels of PTH, about 25% of affected babies will have elevated levels of PTH. Twitchiness or seizure is most often the initial clinical sign of hypocalcemia. Hypocalcemia is associated with hyperphosphatemia, which is due to a high transport maximum of the phosphate/glomerular filtration rate despite elevated PTH levels. Serum levels of magnesium and vitamin D metabolites are typically normal. Intravenous administration of PTH(1-34) produces normal responses of plasma and/or urine cyclic AMP, but the phosphaturic response to the PTH infusion is typically impaired. Affected newborns respond to treatment with calcium and/or 1α hydroxylated metabolites of vitamin D. The condition appears to be transient, with normal serum levels of calcium, phosphorus, and PTH levels maintained without treatment by age 6 months. These features are suggestive of delayed maturation of the post-cyclic AMP signaling pathway in the proximal renal tubule.

Circulating inhibitors as a cause of PTH resistance

Past studies had noted an apparent dissociation between circulating levels of immunoreactive and bioactive PTH in patients with PHP type 1, and plasma from many of these patients diminished the biological activity of exogenous PTH in *in vitro* cytochemical bioassays. Although the basis for this inhibitory effect is unknown, one potential explanation is the accumulation of N-terminally truncated PTH fragments, such as hPTH(7-84), that can inhibit the calcemic and phosphaturic actions of hPTH(1-

34) or hPTH(1-84). Circulating levels of PTH(7-84) immunoreactivity are elevated in patients with PHP 1a and 1b, and the proportion of PTH(7-84)-like fragments to biologically active PTH(1-84) is increased. Calcitriol treatment of patients with PHP type 1 increases the phosphaturic response to PTH (1-34), and one mechanism to explain this observation may be suppression of PTH (7-84)-like fragment levels. Although it is conceivable that circulating hPTH(7-84)-like fragments contribute to PTH resistance in some patients with PHP, it is likely that these circulating antagonists arise as a consequence of sustained secondary hyperparathyroidism and do not have a significant role in the primary pathophysiology of the disorder.

Magnesium deficiency

Magnesium deficiency can impair parathyroid secretion of PTH as well as PTH action. In either case, treatment with magnesium will restore parathyroid function and/or PTH responsiveness.

Syndromes of deficient synthesis or secretion of PTH

Developmental disorders

Genetic forms of HP may derive from dysgenesis of the parathyroid glands. The parathyroid glands (PGs) derive from the pharyngeal pouches, which are transient structures that differentiate from the foregut endoderm during embryonic development. The PGs are evolutionarily homologous to pharyngeal gill slits in fish, and development of both of these organs is critically dependent upon expression of an evolutionarily conserved hierarchy of gene expression. The relevant genes for PG development include the transcription factors Hoxa3, Pax9, Eya1, GCM2, and Tbx1. In humans the PGs first appear during the fifth week of gestation; the superior glands derive from the fourth pharyngeal pouches and the thymus and inferior PGs derive from the third pharyngeal pouches.

DiGeorge sequence/CATCH-22

The DiGeorge sequence (DGS) results from dysembryogenesis of the third and fourth pharyngeal pouches, and is associated with hypoplasia of the thymus and parathyroid glands. The term "DiGeorge sequence" or "anomaly" is more appropriate than "syndrome" as the constellation of defects does not result from a single cause, but rather the failure of an embryological field to develop normally. These patients also often manifest conotruncal cardiac abnormalities, cleft palate, and dysmorphic facies. Hypoparathyroidism is present in up to 60% of patients with DGS. DGS is the leading cause of persistent hypocalcemia of the newborn, but hypoparathyroidism may resolve during childhood. Thymic defects are associated with impaired T-cell mediated immunity and frequent infections.

Molecular mapping has attributed most (70–80%) cases of DGS to hemizygous microdeletions within a critical 250-kb region of 22q11.21-q11.23. Although many genes are located within this region, the presence in some patients with DGS of point mutations that inactivate the *TBX1* gene suggests that this may be the critically important gene. *TBX1* encodes a T-box transcription factor that is widely expressed in non-neural crest cells, cranial mesenchyme, and pharyngeal pouches, and its distribution certainly corresponds to the clinical phenotype of DGS. DGS most commonly arises from *de novo* mutations, but autosomal dominant inheritance can occur.

Microdeletions of 22q11 are the most common cause of continuous gene deletion syndromes in humans, and are present in approximately 1:3,000 newborns. In addition to DGS, deletions within 22q11 can cause the conotruncal anomaly face syndrome and the velocardiofacial syndrome (VCFS). VCFS is typically diagnosed later in childhood, and hypocalcemia has been found to be present in up to 20% of cases. Because of the phenotypic variability of the various overlapping syndromes, these conditions are all included within the acronym "CATCH-22," representing a syndrome of **C**ardiac abnormality, **A**bnormal facies, **T**hymic hypoplasia, **C**left palate, and **H**ypocalcemia with deletion or chromosome **22**q11.

DGS has also been reported to arise in patients with deletions of 10p13, 17p13, and 18q21. Gestational diabetes, as well as exposure to alcohol and other toxins (e.g., retinoids) in the intrauterine stage, can also cause similar phenotypic syndromes.

Hypoparathyroidism, sensorineural deafness, and renal dysplasia syndrome

Deletions within two nonoverlapping regions of 10p have been found to contribute to a phenotype similar to DGS, namely the hypoparathyroidism, sensorineural deafness, and renal dysplasia syndrome (HDR, MIM146255). Unlike DGS/CATCH-22, individuals with HDR do not exhibit cardiac, palatal, or immunologic abnormalities. However, growth hormone insufficiency has been found to be associated with HDR syndrome and may contribute to the typical short stature. The HDR disorder is due to haploinsufficiency of the GATA binding protein-3 (*GATA3*) gene, which is located within a 200-kb critical HDR deletion region on 10p14-10pter and encodes a carboxy-terminal zinc-finger protein essential for DNA binding. It is expressed in the developing vertebrate kidney, otic vesicle, and parathyroids, as well as the central nervous system and organs of T-cell development. A novel missense *GATA3* mutation, Thr272Ile, has been recently identified and shown to result in reduced DNA binding, a partial loss of cofactor FOG2 interaction, and a decrease in gene transcription. The important role of GATA3 in parathyroid function was further highlighted by demonstration that Gata3+/- mice had decreased expression of the parathyroid-specific

transcription factor Gcm2 (see below) and developed mild hypoparathyroidism.

Hypoparathyroidism-retardation-dysmorphism and Kenny-Caffey Syndromes

The hypoparathyroidism-retardation-dysmorphism syndrome (HRD, MIM241410), also known as the Sanjad-Sakati syndrome, is a rare form of autosomal recessive hypoparathyroidism associated with other developmental anomalies. In addition to parathyroid dysgenesis, affected patients have severe growth and mental retardation, microcephaly, microphthalmia, small hands and feet, and abnormal teeth. This disorder is found almost exclusively in individuals of Arab descent. The Kenny-Caffey (KS, MIM244460) Syndrome is an allelic disorder that is characterized by hypoparathyroidism, dwarfism, medullary stenosis of the long bones, and eye abnormalities. Both disorders are due to mutations in the tubulin-specific chaperone E (*TBCE*) gene on chromosome 1q42-43, which encodes a chaperone protein required for folding of α-tubulin and its heterodimerization with β-tubulin, although a second gene locus for this disorder is also probable (KS2).

Isolated hypoparathyroidism

Hypoparathyroidism may also occur as an isolated condition with either an X-linked or autosomal patterns of inheritance. The leading cause of autosomal recessive isolated hypoparathyroidism is inactivation of the *GCM2 (GCMB)* gene at 6p23-24 (MIM146200). *GCM2* encodes a member of a small family of unique transcription factors that were originally identified in Drosophilia that lacked glial cells, hence the name *gcm* for "glial cells missing." Two mammalian homologs exist: *GCM1,* which is principally expressed in the placenta and controls placental branching and vasculogenesis, and *GCM2,* which is expressed predominantly, if not exclusively, in the developing and mature parathyroid gland. Recessive inactivating mutations or dominant inhibitor mutations of *GCM2* cause most cases of isolated hypoparathyroidism in newborns. Heterozygous mutation of *GCM2* does not appear to cause any disturbance in parathyroid development or function.

Isolated hypoparathyroidism can also be inherited as an X-linked recessive trait (MIM307700). Affected males present with infantile hypocalcemic seizures while hemizygous females are unaffected. Autopsy of an affected individual revealed complete agenesis of the parathyroid glands as the cause of hypoparathyroidism. Linkage analysis has localized the underlying mutation to a 1.5-Mb region on Xq26-q27, and recent molecular studies have identified a deletion–insertion involving chromosomes Xq27 and 2p25 as the basis for the defect. These findings have also suggested that a gene known as Sry-box 3 (*SOX3*), within a 906-kb cross-linked recessive HPT critical region, might play a role in the embryonic development of the parathyroid glands.

Parathyroid gland destruction

Surgery

The most common cause of hypoparathyroidism in adults is surgical excision of or damage to the parathyroid glands as a result of total thyroidectomy for thyroid cancer, radical neck dissection for other cancers, or repeated operations for primary hyperparathyroidism. Prolonged hypocalcemia, which may develop immediately or weeks to years after neck surgery, suggests permanent hypoparathyroidism. Postoperative hypoparathyroidism occurs in approximately 1% of thyroid and parathyroid procedures. In patients with a higher risk of developing permanent hypoparathyroidism, parathyroid tissue may be autotransplanted into the brachioradialis or sternocleidomastoid muscle at the time of parathyroidectomy or cryopreserved for subsequent transplantation as necessary. However, transplantation of parathyroid tissue has not advanced to the point where it is a reliable therapeutic option.

Radiation therapy and infiltration

Rarely, hypoparathyroidism has also been described in a small number of patients who receive extensive radiation to the neck and mediastinum. It is also reported in metal overload diseases such as hemochromatosis and Wilson's disease, and in neoplastic or granulomatous infiltration of the parathyroid glands. Hypoparathyroidism may be present in as many as 14% of patients with thalassemia who develop iron overload due to frequent blood transfusion. Hypoparathyroidism has also been observed in association with HIV disease.

Autoimmune polyendocrinopathy-candidiasis-esctodermal dystrophy (APECED)

Autoimmune destruction of the parathyroids occurs most commonly in association with the complex of immune-mediated disorders that comprises the APECED (autoimmune polyendocrinopathy-candidiasis-esctodermal dystrophy, MIM 240300) syndrome, also known as APS I (autoimmune polyglandular syndrome type I). The genetic etiology has been traced to mutations of the autoimmune regulator (*AIRE*) gene on chromosome 21q22.3, which encodes a unique protein with characteristics of a transcription factor. APS I can be either sporadic or autosomal recessive, and has been associated with more than 40 different mutations of the *AIRE* gene. Although the disorder occurs worldwide, it is most prevalent in Finns, Sardinians, and Iranian Jews, and common gene mutations in some populations suggest possible founder effects.

The syndrome's classic triad constitutes the "HAM" complex of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis. The immune defect may be associated with cytotoxic antibodies that damage or destroy the parathyroid glands. Recently, antibodies that react with the NACHT leucine-rich-repeat protein

5 (NALP5), which is expressed predominantly in the cytoplasm of parathyroid chief cells, have been identified in approximately 50% of APS I patients with HP. An alternative pathophysiological mechanism has been proposed that is based on the presence of circulating antibodies bind and activate the calcium-sensing receptor (CaSR), thereby reducing PTH secretion from parathyroid cells. The temporal progression of the HAM complex is quite predictable, with the appearance of mucocutaneous candidiasis and hypoparathyroidism in the first decade of life, followed by primary adrenal insufficiency before 15 years of age. The candidiasis may affect the skin, nails, and mucous membranes of the mouth and vagina, and is often resistant to treatment. Addison's disease can mask the presence of hypoparathyroidism, or may manifest only after improvement of the hypoparathyroidism, with a reduced requirement for calcium and vitamin D. By diminishing gastrointestinal absorption of calcium and increasing renal calcium excretion, glucocorticoid therapy for the adrenal insufficiency may exacerbate the hypocalcemia and could cause complications if introduced before the hypoparathyroidism is recognized.

Some patients do not manifest all three primary elements of the HAM complex, while other individuals may develop additional endocrinopathies such as hypogonadism, insulin-dependent diabetes, hypothyroidism, and hypophysitis. Non-endocrine components of the disorder that occur frequently include malabsorption, pernicious anemia, vitiligo, alopecia, nail and dental dystrophy, autoimmune hepatitis, and biliary cirrhosis.

Reduced synthesis or secretion of PTH

Autosomal dominant hypocalcemic hypercalciuria (ADHH)

Autosomal dominant hypocalcemia (also autosomal dominant hyopocalcemic hypercalciuria, MIM 146200) most commonly occurs as a result of an activating mutation of the *CASR* gene (3q13.3-21) encoding the CaSR. Most mutations have been identified in the transmembrane and extracellular domains of the receptor and lower the set point for extracellular calcium sensing. The CaSR is widely expressed, but activating mutations have their most profound effects on calcium-induced signaling in the parathyroid gland and the kidney. The effect of the activating mutation on the parathyroid cell is to reduce PTH secretion and thereby produce a state of functional hypoparathyroidism. In the tubule cells of the thick ascending limb of the loop of Henle, activated CaSRs stimulate calciuresis and increase the fractional excretion of calcium (FeCa), thus producing relative (or absolute) hypercalciuria relative to the filtered load of calcium. Nephrocalcinosis and nephrolithiasis are common complications of vitamin D therapy. Although in most cases the degree of hypocalcemia and hypercalciuria are mild and well tolerated, in some patients severe hypocalcemia occurs. Some patients can develop a Bartter syndrome type picture (i.e., Type 5 Bartter syndrome).

PTH gene mutations

Rare mutations in the *PTH* gene (11p15.3-p15.1) have been associated with impaired synthesis and secretion of PTH. The human *PTH* gene contains three exons that encode the preproPTH hormone. Isolated hypoparathyroidism has been found in a family with a single base substitution in exon 2 of the *PTH* gene, apparently impeding conversion of preproPTH to proPTH. In another family with autosomal recessive isolated hypoparathyroidism, the entire exon 2 of the *PTH* gene was deleted, preventing generation of a mature secretory peptide. A missense mutation in exon 2 of the preproPTH gene has also been found, potentially impairing proteolytic cleavage of the preprohormone.

Anti-CaSR antibodies

Autoimmune hypoparathyroidism had been previously thought to be caused by the binding of cytotoxic autoantibodies to parathyroid cells. However, many patients with late onset primary hypoparathyroidism have circulating antibodies that activate the CaSR, and which do not produce irreversible destruction of the parathyroid glands. It appears that there might be a specific autoimmune reaction against the CaSR on parathyroid cells, although detection of antibodies against the receptor appears to be influenced by the assay system used. Recently, it was reported that 2 out of 53 patients with idiopathic hypoparathyroidism had remission after 1 year off calcium supplementation, supporting the idea of a possible temporary alteration in CaSR function as an etiology of hypoparathyroidism.

Other causes of hypoparathyroidism

Mitochondrial disease

Several syndromes due to deletions in mitochondrial DNA have been associated with hypoparathyroidism. These include the Kearns-Sayre syndrome (encephalomyopathy, ophthalmoplegia, retinitis pigmentosa, heart block), the Pearson Marrow-Pancreas syndrome (sideroblastic anemia, neutropenia, thrombocytopenia, pancreatic dysfunction), and the maternally inherited diabetes and deafness syndrome. Hypoparathyroidism has also been described in the MELAS (**M**itochondrial myopathy, **E**ncephalopathy, **L**actic Acidosis, and **S**troke-like episodes) syndrome, due to point mutations in mitochondrial tRNA. Because renal magnesium wasting is frequently seen in these conditions, a readily reversible form of hypoparathyroidism caused by hypomagnesemia should also be considered. In addition, mutations in the mitochondrial trifunctional protein (MTP), resulting in long-chain 3-hydroxy-acyl-coenzyme A dehydrogenase (LCHAD) deficiency, or combined MTP deficiency, have been associated with hypoparathyroidism in a few unrelated patients. This condition manifests as nonketotic hypoglycemia, cardiomyopathy, hepatic dysfunction,

and developmental delay, and is associated with maternal fatty liver of pregnancy.

Post-burn

In individuals who have sustained severe burns, there is evidence for upregulation of the CaSR. Lower than normal concentrations of serum calcium suppress PTH secretion, thus leading to hypocalcemia and hypoparathyroidism.

Maternal hyperparathyroidism and hypomagnesemia

An infant who is exposed *in utero* to maternal primary hyperparathyroidism or hypercalcemia can have suppressed parathyroid function and hypocalcemia during the first few weeks of life, but the duration may be up to 1 year of age. Although therapy may be required acutely, the disorder is usually self-limited. Hypomagnesemia caused by defective intestinal absorption or renal tubular reabsorption of magnesium may impair secretion of PTH and cause hypoparathyroidism. Magnesium replacement will correct the hypoparathyroidism.

DIAGNOSTIC ALGORITHM

PHP should be considered in any patient with functional hypoparathyroidism (i.e., hypocalcemia and hyperphosphatemia) and an elevated plasma concentration of PTH. Hypomagnesemia and severe vitamin D deficiency can produce biochemical features of PTH resistance in some patients, and thus plasma concentrations of magnesium and 25(OH)D must be measured. Unusual initial manifestations of PHP include neonatal hypothyroidism, unexplained cardiac failure, seizures, intracerebral calcification of basal ganglia and frontal lobes, dyskinesia and other movement disorders, and spinal cord compression.

PHP or pseudoPHP may be suspected in patients who present with somatic features of AHO. However, several aspects of AHO, such as obesity, round face, brachydactyly, and mental retardation also occur in other congenital disorders (e.g., Prader-Willi syndrome, acrodysostosis, Ullrich-Turner syndrome). An interesting phenocopy of AHO occurs in subjects who have small terminal deletions of chromosome 2q37 [del(2)(q37.3)]. These patients have normal endocrine function and normal $G\alpha_s$ activity.

The classical tests for PHP, the Ellsworth-Howard test, and later modifications by Chase, Melson, and Aurbach, involved the administration of 200–300 USP units of purified bovine PTH or parathyroid extract. Although these preparations are no longer available, a form of teriparatide, the 1-34 sequence of human PTH, is available and several protocols for its use in the differential diagnosis of hypoparathyroidism have been developed. These protocols are based on intravenous infusion of the peptide, but similar results may be obtained following subcutaneous injection. The patient should be fasting except for fluids (250 ml of water hourly from 6 a.m. to noon). Two control urine specimens are collected before 9 a.m. Teriparitide (0.625 µg/kg body weight to a maximum of 25 µg for intravenous use and 40 µg for subcutaneous use) is administered at 9 a.m. either by subcutaneous injection or intravenous infusion over 15 min, and experimental urine specimens are collected from 9:00 to 9:30, 9:30 to 10:00, 10:00 to 11:00, and 11:00 to 12:00. Blood samples should be obtained at 9 a.m. and 11 a.m. for measurement of serum creatinine and phosphorus concentrations. Urine samples are analyzed for cAMP, phosphorus, and creatinine concentrations, and results are expressed as nanomoles of cAMP per 100 ml GF and TmP/GFR.

Normal subjects usually show a 10- to 20-fold increase in urinary cAMP excretion and a 20–30% decrease in TmP/GFR, whereas patients with PHP type 1 (both 1a and 1b), regardless of their serum calcium concentration, will show markedly blunted responses (Fig. 72.2). Normal children and patients with HP have more robust responses. Thus, this test can distinguish patients with so-called normocalcemic PHP (i.e., patients with PTH resistance who are able to maintain normal serum calcium levels without treatment) from subjects with pseudoPHP (who will have a normal urinary cAMP response to PTH). Measurement of plasma cAMP or plasma 1,25-dihydroxyvitamin D after infusion of hPTH(1-34) may also differentiate PHP type 1 from other causes of hypoparathyroidism.

The diagnosis of PHP type 2 requires exclusion of magnesium depletion or vitamin D deficiency. Documentation of elevated serum PTH and nephrogenous cAMP is a prerequisite for a definitive diagnosis of PHP type 2. These subjects have a normal urinary cAMP response to infusion of PTH but characteristically fail to show a phosphaturic response. Unfortunately, interpretation of the phosphaturic response to PTH is often complicated by random variations in phosphate clearance, and it is sometimes not possible to classify a phosphaturic response as normal or subnormal regardless of the criteria employed.

Genetic testing can assist with the diagnosis of HP and PHP. Mutational analysis of the *CASR*, *AIRE*, *GCM2*, and *GNAS* genes is available from several approved clinical laboratories. By contrast, genetic testing for PHP 1b and most other forms of genetic hypoparathyroidism is still considered investigational.

THERAPY

Calcium and vitamin D

The goal of therapy in hypoparathyroidism is to restore serum calcium as close to normal as possible. The main pharmacologic agents available are supplemental calcium and vitamin D preparations. Phosphate binders, to lower

serum phosphate, and thiazide diuretics, to decrease urinary calcium excretion, may be useful ancillary agents. The major limitation to restoration of normocalcemia is the development of hypercalciuria, with a resulting risk for nephrolithiasis. With the loss of the renal calcium-conserving effect of PTH, the enhanced calcium absorption of the gut induced by vitamin D therapy results in an increased filtered load of calcium that is readily cleared through the kidney. Consequently, urinary calcium excretion frequently increases in response to vitamin D supplementation well before serum calcium is normalized. It is thus often advisable to maintain a low normal serum calcium concentration, so as to prevent chronic hypercalciuria. Avoidance of hypercalciuria is probably most important for patients with hypercalciuric hypocalcemia caused by activating mutations of the *CaSR* gene. Fortunately, patients with PHP type 1 rarely develop hypercalciuria as long as PTH levels remain unsuppressed as the distal tubule remains responsive.

Approximately 1–2 grams (25–50 mg/kg) of elemental calcium per day are recommended to supply adequate calcium and to manage dietary phosphorus intake, and optimal results are achieved when calcium supplements are taken with meals. Patients are unable to convert parent compounds of vitamin D to fully active forms as the lack of PTH and hyperphosphatemia both inhibit the renal 1-α hydroxylase enzyme that converts 25-hydroxyvitamin D to 1,25-dihydoxyvitamin D. The 1-α hydroxylated vitamin D metabolites (e.g., calcitriol) are the preferred forms of vitamin D as these drugs circumvent the enzymatic block in vitamin D activation. Because calcitriol has a plasma half-life of only hours and body stores do not accumulate, calcitriol must be given several times each day. By contrast, alfacalcidol (1α (OH)D_3) has a longer half-life and may be given once daily. A variety of parent vitamin D preparations have been used in the past, including vitamin D_3 or D_2; however, typically very large concentrations are required to raise the serum calcium. In this case, body stores of vitamin D can accumulate in massive amounts, increasing the risk of severe and prolonged vitamin D toxicity. Hydrochlorothiazide therapy has been effective in reducing the vitamin D requirement, but potassium supplementation is necessary to offset the thiazide-induced hypokalemia.

PTH treatment

Treatment of HP with PTH is an attractive option because it represents replacement with the hormone that is missing. Moreover, reducing calcium and calcitriol intake in HP offers the potential advantage of reducing urinary calcium excretion. An additional possible advantage is that because of its phosphaturic properties, PTH use may reduce the risk of soft tissue deposition of calcium in the kidneys (nephrocalcinosis, nephrolithiasis) and possibly in other soft tissues.

Replacement therapy using teriparatide in adults and children with HP has demonstrated that twice-daily administration could maintain serum calcium concentrations in the low-normal or just below normal range for prolonged periods of time. Markers of bone turnover are elevated in patients taking teriparatide. Bone density as measured by dual-energy X-ray absorptiometry (DXA) remains stable in adults, but, Z-scores at the 1/3 radius site are significantly decreased in children treated with teriparatide compared to treatment with calcitriol.

Treatment of adult patients with HP with PTH(1–84) every other day has shown a significant reduction in requirements for supplemental calcium and calcitriol. The every-other-day regimen produced significant increases in bone density at the lumbar spine and modest decreases at the distal 1/3 radius. PTH(1-84) treatment was associated with increases in markers of bone turnover, and bone biopsy showed structural changes that are consistent with an increased remodeling rate in both trabecular and cortical compartments, with tunneling resorption in the former and increased porosity in the latter.

The term "pseudohypoparathyroidism (PHP)" was first used in 1942 to describe a disorder of hormone resistance in which the most prominent defect involves target organ resistance to the actions of parathyroid hormone (PTH) thus leading to hypocalcemia and hyperphosphatemia [1], which is combined with reduced serum concentrations of 1,25-dihydroxyvitamin D_3 [2, 3]. As an indication of PTH-resistance, rather than PTH-deficiency as in hypoparathyroidism, serum PTH levels are elevated and administration of exogenous biologically active PTH fails to result in an appropriate increase in urinary phosphate and cyclic adenosine monophosphate (cAMP) excretion [1, 4]. PTH-resistance occurs in the proximal renal tubule, whereas no resistance appears to exist in other PTH target tissues, such as bone [5, 6] and the thick ascending tubule [7]. It is probably due to these non-impaired PTH functions that patients can sometimes maintain normocalcemia without treatment for prolonged periods of time. However, clinical manifestations of hypocalcemia, such as increased neuromuscular excitability or seizures, usually develop unless patients are appropriately treated with oral calcium supplements and 1,25 dihydroxyvitamin D. Treatment is also recommended for asymptomatic patients with normal calcium and phosphate levels if serum PTH levels are elevated, since long-term secondary hyperparathyroidism can result in severe hyperparathyroid bone disease [8].

Since the first description of PHP by Albright and colleagues [1], different variants of this disorder have been defined (Table 73.1). Patients with PHP type I (PHP-I) exhibit both impaired nephrogenous cAMP generation and impaired phosphate excretion following exogenous PTH administration [1, 4], while patients with PHP type II (PHP-II) exhibit a dissociation between these two responses, i.e., these patients have normal nephrogenous cAMP generation but impaired phosphate excretion [9]. Recently, it was shown that acrodysostosis, which represents a form of PHP-II, is caused by a mutation in the regulatory subunit of protein kinase A (PRKAR1A) downstream of Gsα because of increased basal and PTH-stimulated urinary cAMP excretion and the lack of a PTH-induced phosphaturic response. Consistent with these molecular findings, the impaired response to PTH was associated with resistance toward multiple other hormones that mediate their actions through several G protein-coupled receptors. These findings further highlight the importance of cAMP/PKA-mediated actions of PTH and other hormones that show resistance in different PHP variants [10]. However, this chapter will largely focus on the clinical and molecular definition of PHP-I and the subtypes thereof.

Acrodysostosis (PHP-II variant)	Yes	Yes	No	PRKAR1A

PHP-Ia, PHP-Ic, PPHP, AND POH: PHP VARIANTS THAT ARE CAUSED BY CODING MUTATIONS IN Gsα

Patients with PHP-Ia present with resistance to PTH and Albright's hereditary osteodystrophy (AHO), a constellation of physical features, which may include obesity, short stature, ectopic ossifications, brachydactyly, and/or mental retardation. PHP-Ia patients often also show resistance to other hormones, including thyroid-stimulating hormone (TSH), gonadotropins, calcitonin, and growth hormone-releasing hormone (GHRH) [11–16]. A common feature of these hormones is that their actions require cell surface receptors that couple to the stimulatory G protein. Accordingly, PHP-Ia is caused by heterozygous inactivating mutations located in *GNAS*, the gene encoding the α-subunit of the stimulatory G protein (Gsα) (Fig. 73.1); these mutations are all located on the maternal allele.

Gsα is a ubiquitous signaling protein required for agonist activated stimulation of adenylyl cyclase, which in turn generates cyclic AMP (cAMP), an intracellular second messenger involved in numerous cellular responses throughout the body [17]. Illustrating the importance of the Gsα-mediated cellular responses, homozygous ablation of Gsα leads to embryonic lethality in mice [18–20]. Numerous different *GNAS* mutations, including missense and nonsense amino acid changes, as well as insertions and deletions, have been identified in patients with PHP-Ia (see Online Mendelian Inheritance in Man #103580 at http://www.ncbi.nlm.nih.gov/ for a list of allelic variants). Consistent with their loss-of-function effects, these mutations are located in nearly all of the 13 exons that encode Gsα and lead to an approximately 50% reduction in Gsα mRNA/protein, which can be demonstrated in skin fibroblasts and erythrocyte membranes derived from PHP-Ia patients [12].

PHP-Ic is a variant originally used to describe patients who present with clinical findings that are identical to those found in patients with PHP-Ia but demonstrate normal Gsα bioactivity in red blood cells [21]. However, recent studies suggest that a substantial portion of PHP-Ic cases are allelic variants of PHP-Ia [22–24]. Several PHP-Ic patients have been reported to carry mutations that render Gsα seemingly functional in routinely used Gsα bioactivity tests in which the stimulation is done by guanosine triphosphate (GTP). The mutations disrupt the receptor-coupling ability of Gsα but do not impair its basal activity, thus allowing a full response to GTP stimulation. However, it remains possible that some PHP-Ic patients carry mutations in a different gene, which, when mutated, prevents elevation of cAMP. This gene could perhaps encode one of the cAMP phosphodiesterases or adenylyl cyclases.

Inactivating Gsα mutations are also found in patients who display AHO features but lack hormone resistance. This disorder has been named pseudopseudohypoparathyroidism (PPHP) [25]. Patients with PHP-Ia and those with PPHP are typically found in the same kindreds but never within the same sibship. While AHO occurs in the offspring irrespective of the gender of the parent transmitting the Gsα mutation, development of hormone resistance is subject to imprinting such that it develops only in the offspring of female obligate carriers [26, 27]. Thus, paternal inheritance of a Gsα mutation results in PPHP (AHO only), whereas maternal inheritance of the same mutation results in PHP-Ia (AHO and hormone resistance). Consistent with the imprinted mode of inheritance observed for the hormone resistance, recent investigations of the *GNAS* locus have revealed predominantly maternal expression of Gsα in some, but not all, tissues, including renal proximal tubules, thyroid, pituitary, and gonads (see below).

Heterozygous inactivating Gsα mutations are also found in patients with progressive osseous heteroplasia (POH), who have severe heterotopic ossifications that affect skeletal muscle and deep connective tissue [28]. Some of these Gsα mutations are identical to those found in PHP-Ia or PPHP patients, indicating that POH is an extreme manifestation of heterotopic ossifications associated with AHO [28–32]. Only few POH patients present with hormone resistance and/or AHO features [29, 33],

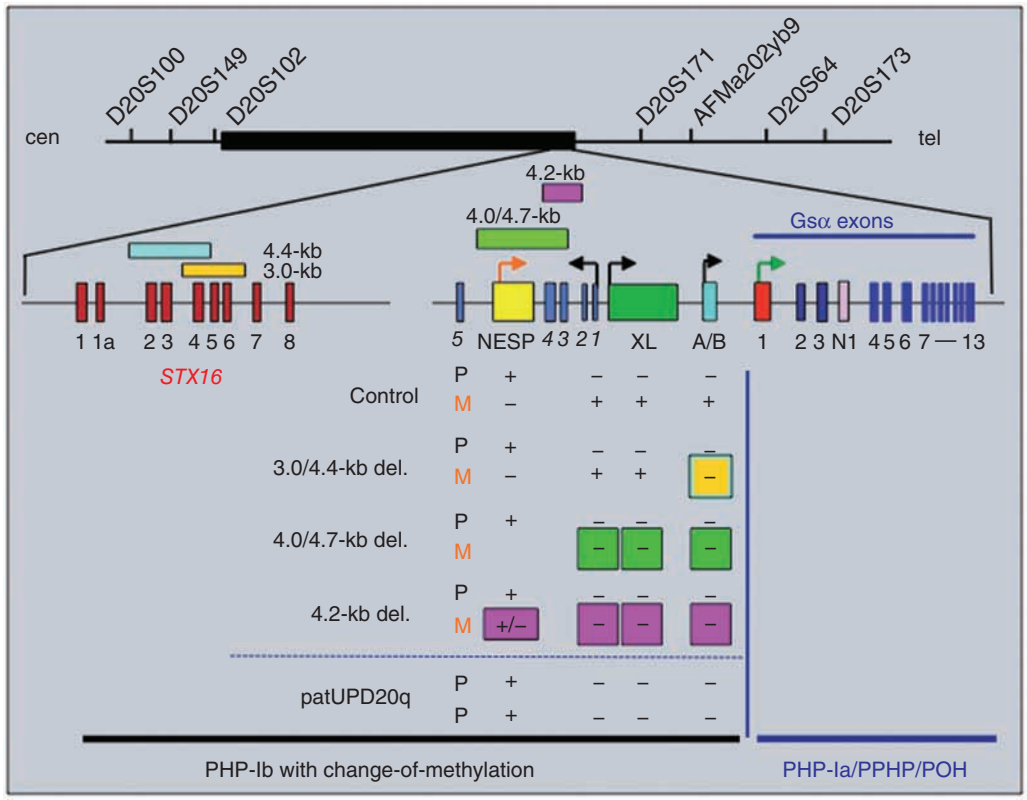

Fig. 73.1. The *GNAS* locus: parent-specific exon methylation and locations of heterozygous mutations. Gsα mutations (dark blue exons) cause PHP-Ia/PPHP/POH (Refs. 96, 97). AD-PHP-Ib is caused by *STX16* deletions located more than 200 kb upstream of *GNAS* (yellow and light blue horizontal bars) or by deletions within *GNAS* (green and purple bars); these disease variants are associated with loss of *GNAS* methylation restricted to exon A/B alone or with methylation changes at multiple exons. Sporadic PHP-Ib can be caused by paternal uniparental isodisomy for chromosome 20q (patUPD20q). Boxes, exons; connecting lines, introns. Paternal (P), maternal (M); methylated (+); unmethylated (–); paternal transcription (black arrows); maternal transcription (orange arrow); green arrow, biallelic Gsα transcription in some tissues.

and consistent with this observation, nearly all cases with POH are caused by paternally inherited mutations. The reasons for this strong parental bias in the development of POH currently remains unknown, although it is possible that deficiency of other products of the *GNAS* gene, which show imprinted expression and are also disrupted by most of these mutations, contribute to the molecular pathology.

Gsα TRANSCRIPTS ARE DERIVED IN SOME TISSUES ONLY FROM THE MATERNAL ALLELE

Inactivating Gsα mutations can lead to various different phenotypes, and genomic imprinting appears to play an important role in the development of these phenotypes. Genomic imprinting refers to differential expression of genes specifically from either maternal or paternal alleles [34–36]. This monoallelic, parental origin-specific expression correlates with allele-specific epigenetic marks within the imprinted gene (often at the promoter region), including methylation of the cytosine residues in CpG dinucleotides. Although the Gsα promoter itself lacks differential methylation [37–39], several studies in genetically manipulated animals have established that Gsα expression is predominantly maternal in a small number of tissues, i.e., Gsα transcription from the paternal *GNAS* allele is silenced [18, 40, 41]. Consistent with these findings in mutant mouse strains, kindreds with PHP-Ia and PPHP have revealed the importance of Gsα silencing in different tissues, particularly the proximal renal tubules where Gsα is predominantly or exclusively derived from the maternal allele. Thus, hormonal resistance develops in the proximal tubule if a Gsα mutation occurs on the maternal allele, while distal tubular functions, such as PTH-dependent calcium reabsorption, remain intact because of the biallelic expression of Gsα in this portion of the renal tubules. Note that such a mutation would reduce the level of Gsα by 50% in the distal tubule, but this reduction appears to be compatible with complete function (Fig. 73.2).

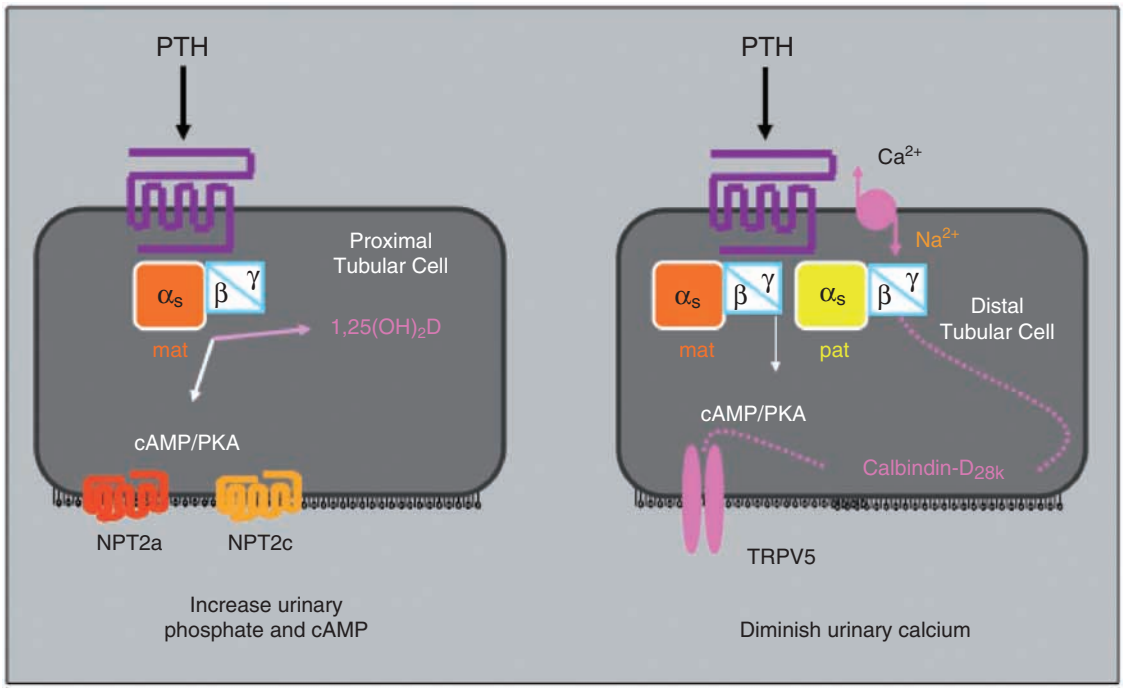

Fig. 73.2. PTH/PTHrP receptor activation in the kidney. The stimulatory G protein (Gsα), which mediates most PTH actions, is transcribed in the proximal renal tubules predominantly from the maternal allele; Gsα is biallelically transcribed in the distal tubules. PTH-stimulated cAMP production in proximal tubules and subsequent PKA activation reduces NPT2a and NPT2c (Refs. 98, 99) and increases 1,25(OH)$_2$ vitamin D production (Refs. 100, 101) ; cAMP is exported through unknown transporters into urine, a unique mechanism for limiting the intracellular level of this second messenger. In the distal tubules, PTH enhances expression of the calcium transporter TRPV5, at least partially through cAMP/PKA-dependent mechanisms, thereby reducing urinary calcium losses (Refs. 10, 102).

Analysis of various fetal and adult human tissues has also revealed imprinting of Gsα in some other tissues. Besides the proximal renal tubules, Gsα expression appears to be predominantly maternal in thyroid gland [42–44], gonads [42], and pituitary [45]. Conversely, Gsα expression has been shown to be biallelic in a number of different fetal tissues [46], as well as adult adrenal gland, bone, and adipose tissue [42, 47]. In addition, one study demonstrated biallelic Gsα expression in human fetal renal cortices [48]. Although apparently contradictory to the findings in mice [18], the latter finding may suggest that Gsα imprinting in this tissue is postnatal and/or exists only in a small number of renal cortical cells. Overall, however, the tissue distribution of imprinted Gsα expression appears to correlate well with the tissue distribution of hormone resistance in patients with PHP-Ia. This is consistent with the prediction that an inactivating Gsα mutation leads to a dramatic decrease in the Gsα level/activity and, thereby, hormone resistance only in tissues in which Gsα expression is predominantly maternal. Conversely, the same mutation causes no detectable change in the Gsα level/activity in the same tissues following paternal inheritance. Tissues in which Gsα is expressed biallelically are predicted to have approximately 50% reduction of Gsα level/activity. While this reduction may be sufficient for maintaining normal cellular responses in some cells, it may lead to defective function in others, i.e., haploinsufficiency. In fact, because AHO features appear to develop independently of the gender of the parent transmitting the Gsα mutation, these features are thought to result from haploinsufficiency of Gsα signaling in various tissues. This conclusion is consistent with the growth plate findings in mice chimeric for wild-type and *Gnas* exon 2-disrupted embryonic stem cells that show only minor differences in the acceleration of hypertrophic differentiation irrespective of whether the genetically manipulated cells were maternally or paternally derived [49]. Similarly, subcutaneous heterotopic ossifications indistinguishable from those observed in AHO occur with disruption of *Gnas* exon 1 on either parental allele [50]. Nonetheless, given the patient-to-patient variability in the expression and severity of individual AHO features, it remains possible that imprinting of Gsα (or other imprinted *GNAS* transcripts) also contributes to the development of certain AHO features. In fact, it has been recently revealed that obesity and cognitive impairment, two classic features of AHO, develop primarily after maternal inheritance of Gαs mutations [51, 52], and this imprinted mode of inheritance correlates well with the monoallelic expression of Gαs in certain brain regions, as demonstrated in mice [53]. The imprinting of *GNAS* could also play a role

in the pathogenesis of POH, considering the predominantly paternal inheritance of POH [30–32].

MULTIPLE MATERNAL OR PATERNAL TRANSCRIPTS ARE DERIVED FROM THE *GNAS* LOCUS

Recent studies have revealed that in addition to Gsα, the *GNAS* locus gives rise to multiple coding and non-coding transcripts that show parental origin-specific expression (Fig. 73.1). Gsα is encoded by 13 exons that span about 20 kb [54]. There are four different splice variants of Gsα formed through the alternative use of exon 3, as well as an additional codon inserted alternatively at the 5′ end of exon 4 [55, 56]. In addition, the use of another alternative exon (N1) between exons 3 and 4 leads to a truncated Gsα mRNA and protein [57].

Studies of the genomic region comprising *GNAS* have led to the identification of several novel exons located upstream of exon 1 both in humans and mice. XLαs and NESP55 transcripts individually use separate upstream promoters and first exons that splice onto exons 2-13 of the Gsα transcript [38, 39]. Protein sequence identity over this region, however, exists only between XLαs and Gsα [58], since exons 2-13 in the NESP55 transcript are part of the 3′ untranslated region [59, 60]. XLαs and the neuroendocrine secretory protein-55 (NESP55) are oppositely imprinted; while XLαs is expressed from the paternal *GNAS* allele [38, 39], NESP55, which is a chromogranin-like protein abundant in neuroendocrine tissues, is expressed from the maternal *GNAS* allele [39, 60]. XLαs also shows abundant expression in neuroendocrine tissues and the central nervous system, although its mRNA is detected in multiple other tissues, including adipose tissue, pancreas, and kidney [61–63]. In addition to these protein products, the *GNAS* locus gives rise to a sense and an antisense non-coding transcript, each of which is expressed from the paternal allele. The transcript from the antisense strand (AS) has a promoter that is adjacent to the promoter of the XLαs transcript [64, 65]. The non-coding transcript from the sense strand, termed "A/B" (also referred to as 1A or 1′), comprises exons 2-13, but uses, like XLαs and NESP55 transcripts, a separate promoter and first exon [37, 66, 67]. As in other imprinted genomic loci, the promoters of these additional *GNAS* transcripts, but not the promoter of Gsα, are within differentially methylated regions (DMRs), and the non-methylated promoter drives the expression in each case [37–39, 60, 64, 65].

Currently, the biological significance of the imprinted *GNAS* transcripts is poorly understood. As mentioned above, NESP55 belongs to the family of chromogranins and is associated with constitutive secretory pathway in neurons and neuroendocrine cells [68]. Targeted disruption of the NESP55 protein in mice leads to abnormal reactivity to novel environments [69]. XLαs shares marked amino acid sequence identity with Gsα and comprises most of the domains shown to be functionally important for the latter [58]. Accordingly, XLαs can mediate basal and agonist-induced adenylyl cyclase stimulation [70, 71]. In addition, when targeted to the renal proximal tubule in mice, XLαs can mitigate the PTH-resistance phenotype caused by Gsα deficiency [72]. Targeted disruption of the XLαs protein in mice, however, has thus far failed to reveal phenotypes that are unequivocally caused by a loss of the "Gsα-like" signaling activity of this protein *in vivo* [63]. In fact, current evidence from the XLαs knockout mice suggests that XLαs may oppose Gsα actions in certain tissues, such as brown fat [63]. Mice lacking XLαs fail to adapt to feeding and show high early postnatal mortality. In addition, these mice show various defects in energy and glucose metabolism, including reduced adiposity in both brown and white fat and impaired metabolic responses to hypoglycemia [63]. The subcellular trafficking of XLαs upon activation has been shown to differ markedly from that of Gsα [73], and this difference could perhaps provide some explanation as to why XLαs appears to oppose Gsα actions in certain settings. Furthermore, recent studies have shown that an exon A/B-derived transcript results in a Gsα variant that is amino-terminally truncated and reduces the activity of full-length Gsα [74].

PHP-Ib: HORMONE-RESISTANCE CAUSED BY ABNORMAL Gsα IMPRINTING

PHP-Ib was initially defined as a disorder characterized by selective PTH-resistance, normal Gsα activity in fibroblasts and red blood cells, and lack of AHO features [12]. However, although PTH resistance remains the most prominent biochemical defect, numerous PHP-Ib patients were shown to present also with resistance toward TSH [44, 75, 76]; furthermore, recent findings have revealed usually mild, but distinct AHO features in a significant number of patients with PHP-Ib due to *GNAS* methylation changes [77–81].

Based on epigenetic changes at different *GNAS* exons/promoters and different microdeletion within or upstream of the *GNAS* locus, several different forms of PHP-Ib have been defined (see Figs. 73.1 and 73.3). As in PHP-Ia, the genetic defects in the autosomal dominant forms of PHP-Ib (AD-PHP-Ib) lead to hormone resistance only after maternal transmission. The most frequent genetic mutation leading to AD-PHP-Ib is a 3-kb deletion within the gene encoding syntaxin-16 (*STX16*) located about 220 kb centrometric of the *GNAS* locus [82–85]. This deletion is associated with a loss of methylation at *GNAS* exon A/B and biallelic expression of this transcript, which is thought to reduce Gsα expression in those tissues that normally express Gsα from the maternal allele, thus causing hormonal resistance. In a single AD-PHP-Ib kindred, another heterozygous, maternally inherited *STX16* deletion has been discovered, which is 4.4 kb in size [86]. The latter deletion overlaps with the

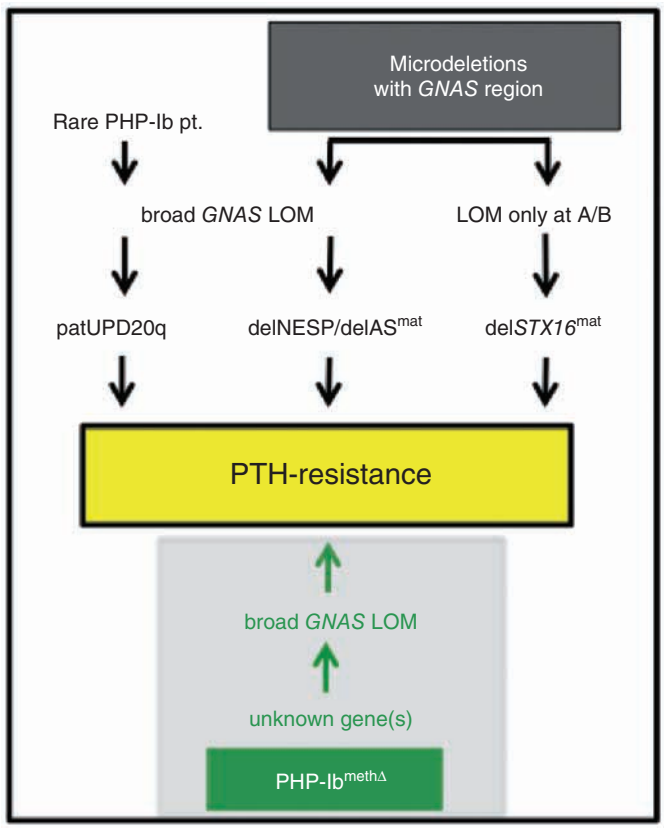

Fig. 73.3. Grouping of PHP-Ib variants according to their epigenetic and genetic findings. Autosomal dominant PHP-Ib (AD-PHP-Ib) can be caused either by *STX16* deletions with associated loss-of-methylation (LOM) at *GNAS* exon A/B alone (del*STX-16*^{mat}) (Refs. 82–86) or deletions involving NESP55 and/or antisense exons 3-4 with associated LOM at *GNAS* exons XL, AS, and A/B (delNESP/delAS^{mat}) (Refs. 88, 89). Sporadic PHP-Ib with complete LOM at *GNAS* exons XL, AS, and A/B, and complete gain-of-methylation at exon NESP55 can be due to uniparental paternal isodisomy involving chromosome 20q (patUPD20q) (Refs. 76, 91). Sporadic PHP-Ib variants with LOM at *GNAS* exons XL, AS, and A/B (often incomplete) and occasionally incomplete gain-of-methylation at exon NESP55 (PHP-Ib$^{meth\Delta}$); linkage to *GNAS* has been excluded in some of these sporadic patients and is highly unlikely in others (Refs. 90, 94).

frequently observed 3-kb deletion and removes exons 2-4 of *STX16*. Thus, both the 3-kb and 4.4-kb deletions are predicted to lead to an inactive syntaxin-16 protein on one allele. Nevertheless, given that PHP-Ib develops after maternal inheritance of the genetic defect only, which is consistent with the inheritance mode of the identified mutations in affected individuals, loss of one copy of *STX16* could cause PHP-Ib only if this gene were also imprinted. However, based on methylation and allelic expression analyses using lymphoblastoid cells derived from PHP-Ib patients and normal controls, *STX16* does not appear to be imprinted [86], and therefore it appears unlikely that syntaxin-16 is involved in the molecular pathogenesis of PHP-Ib. In fact, disruption of *Stx16* in mice does not lead to any epigenetic or laboratory abnormalities in mice [87].

In other AD-PHP-Ib forms, deletions within the *GNAS* locus that remove either exon NESP55 and antisense exons 3 and 4 [88], or both antisense exons alone [89] have been identified (see Fig. 73.1). These deletions are associated with loss of all maternal *GNAS* methylation imprints, although the biochemical abnormalities appear to be indistinguishable from those observed in patients with AD-PHP-Ib caused by *STX16* deletions [90]. Demonstrating that defective *GNAS* imprinting alone can lead to PTH-resistance, some sporadic cases of PHP-Ib are caused by paternal uniparental isodisomy of chromosome 20q and, as a consequence, a "paternal-only" imprinting profile throughout the *GNAS* locus [76, 91, 92].

Similar to the PHP-Ib caused by *GNAS* deletions or patUPD20q, most sporadic PHP-Ib cases exhibit methylation defects involving exon A/B and all or some of the other *GNAS* DMRs [75, 80, 88, 90, 93–95]. NESP55 or antisense deletions similar to those found in three AD-PHP-Ib kindreds [88, 89] or patUPD20q have been ruled out in a large number of such sporadic PHP-Ib cases; in fact, in some patients the *GNAS* locus could be excluded genetically [94]. It is therefore conceivable that sporadic PHP-Ib cases carry defects in a gene that is distinct from *GNAS*. The identification of the genetic defects in sporadic PHP-Ib cases may help identify additional genes that are involved in establishing or maintaining *GNAS* methylation or that contribute to Gsα silencing in different tissues.

TREATMENT

In treatment, the goal is to correct abnormal serum biochemistries that result from PTH and, in some cases, other hormone resistance. The distal tubular actions of PTH in PHP patients are not impaired, providing sufficient calcium reabsorption from the glomerular filtrate. This makes clinical management of hypocalcemia in PHP easier than that of hypoparathyroidism. The treatment involves oral calcium supplements and $1,25(OH)_2D$ (calcitriol) preparations. It is important to note that the active form of vitamin D is required in the treatment due to the lowered capacity of the proximal tubule to convert 25(OH)D into the biologically active $1,25(OH)_2D$. The treatment should aim to keep the serum PTH level within or close to the normal range rather than simply avoiding symptomatic hypocalcemia, because persistent elevation of serum PTH will increase bone resorption and may eventually lead to hyperparathyroid bone disease. During the course of the treatment, urinary calcium typically does not rise owing to intact PTH actions in the distal tubule. Nevertheless, annual monitoring of blood chemistries and urinary calcium excretion is necessary in patients undergoing treatment. More

frequent analyses are recommended during pubertal development and once skeletal growth is completed, as the dosing of calcium supplements and $1,25(OH)_2D$ preparations may need to be adjusted.

SUMMARY AND CONCLUSIONS

Maternally inherited mutations involving the *GNAS* exons that encode Gsα are responsible for PHP-Ia, while these mutations, when inherited paternally, lead to PPHP or POH. AD-PHP-Ib is caused by maternally inherited microdeletions within or upstream of *GNAS*, and these are associated with loss of some or all maternal *GNAS* methylation imprints; thus, impaired Gsα expression in those tissues where paternal Gsα expression is silenced. Indistinguishable *GNAS* methylation changes are also observed in PHP-Ib due to patUPD20q, while the cause of sporadic PHP-Ib and the associated *GNAS* methylation changes remains to be determined.

INTRODUCTION

Phosphorus is a critical element in skeletal development, bone mineralization, membrane composition, nucleotide structure, and cellular signaling. The physiological control of phosphate homeostasis and the major hormonal regulators of phosphate homeostasis [e.g., fibroblast growth factor 23 (FGF23), $1,25(OH)_2D$, PTH] are discussed in detail elsewhere in the *Primer*. Serum phosphorus concentration is regulated by diet, hormones, pH, and changes in renal, skeletal, and intestinal function. The focus of this chapter is the molecular basis of human disorders of phosphate homeostasis. In recent years, advances in defining the precise molecular defects in both acquired and inherited hypo and hyperphosphatemic syndromes have catapulted our understanding of phosphate homeostatic mechanisms to a new level.

HYPOPHOSPHATEMIA

Clinical consequences

Hypophosphatemia is common and is observed in up to 5% of hospitalized patients [1, 2]. Among alcoholic patients and those with severe sepsis, up to a 30–50% prevalence has been reported.

The clinical manifestations of hypophosphatemia are dependent on the severity and chronicity of the phosphorus depletion.

Common clinical settings in which severe hypophosphatemia is observed include chronic alcoholism, nutritional repletion in at risk individuals, treatment of diabetic ketoacidosis, and in critical illness.

The symptoms of hypophosphatemia are a direct consequence of intracellular phosphorus depletion: (1) tissue hypoxia caused by reduced 2,3-diphosphoglycerate (2,3-DPG) in the erythrocyte that increases affinity of hemoglobin for oxygen and (2) diminished tissue content of ATP that compromises cellular function.

Causes of hypophosphatemia

The three major mechanisms by which hypophosphatemia can occur are (1) redistribution of phosphorus from extracellular fluid into cells, (2) increased urinary excretion, and (3) decreased intestinal absorption. The diagnosis of hypophosphatemia is often evident from the history; if, however, the diagnosis remains obscure, measurement of urinary phosphate excretion is indicated. Urinary phosphate excretion can be measured from a 24-hour collection or from a random urine specimen by calculation of fractional excretion of filtered phosphate (FEPO4): $FEPO_4 = [UPO_4 \times PCr \times 100]/[PPO_4 \times UCr]$, where U and P are urine and plasma concentrations of phosphate (PO_4)

and creatinine (Cr). In the setting of hypophosphatemia, fractional excretion of phosphate greater than 5% or a 24-hour urinary phosphate excretion that exceeds 100 mg/day is indicative of renal phosphate wasting.

The causes of hypophosphatemia are found in Table 74.1. Hypophosphatemia secondary to renal phosphate wasting has a wide differential diagnosis. These disorders can result from primary renal transport defects, excess PTH, FGF23, KLOTHO or other phosphaturic proteins (Fig. 74.1). The etiologies of hypophosphatemia due to renal phosphate wasting are discussed in more detail below.

Table 74.1. Causes of Hypophosphatemia

Decreased intestinal absorption
- Vitamin D deficiency or resistance
  - Nutritional deficiency
    - Low sun exposure, low dietary intake
  - Malabsorption
    - Celiac disease, Crohn's disease
    - Gastrectomy, bowel resection, gastric bypass
    - Pancreatitis
    - Chronic diarrhea
  - Chronic liver disease
  - Chronic renal disease
  - Increased catabolism
    - Anticonvulsant therapy
  - Vitamin D receptor defects
    - Vitamin D-dependent rickets, type 2
  - Vitamin D synthetic defects
    - CYP27B1 (vitamin D-dependent rickets, type 1)
    - CYP27A1
- Nutritional deficiencies
  - Alcoholism, anorexia, starvation
- Antacids containing aluminum or magnesium

Increased urinary losses
- Renal phosphate wasting disorders (Table 74.2)
- Primary and secondary hyperparathyroidism
- Diabetic ketoacidosis (osmotic diuresis)
- Medications
  - Calcitonin, diuretics, glucocorticoids, bicarbonate
- Acute volume expansion

Intracellular shifts
- Increased insulin
  - Re-feeding, treatment of DKA, insulin therapy
- Hungry bone syndrome
- Acute respiratory alkalosis
- Tumor consumption
  - Leukemia blast crisis, lymphoma
- Sepsis
- Sugars
  - Glucose, fructose, glycerol
- Recovery from metabolic acidosis

TUMOR-INDUCED OSTEOMALACIA

Tumor-induced osteomalacia (TIO), or oncogenic osteomalacia, is an acquired, paraneoplastic syndrome of renal phosphate wasting that resembles genetic forms of hypophosphatemic rickets. First described in 1947 [3], clinical and experimental studies implicate the humoral factor(s) that tumors produce in the profound biochemical and skeletal alterations that characterize TIO. To date 337 cases have been reported in the literature [4].

Clinical and biochemical manifestations

Although the preponderance of TIO patients are adults (usually diagnosed in the sixth decade), this syndrome may present at any age. These patients report long-standing progressive muscle and bone pain. Children with TIO display rachitic features including gait disturbances, growth retardation, and skeletal deformities. The occult nature of TIO delays its recognition, and the average time from onset of symptoms to a correct diagnosis often exceeds 2.5 years [5]. Once the syndrome is recognized, an average of 5 years elapses from the time of diagnosis to the identification of the underlying tumor [6]. Until the underlying tumor is identified, other renal phosphate wasting syndromes must be considered. Identification of a previously normal serum phosphorus level in an adult patient supports the diagnosis of TIO, although in rare instances patients with autosomal dominant hypophosphatemic rickets (ADHR) can present in adulthood. In situations when inherited hypophosphatemic rickets must be excluded, genetic testing for mutations in the *PHEX* gene, *FGF23* gene, and *DMP1* and *ENPP1* gene is indicated.

The biochemical hallmarks of TIO are low serum concentrations of phosphorus, phosphaturia (secondary to reduced proximal renal tubular phosphate reabsorption), and frankly low or inappropriate normal levels of serum calcitriol [$1,25(OH)_2D_3$] that are expected to be elevated in the face of hypophosphatemia (Table 74.2). Calcium and PTH are typically normal. Bone histomorphometry shows severe osteomalacia with clear evidence of a mineralization defect with increased mineralization lag time and excessive osteoid (Fig. 74.2). The dual defect of renal phosphate wasting in concert with impaired calcitriol [$1,25(OH)_2D_3$] synthesis results in poor bone mineralization and fractures [7].

The mesenchymal tumors that are associated with TIO are characteristically slow-growing, polymorphous neoplasms with the preponderance being phosphaturic mesenchymal tumor, mixed connective tissue type [8, 9] (PMTMCT; Fig. 74.2). Characterized by an admixture of spindle cells, osteoclast-like giant cells, prominent blood vessels, cartilage-like matrix, and metaplastic bone, these tumors occur equally in soft tissue and bone. Although typically benign, malignant variants of PMTMCT have been described. These mesenchymal tumors ectopically express and secrete FGF23 and other

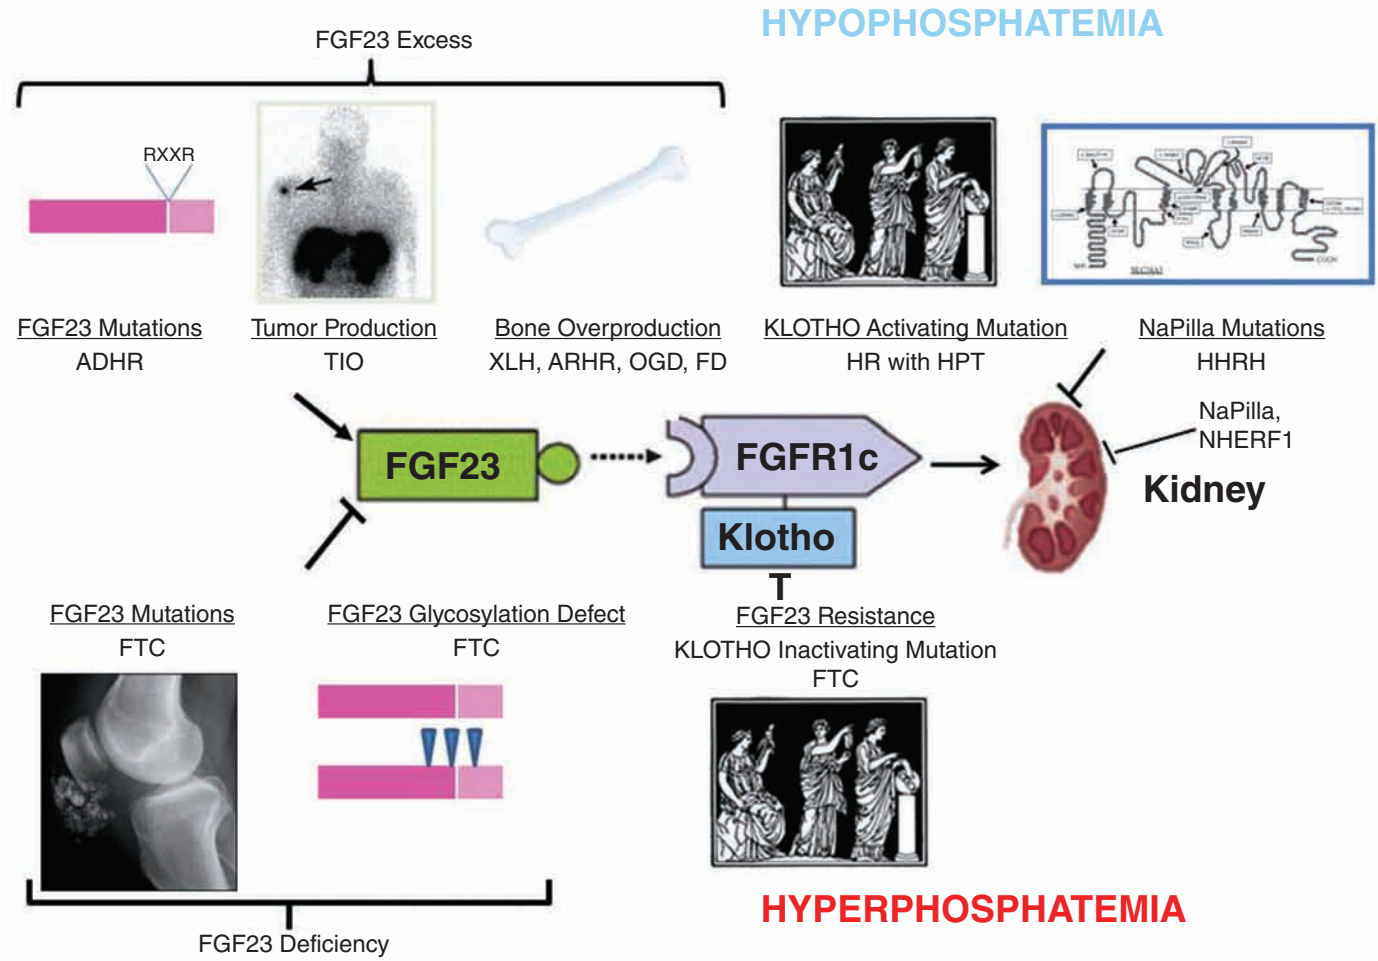

Fig. 74.1. Molecular mechanisms of disorders of phosphate homeostasis. Three major mechanisms of hypophosphatemia are (1) FGF23 excess owing to ectopic production as in TIO; (2) excess bone production seen in XLH, ARHR, ADHR, FD and OGD; and (3) mutation in the FGF23 gene that renders the protein resistant to inactivation. Hypophosphatemia may also be secondary to excess KLOTHO, the cofactor necessary for FGF23 signaling as seen in a patient with hypophosphatemic rickets with hyperparathyroidism. Finally, homozygous inactivating mutations in SLC34A3, which encodes NaPiIIc, or dominant negative mutations in SLC34A2 that encodes NaPiIIa, result in phosphate wasting due to absence of sodium–phosphate cotransporters.

Hyperphosphatemia is due to FGF23 deficiency, either through inactivating mutations in FGF23, aberrant glycosylation of FGF23 owing to GALNT3 mutations, or FGF23 resistance due to inactivating KLOTHO mutations.

phosphaturic proteins [10, 11]. FGF23, a circulating fibroblast growth factor produced by osteocytes and osteoblasts [12, 13] has two currently known physiologic functions: first, FGF23 promotes internalization of NaPiIIa and NaPiIIc from the renal brush border membrane and thus reduces reabsorption of urinary phosphorus resulting in hypophosphatemia [14, 15]. Second, it diminishes protein expression of the 25 hydroxy-l-α-hydroxylase enzyme that converts vitamin D to its active form, $1,25(OH)_2D_3$ [16] while increasing the activity of the vitamin D 24-hydroxylase enzyme, which converts vitamin D to an inactive form. This leads to disruption in the compensatory increase in $1,25(OH)_2D_3$ triggered by hypophosphatemia [17]. Circulating levels of FGF23 are elevated in most patients with TIO [18]. After surgical resection, FGF23 levels plummet. Other secreted proteins such as MEPE (matrix extracellular phosphoglycoprotein), FGF7, and sFRP4 (secreted frizzled related protein 4) are highly expressed in mesenchymal tumors associated with TIO, but the role of each of these "phosphatonins" in the disease process remains obscure.

Treatment

Detection and localization of the culprit tumor in TIO is imperative because complete surgical resection is curative. However, the mesenchymal tumors that cause this syndrome are often small, slow growing, and frequently found in a variety of anatomical locations, including the

Table 74.2. Characteristics of Renal Phosphate Wasting Disorders

Disease (OMIM)	Defect	Pathogenesis
TIO	Mesenchymal tumor	Ectopic, unregulated production of FGF23 and other phosphatonins sFRP4, MEPE, FGF7
XLH (307800)	*PHEX* mutation	Inappropriate FGF23 synthesis from bone
ADHR (193100	*FGF23* mutation	Increased circulating intact FGF23 caused by mutations that render it resistant to cleavage
HHRH (241530)	*SLC34A3* mutation	Loss of function NaPiIIc mutations that result in renal phosphate wasting without a defect in $1,25(OH)_2D_3$ synthesis
ARHR1 (241520)	*DMP1* mutation	Loss of DMP1 causes impaired osteocyte differentiation and increased production of FGF23
ARHR2 (613312)	*ENPP1* mutation	Increased production of FGF23
HR and HPT (612089)	*α-KLOTHO* translocation	Increased KLOTHO, FGF23, and downstream FGF23 signaling
Fibrous dysplasia (139320)	*GNAS* mutation	Increased FGF23 production from the dysplastic bone
Linear nevus sebaceous syndrome	Excess FGF23 production	Increased FGF23 production from the dysplastic bone and from the nevi
OGD (166250)	*FGFR1* mutation	Increased FGF23 production from the dysplastic bone
NPHLOP1 (612286)	*SLC34A1* mutation	Renal phosphate wasting without a defect in $1,25(OH)_2D_3$ synthesis
NPHLOP2 (612287)	*SLC9A3R1* mutation	Renal phosphate wasting through potentiation of PTH-mediated cAMP production
FRTS2 (613388)	*SLC34A1* mutation	Renal phosphate wasting without a defect in $1,25(OH)_2D_3$ synthesis

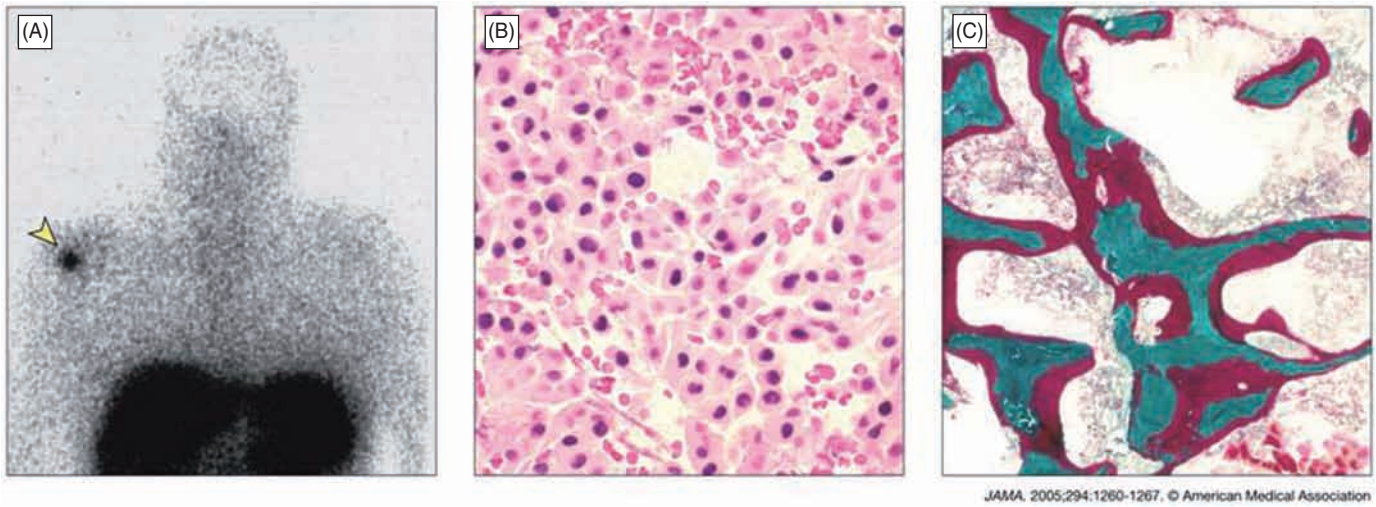

Fig. 74.2. Radiographic and histologic features in TIO. (A)Octreotide scan showing a small mesenchymal tumor in the head of the humerus. (B) Hemiangiopericytoma with numerous pericytes and vascular channels (H&E strain). (C) Bone biopsy with Goldner stain. Excessive osteoid or unmineralized bone matrix composed mainly of collagen stains pink. Mineralized bone stains blue. This bone biopsy shows severe osteomalacia.

long bones, the distal extremities, the nasopharynx, the sinuses, and the groin. A thorough physical examination should be performed in order to assess any palpable masses as the tumors have been found in the subcutaneous tissues. The size and obscure locations make the tumors difficult to localize with conventional imaging techniques. Frequently, a combination of functional and anatomical approaches must be pursued in order to localize the tumor [4]. Because *in vitro* studies show that many mesenchymal tumors express somatostatin receptors (SSTRs)^{111}In-pentetreotide scintigraphy (octreotide scan; Fig. 74.2), a scanning technique that uses a radiolabeled somatostatin analog, has been used to successfully detect and localize these tumors in some patients with TIO [19–21]. Successful tumor localization has been reported with other imaging techniques such as whole body MRI [22] and FDG-PET/CT [23]. Venous sampling for FGF23 has also been used in order to localize causative tumors in patients with TIO but seems to be more suited for confirmation that a mass seen on imaging is producing FGF23 than the *de novo* localization of the tumor [24].

The definitive treatment for TIO is complete tumor resection, which results in rapid correction of the biochemical perturbations and remineralization of bone. Radiofrequency ablation has been reported to have been beneficial in a case report [25]. However, even after the diagnosis of TIO is made, the tumor often remains obscure or incompletely resected. Therefore, medical management is frequently necessary. The current practice is to treat TIO with phosphorus supplementation in combination with calcitriol. The phosphorus supplementation serves to replace ongoing renal phosphorus loss, and the calcitriol supplements replace insufficient renal production of $1,25(OH)_2D_3$ and enhances renal and gastrointestinal phosphorus reabsorption. Generally, patients are treated with phosphorus (1–2 g/day), in divided doses 3–4 doses daily, and calcitriol (1–3 μg/day). In some cases, administration of calcitriol alone may improve the biochemical abnormalities seen in TIO and heal the osteomalacia. Therapy and dosing should be tailored to improve symptoms and normalize alkaline phosphatase. With appropriate treatment, muscle and bone pain will improve, and healing of the osteomalacia will ensue.

Monitoring for therapeutic complications is important to prevent unintended hypercalcemia, nephrocalcinosis, and nephrolithiasis. The true incidence of hyperparathyroidism with prolonged treatment with phosphorus (alone or in combination with calcitriol) is unknown. To assess safety and efficacy of therapy, monitoring of serum and urine calcium, renal function, and parathyroid status is recommended at least monthly at the initiation of treatment and every 3 months when on chronic therapy. There have been reports of the use cinacalcet in patients who did not tolerate medical therapy with phosphorus and calcitriol [26]. This therapy allowed a decrease in the phosphorus dose to one that was tolerated. Octreotide *in vitro* and *in vivo* has been shown to inhibit secretion of hormones by many neuroendocrine tumors; however, because of the limited and mixed experience with octreotide treatment in TIO [21, 27] this therapy should be reserved for the most severe cases that are refractory to current medical therapy.

X-LINKED HYPOPHOSPHATEMIC RICKETS

First described by Albright in 1939 [28], X-linked hypophosphatemic rickets (XLH) is characterized by growth retardation, rachitic and osteomalacic bone disease, and dental abscesses. It is the most common disorder of renal phosphate wasting, occurring in 3.9–5 per 100,000 live births.

Genetics

Although the X-linked inheritance was first detailed in 1958 [29], it was not until the 1990s that the genetic basis of XLH was elucidated as mutations in *PHEX* (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) [30]. To date, more than 285 mutations have been described (PHEX database: www.PHEXdb.mcgill.ca). The *PHEX* gene codes for a protein of unknown function that is a member of the M13 family of membrane-bound metalloproteases that is present in osteoblasts, osteocytes, and odontoblasts but not in kidney tubules [31].

Clinical and biochemical manifestations

Before children begin to walk, clinical findings may be limited. The majority of testing that is done on infants is because of a known family history of XLH. After the child is ambulatory, progressive lower extremity bowing may become apparent with a decrease in height velocity and be associated with bone and/or joint pain. There may be dental manifestations, including abscessed noncarious teeth, enamel defects, enlarged pulp chambers, and taurodontism. Cranial abnormalities with frontal bossing and an increased anteroposterior skull length have been reported. Adults may exhibit bone and joint pain from osteomalacia, pseudofractures, and enthesopathy. Biochemically, the laboratory findings in XLH are indistinguishable from TIO (Table 74.1), with low serum concentrations of phosphorus, phosphaturia, and frankly low or inappropriate normal levels of serum $1,25(OH)_2D_3$. Calcium and parathyroid hormone (PTH) are typically normal. In infants the diagnosis may be difficult to establish as the phosphorus levels may initially be normal. This can be compounded by the fact that the infant normal range is substantial higher than that of older children and so the low phosphorus may go unrecognized. The biochemical profile suggests that regulators of phosphate other than PTH and vitamin D play a role

in the development of XLH. Increasing evidence suggests that FGF23 is key in the pathogenesis of XLH. Whereas PHEX does not seem to cleave FGF23 directly, serum FGF23 levels are inappropriately normal or elevated in XLH patients, and FGF23 expression is increased in the bones of *hyp* mice, a murine model of XLH [18, 32–36]. These observations suggest that PHEX is involved in downregulation and control of FGF23; however, the precise interplay between FGF23 and PHEX is not currently understood. The diagnosis of XLH is based on a consistent medical history and physical examination, radiological evidence of rachitic disease, appropriate biochemical findings, and a family history consistent with multigenerational or sporadic occurrence of the disorder. Mutational analysis of the *PHEX* gene is available; however, studies have shown that mutations can only be found in 50–70% of affected individuals [37].

Treatment and complications

Treatment is similar for most patients and consists of oral phosphate administered three to five times daily and high-dose calcitriol. The treatment is generally started at a low dose to avoid gastrointestinal side effects. The doses are then titrated to a weight-based dose of calcitriol at 20 to 30 ng/kg/day along with phosphorus at 20 to 40 mg/kg/day administered in three to five divided doses [38]. Some clinicians favor a high-dose phase of treatment for up to a year. The high-dose phase consists of calcitriol at 50–70 ng/kg/day (up to a maximum dose of 3.0 mcg daily) along with the phosphate [39]. There has been no comparison between the two different regimens.

The treatment leads to resolution of radiographic rickets and improved, but not normal, growth. Subsequent studies have shown that age at initiation of therapy, height at initiation of therapy, and possibly the sex of the patient influence peak height attainment. Patients who do not respond to pharmacologic therapy may require surgical intervention to correct the lower extremity deformities. Because of lower bone turnover and the closure of the epiphyseal plates, the therapeutic requirements drop dramatically as children enter adulthood. In adults, the role of therapy is unclear. As adults, patients may be treated with no medications, a low dose of calcitriol, low doses of phosphorus, or with both calcitriol and phosphorus. It is unknown which patients require long-term treatment and which patients can have their treatment safely discontinued as adults. Symptomatic adults may benefit from therapy with improvement of symptoms and in bone architecture and prevention of osteomalacia. In adults, treatment is indicated in those with spontaneous insufficiency fractures, pending orthopedic procedures, biochemical evidence of osteomalacia and disabling skeletal pain [40]. There is a current clinical trial evaluating the use of a monoclonal antibody to FGF23 for the treatment of XLH in adults (http://www.clinicaltrials.gov, keyword KRN23). Although data have shown that bone mineral density (BMD) may be increased at the spine of patients with XLH, this may reflect, in part, calcific enthesopathy, and it is unclear if there is a change in long-term fracture rates. It has been shown that serum FGF23 levels increase with calcitriol and phosphorus treatment. The clinical significance of this is unknown [41]. Interestingly, in a small study of short-term treatment of adult XLH patients with subcutaneous calcitonin, there was a transient increase in serum phosphorus with a decrease in serum FGF23 levels [42]. Further studies are needed to determine if this is an efficacious treatment for XLH. Complications of treatment are similar to those in TIO.

AUTOSOMAL DOMINANT HYPOPHOSPHATEMIC RICKETS

Autosomal dominant hypophosphatemic rickets (ADHR) is a rare form of hypophosphatemic rickets with clinical characteristic similar to XLH.

Genetics

Multiple early reports documented an inheritance renal phosphate wasting syndrome with a pattern that included male-to-male transmission that distinguished it from XLH [43, 44]. Furthermore, the incomplete penetrance of disease observed within affected families was atypical of XLH. Positional mapping, cloning, and sequence analysis established that FGF23 was mutated in ADHR [45, 46]. Missense mutations in one of two arginine residues at positions 176 or 179 have been identified in affected members of ADHR families. The mutated arginine residues, located in the consensus proprotein convertase cleavage RXXR motif, prevent inactivation of FGF23 and thus result in prolonged or enhanced FGF23 action [47].

Clinical and biochemical manifestations

The clinical and biochemical findings in ADHR are similar to those observed in XLH (Table 74.1). In contrast to XLH, there are instances of delayed onset and rarely, resolution of the phosphate wasting [48]. FGF23 levels have been shown to vary with disease status in ADHR [49]. Within the same family, there can be variable presentations with two subgroups of affected individuals described. Those with childhood onset have biochemical and clinical similarities to XLH, whereas those presenting later often lack lower extremity deformities, presumably because of fusion of the growth plate before the development of hypophosphatemia. Recent studies have implicated iron-deficient states in the late manifestation of ADHR. Furthermore, low levels of iron in ADHR subjects are associated with higher FGF23 levels [50].

Treatment

Treatment is similar to that of patients with XLH, consisting of phosphate and calcitriol. As in XLH, patients who do not respond to pharmacologic therapy may require surgical intervention to straighten bowed limbs.

OTHER DISORDERS OF RENAL PHOSPHATE WASTING

Hereditary hypophosphatemic rickets with hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare genetic form of hypophosphatemic rickets characterized by hypophosphatemia, renal phosphate wasting, and preserved responsiveness of $1,25(OH)_2D_3$ to hypophosphatemia (Table 74.1). This appropriate increase in calcitriol leads to increased calcium absorption from the gastrointestinal tract and thus to hypercalciuria and nephrolithiasis. The genetic defect in HHRH is loss of function mutations in the gene that encodes NaPiIIc (SLC34A3) [51, 52], one of three subtypes of the type II sodium phosphate cotransporters. The mutations can be either heterozygous or homozygous loss-of-function mutations in SLC34A3 [53]. HHRH is clinically similar to TIO, yet the distinction is easily made with biochemical testing, with HHRH exhibiting elevated levels of calcitriol and hypercalciuria. Treatment consists of phosphate supplements alone.

Autosomal recessive hypophosphatemic rickets

Mutations in two different genes have been identified in autosomal recessive hypophosphatemic rickets (ARHR). Loss-of-function mutations in dentin matrix protein 1 (DMP-l), a matrix protein related to MEPE and a member of the SIBLING (small integrin binding ligand N-linked glycoprotein) family have been described in ARHR1 [54, 55]. Interestingly, this protein seems to have two functions: it translocates into the nucleus to regulate gene transcription early in osteocyte proliferation and, likely in response to calcium fluxes, becomes phosphorylated and is exported to the extracellular matrix to facilitate mineralization by hydroxyapatite in a process that requires appropriate cleavage of the full-length protein. Loss of DMP-1 function in ARHR leads to modestly and variably increased serum FGF23, dramatically increased expression of FGF23 in bone, defects in osteocyte differentiation, and impaired skeletal mineralization. It seems that the immature osteocytes overproduce FGF23, which acts on the kidney, resulting in phosphaturia and impaired calcitriol synthesis.

Mutations in a second gene, ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) have also been described in ARHR (ARHR2). ENPP1 has been previously linked to the development of generalized arterial calcification of infancy. It is a regulator of extracellular pyrophosphate and is required for bone mineralization with phosphate. Loss-of-function mutations were observed in five families with ARHR2 [56, 57]. As in XLH, treatment consists of high dose phosphate and calcitriol.

Hypophosphatemic rickets with hyperparathyroidism

Brownstein et al. reported a patient with hypophosphatemic rickets and hyperparathyroidism [58]. The patient had renal phosphate wasting, inappropriately normal $1,25(OH)_2D_3$, and hyperparathyroidism secondary to a genetic translocation resulting in increased levels of α-KLOTHO, the cofactor necessary for FGF23 to bind and activate its receptor (Table 74.1). Interestingly and somewhat unexpectedly, FGF23 serum levels are also markedly elevated in this disorder. These findings implicate α-KLOTHO in the regulation of serum phosphate, FGF23 expression, and parathyroid function.

Fibrous dysplasia

Polyostotic fibrous dysplasia is caused by activating missense mutations in *GNAS* gene, which leads to hormone-independent activation of G-protein (Gsα)-coupled signaling. In fibrous dysplasia, there is replacement of medullary bone and bone marrow with undermineralized bone and fibrotic bone marrow. Evaluation of the fibrous dysplastic bone with pyrosequencing has shown that the presence of GSα mutations in the bone can differentiate fibrous dysplasia from benign fibrous osseous lesions [59].

McCune-Albright syndrome is characterized by the triad of precocious puberty, *café au lait* lesions, and fibrous dysplasia, although other hyperfunctioning endocrine disorders and phosphate wasting may also be found in this condition. Recent evidence has implicated FGF23 as a key component of the phosphate loss in both McCune-Albright related and isolated fibrous dysplasia, the degree of fibrous dysplasia correlating with the degree of phosphate wasting [13]. There has been some debate over whether the hypophosphatemia should be treated if there is no evidence for pathologic rickets. When it is treated, treatment and complication considerations are as for XLH [60].

Linear nevus sebaceous syndrome

Linear nevus sebaceous syndrome (also known as epidermal nevus syndrome) is a rare form of hypophosphatemic rickets. Affected individuals have clinical evidence of multiple cutaneous nevi with radiological evidence of fibrous dysplasia. It is frequently associated with a severe form of hypophosphatemic rickets. Elevated levels of FGF23 are thought to contribute to the renal phosphate

wasting [61]. As in XLH, treatment consists of frequently dosed phosphate and calcitriol.

Osteoglophonic dysplasia

As in fibrous dysplasia, renal phosphate wasting and lower than expected calcitriol levels have been observed in osteoglophonic dysplasia (OGD). This is a rare autosomal dominantly inherited form of dwarfism caused by activating mutations in FGF receptor 1 (FGFR1; Table 74.1) [62]. Some but not all patients display phosphate wasting, with the mechanism of the phosphate wasting presumed to be from the high burden of nonossifying bony lesions often seen in these patients. FGF23 produced by the abnormal bone is likely responsible, because the extent of bone lesions is correlated with FGF23 levels and the degree of phosphate wasting.

Hypophosphatemic nephrolithiasis/osteoporosis 1 and 2

Two patients with hypophosphatemia secondary to renal phosphate wasting and osteopenia or nephrolithiasis (NPHLOP1) were found to have heterozygous, dominant negative, mutations in the renal type IIa sodium–phosphate cotransporter gene (SLC34A1) [63]. The prominent symptoms of bone pain and muscle weakness seen in TIO were absent in the affected patients.

Hypophosphatemia associated with nephrolithiasis and low BMD (NPHLOP2) has also been found in connection with mutations in the sodium/hydrogen exchanger regulatory factor 1 (SLC9A3R1)[64].

Fanconi renotubular syndrome 2

Another hypophosphatemic syndrome associated with SLC34A1 mutations has been described [65]. Two patients with autosomal recessive renal Fanconi's syndrome and hypophosphatemic rickets (FRTS2) harbored in-frame duplication of SLC34A1. The patients presented with bone deformities, fractures, and severe short stature. Similar to HHRH, in both SLC34A1 loss of function syndromes, there are hypercalciuria and elevated calcitriol levels.

In summary, either through mutations of the sodium–phosphate transporters themselves, damage to the proximal renal tubule or through aberrant regulation of FGF23, decreased expression or function of the renal sodium–phosphate cotransporters likely represents the common pathway in renal phosphate wasting observed in these syndromes (Fig. 74.1).

HYPERPHOSPHATEMIA

Serum inorganic phosphorus levels are generally maintained 2.5–4.5 mg/dl (0.8075–1.45 mmol/L) in adults and between 6 and 7 mg/dl in children younger than 2 years old. In steady state, oral phosphate loads of up to 4,000 mg/day can be efficiently excreted by the kidneys with minimal rise in serum phosphorus through down-regulation of the sodium–phosphate cotransporter in the proximal renal tubules. Increased PTH secretion also contributes to increased renal phosphate excretion because excess phosphorus complexes with calcium, resulting in a decrease in ionized calcium, which stimulates PTH secretion. There are four general mechanisms whereby phosphate entry into the extracellular fluid can outstrip the rate of renal excretion: (1) acute exogenous phosphate loads, (2) redistribution of intracellular phosphate to the extracellular space, (3) decreased renal excretion, and (4) pseudohyperphosphatemia caused by interference with analytical detection methods.

Clinical Manifestations of hyperphosphatemia

The most common and clinically significant consequence of acute, short-term hyperphosphatemia is hypocalcemia and tetany. With rapid elevations in phosphate load, hypocalcemia and tetany can occur. Hyperphosphatemia suppresses the renal 1 α hydroxylase enzyme, reducing circulating $1,25(OH)_2D_3$, which further aggravates hypocalcemia by impairing intestinal calcium absorption.

In contrast, consequences of chronic hyperphosphatemia include soft tissue calcification and in the case of renal failure, secondary hyperparathyroidism, and renal osteodystrophy. In the setting of chronic kidney disease, the defenses against mineralization are compromised and hyperphosphatemia promotes mineral deposition in soft tissues. Hyperphosphatemia stimulates vascular cells to undergo osteogenic differentiation. Calcification of coronary arteries and heart valves is associated with hypertension, congestive heart failure, coronary artery disease, and myocardial infarction. Medial calcification of peripheral arteries associated with hyperphosphatemia may lead to calciphylaxis, a disorder with high mortality and morbidity.

Hyperphosphatemia that results from renal failure plays a major role in the development of secondary hyperparathyroidism and renal osteodystrophy. This is discussed in detail in Chapter 77 and Chapter 78.

Causes of hyperphosphatemia

The causes of hyperphosphatemia are enumerated in Table 74.3. Genetic causes of hyperphosphatemia are discussed in more detail below.

FAMILIAL TUMORAL CALCINOSIS

Hyperphosphatemic familial tumoral calcinosis (HFTC; MIM# 211900) is an inherited disorder notable for pro-

Table 74.3. Causes of Hyperphosphatemia

Mechanism	Etiology
Decreased renal excretion	Renal insufficiency/failure
	Hypoparathyroidism
	Pseudohypoparathyroidism
	Tumoral calcinosis
	Acromegaly
	Bisphosphonates
Acute phosphate load	Phosphate containing laxatives
	Fleet's phosphosoda enemas
	Intravenous phosphate
	Parental nutrition
Redistribution to the extracellular space	Tumor lysis
	Rhabdomyolysis
	Acidosis
	Hemolytic Anemia
	Severe Hyperthermia
	Fulminant Hepatitis
	Systemic infections
Pseudohyperphosphatemia	Hyperglobulinemia
	Hyperlipidemia
	Hemolysis
	Hyperbilirubinemia

gressive deposition of calcium phosphate crystals in periarticular spaces and soft tissues. There are both hyperphosphatemic and normophosphatemic forms (NFTC; MIM# 610455) of this disorder.

Genetics

To date, there have been mutations found in four different genes among the families with FTC. In the normophosphatenic form, mutations in sterile α motif domain-containing-9 protein (SAMD9; MIM# 610456) have been described. For the hyperphosphatemic form, inactivating mutations have been found in UDP-N-acetyl-α-D-galactosamine: polypeptide N-acetylgalactosaminyltransferase 3(GALNT3; MIM# 601756)[66], FGF23 [67], and KLOTHO [68] (Fig. 74.1). The mutations lead to loss of function resulting in inadequate FGF23 protein levels or FGF23 action. All patients have biallelic mutations indicating an autosomal recessive inheritance pattern.

Clinical and biochemical manifestations

Patients with FTC have heterotopic calcifications that are typically painless and slow growing; however, the masses can become painful if they infiltrate into adjacent structures. The clinical complications are related to masses near and the infiltration of skin, marrow, teeth, blood vessels, and nerves. Range of motion is generally not affected unless the masses become large. A variably present feature of the disease is an abnormality in dentition, characterized by short bulbous roots, pulp stones, and radicular dentin deposited in swirls. Biochemically, along with the hyperphosphatemia, there is increased $1,25(OH)_2D_3$ with normal calcium and alkaline phosphatase levels. Urinary phosphate excretion is frequently low. Radiographs show large aggregates of irregularly dense calcified lobules.

TREATMENT OF HYPERPHOSPHATEMIA

Treatment of hyperphosphatemia should address the underlying etiology. In the case of acute exogenous phosphorus overload, prompt discontinuation of supplemental phosphate and hydration allow for rapid renal excretion and correction of hyperphosphatemia. When transcellular shifts are the cause of hyperphosphatemia (e.g., tumor lysis, rhabdomyolysis), dietary phosphate restriction and diuresis are often successful. In diabetic ketoacidosis (DKA), treatment with insulin and treatment of acidosis reverses the hyperphosphatemia. Phosphate binders such as calcium salts, sevelamer, and lanthanum carbonate, along with dietary restriction, are indicated in renal failure. Hemodialysis may be indicated in acute hyperphosphatemia in the setting of renal dysfunction.

In familial tumoral calcinosis (FTC), medical therapy with aluminum hydroxide along with dietary phosphate and calcium deprivation has been utilized.

Use of the phosphate binder, sevelamer, and the carbonic anhydrase inhibitor, acetazolamide, have been reported to successfully decrease tumor burden. Surgical intervention is generally considered an option in patients when the masses are painful, interfere with function, or are cosmetically unacceptable.

INTRODUCTION

Nutritional vitamin D deficiency causes insufficient mineralization and rickets in the growing child (Fig. 75.1) or osteomalacia in the adult, when the epiphyseal lines have closed. This is the classical vitamin D–related disease [1]. The active vitamin D metabolite 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] stimulates the absorption of calcium and phosphate from the gut and makes calcium and phosphate available for mineralization. In mild or moderate vitamin D deficiency, a lower serum calcium concentration causes stimulation of the parathyroid glands. The increased serum parathyroid hormone (PTH) increases the conversion of 25-hydroxyvitamin D [25(OH)D] to 1,25$(OH)_2$D as a compensatory mechanism. However, the rise of PTH increases bone resorption. In this way, vitamin D deficiency may also cause bone loss and contribute to the pathogenesis of osteoporosis [2].

Rickets and osteomalacia are associated with muscular weakness, and recently it has become clear that mild and moderate vitamin D deficiency may be associated with decreased physical performance and falls [3–5]. *In vitro* and *in vivo* studies have shown that 1,25$(OH)_2$D has many actions such as stimulating osteoblasts and longitudinal growth, stimulating the development of the immune system, decreasing proliferation and stimulating differentiation of many cell types, stimulating insulin release and increasing insulin sensitivity [6–8]. During the past few years, vitamin D deficiency has been associated with autoimmune diseases such as diabetes mellitus type 1 and multiple sclerosis, infectious diseases such as tuberculosis, diabetes mellitus type 2, cardiovascular diseases, several types of cancer, and depression [9–11]. In this chapter, the more classical vitamin D–related disorders will be discussed such as nutritional rickets and osteomalacia, genetic disorders of vitamin D synthesis and function. Vitamin D intoxication will be discussed.

NUTRITIONAL RICKETS AND OSTEOMALACIA

The classical picture of nutritional rickets was first described in the 17th century by Whistler and Glisson [2]. The association between rickets and low sunshine exposure was first recognized in the 19th century, and in the beginning of the 20th century rickets, it was experimentally cured by artificial UV light or sunshine [12]. The spectrum of rickets and osteomalacia includes

Table 75.1. Causes of Rickets and Osteomalacia

Vitamin D–related rickets/osteomalacia
- Nutritional: low sunshine exposure, low dietary intake
- Malabsorption: celiac disease, Crohn's disease, gastrectomy, gastric bypass, bowel resection, pancreatitis
- Impaired hydroxylation in liver: severe chronic liver disease
- Impaired renal function: renal osteodystrophy/ osteomalacia
- Increased renal loss: nephrotic syndrome
- Increased catabolism: anticonvulsant therapy
- Non-functioning 25-hydroxylase OMIM #600081
- Absent 1α-hydroxylase: pseudo-vitamin D deficiency rickets (vitamin D–dependent rickets type 1) OMIM #264700*
- Non-functioning VDR: hereditary vitamin D–resistant rickets (vitamin D–dependent rickets type 2), OMIM #277440

Hypophosphatemic rickets/osteomalacia: renal phosphate wasting
- X-linked hypophosphatemic rickets, OMIM #307800*
- Autosomal dominant hypophosphatemic rickets, OMIM #193100*
- Autosomal recessive hypophosphatemic rickets type 1, OMIM # 241520, type 2 OMIM #613312
- Hereditary hypophosphatemic rickets with hypercalciuria, OMIM #241530
- Oncogenic osteomalacia*
- Fanconi syndrome, metabolic acidosis

Calcium deficiency: very low calcium intake in children

Miscellaneous:
- Aluminium intoxication
- Cadmium intoxication
- Etidronate overdose (in Paget's disease)
- Hypophosphatasia, OMIM #146300

*Associated with low serum $1,25(OH)_2D$.

vitamin D–related and other causes such as liver disease, malabsorption, drugs and renal diseases (Table 75.1).

VITAMIN D DEFICIENCY: DEFINITION, THRESHOLD

Vitamin D_3 is produced by the skin after sunlight exposure and is for a small part available from dietary sources. Fatty fish is the most important dietary source. Fortification of foods, e.g., milk, with vitamin D is practiced in the United States of America, Sweden, and Ireland. Following production in the skin, vitamin D is hydroxylated in the liver to 25(OH)D, which is further hydroxylated in the kidney to $1,25(OH)_2D$, the active metabolite.

Vitamin D status is usually assessed by measuring the serum concentration of 25(OH)D [13]. There is no consensus about the required level of serum 25(OH)D. It has been defined by some as the concentration of serum 25(OH)D that maximally suppresses serum PTH. In some studies among healthy elderly, serum PTH was at its lowest point when serum 25(OH)D was around 75 nmol/l (30 ng/ml), but in other studies serum PTH still decreased when serum 25(OH)D was higher than 100 nmol/l [14]. Another approach is to define thresholds of serum 25(OH)D for different outcomes. Clinical rickets or osteomalacia usually occurs with severe vitamin D deficiency, i.e., very low levels of serum 25(OH)D, often lower than 15 nmol/l (6 ng/ml). At this concentration, serum $1,25(OH)_2D$ is decreased as is calcium absorption [15]. In a round table discussion of experts, the proposed

Table 75.2. Classification of Vitamin D Deficient Status

	25(OH)D nmol/l (ng/ml)	$1,25(OH)_2D$ pmol/l (pg/ml)	PTH Increase	Bone Histology
Severe deficiency	<12.5 (<5)	(relatively) low	>30%*	incipient or overt osteomalacia
Deficiency	12.5–25 (5–10)	normal	15–30%	high turnover
Insufficiency	25–50 (10–20)	normal	5–15%	normal or high turnover
Replete	>50 (>20)	normal	–	normal

*Often accompanied by low serum calcium and phosphate, increased alkaline phosphatase, and low 24-hour urinary calcium excretion.

minimally required level of serum 25(OH)D, optimal for fracture prevention, varied between 50 and 75 nmol/l (20–30 ng/ml) [16]. According to a review based on epidemiological data, the most advantageous serum concentration of 25(OH)D for bone mineral density, lower extremity function, falls, fractures, and colorectal cancer is more than 75 nmol/l (30 ng/ml) [17]. In a Dutch cohort study, optimal serum 25(OH)D levels were observed at 40 nmol/l (16 ng/ml) for bone turnover markers, at 50 nmol/l (20 ng/l) for bone mineral density, and at 50–60 nmol/l for physical performance [14]. A consensus at the 13th Vitamin D Workshop agreed that serum 25(OH)D should be higher than 50 nmol/l (20 ng/ml) [18]. In 2010, the Institute of Medicine defined the required serum 25(OH)D level to be 50 nmol/l (20 ng/ml). The Recommended Daily Allowance, i.e., the intake level that is likely to meet the needs of about 97.5% of the population, was defined as 600 IU/day for children from 1 year to adulthood, and 800 IU/day for persons older than 70 years [19]. For the purpose of this chapter, vitamin D deficiency is defined as serum 25(OH)D lower than 25 nmol/l (10 ng/ml). Higher levels of serum 25(OH)D between 25 and 50 nmol/l (10–20 ng/ml), i.e., vitamin D insufficiency, are also associated with secondary hyperparathyroidism and decreased physical performance [14]. Both vitamin D deficiency and insufficiency should be prevented, i.e., serum 25(OH)D should be over 50 nmol/l. The staging of vitamin D status is presented in Table 75.2.

EPIDEMIOLOGY AND RISK GROUPS

Vitamin D deficiency is very common in certain risk groups, such as children (especially premature and dysmature children), pregnant women, the elderly, and non-Western immigrants. Low serum 25(OH)D levels were not only reported in children [20], but also in adolescents and young adults [21]. This may be caused by low sun exposure, reduced synthesis or intake of vitamin D_3 (e.g., being born to a vitamin D deficient mother, dark skin color), malabsorption (e.g., small-bowel disorders), or increased degradation of 25(OH)D (antiepileptics) [22]. Elderly people have decreased dermal synthesis, and especially elderly people who do not come outside frequently are at high risk. Non-Western immigrants migrating to countries at higher latitudes with limited UV-B irradiation are at high risk because of more pigmented skin, the habit to stay out of the sun, the wearing of well-covering clothes, and their diet. Non-Western pregnant women and their children are at a very high risk, and serum 25(OH)D was lower than 25 nmol/l (10 ng/ml) in 85% of pregnant women in a Dutch survey [23, 24].

Large differences in vitamin D status exist between various countries worldwide. It was estimated that less than 50% of the world population has an adequate vitamin D status (greater than 50 nmol/l or 20 ng/ml) [25]. In Europe, a north–south gradient was observed for serum 25(OH)D with higher levels in Scandinavia and lower levels in Southern and Eastern European countries [26]. This points to other determinants, e.g., nutrition, food fortification and supplement use, and cultural habits, e.g., sun-seeking or sun-avoiding behavior. Severe vitamin D deficiency has been reported in the Middle East, China, Mongolia, and India [25].

PATHOGENESIS

While 25(OH)D is the major circulating metabolite and store of vitamin D, almost all vitamin D actions are ascribed to the active metabolite $1,25(OH)_2D$. This metabolite behaves as a steroid hormone that functions through a nuclear receptor, the vitamin D receptor (VDR). After binding to the VDR and dimerization with the retinoid X receptor, the complex binds to specific DNA regions and more than 300 genes can be activated [8]. Proteins are formed such as the calcium binding protein or calbindin thereby increasing the active calcium absorption in the gut. The enzymatic conversion of 25(OH)D into $1,25(OH)_2D$ is stimulated by PTH. The active metabolite also stimulates bone resorption and decreases PTH secretion. In osteocytes $1,25(OH)_2D$ stimulates fibroblast growth factor 23 (FGF23) expression. FGF-23 functions in the kidney as a phosphaturic hormone, and inhibits 1-alphahydroxylase, resulting in less $1,25(OH)_2D$. This results in a balanced serum calcium concentration [27].

Studies in the vitamin D receptor null mouse have demonstrated the pleiotropic effect of $1,25(OH)_2D$.

Studies in transgenic mice demonstrated that direct binding of $1,25(OH)_2D$ to the VDR in cells of the osteoblastic lineage results in a catabolic or anabolic effect depending on the maturation of these cells. The predominant action seems enhancement of the receptor activator of nuclear factor-κB ligand (RANKL) and reduction of osteoprotegerin, thereby stimulating osteoclast formation, but stimulation of osteoblastic genes involved in bone formation such as osteocalcin and osteopontin has also been demonstrated [28, 29].

In cases of children with vitamin D deficiency, the newly formed bone of the growth plate does not mineralize, and cartilage proliferation is prolonged. The growth plate becomes thick, wide and irregular. This results in the clinical diagnosis of rickets [1].

In adults, the newly formed bone matrix, the osteoid, does not mineralize and osteomalacia occurs. Osteomalacia may be suspected on a clinical basis, especially in case of risk factors, including malabsorption, celiac disease or severe liver disease (Table 75.1). Laboratory abnormalities may also point to the diagnosis. Vitamin D also has many nonskeletal effects. The VDR is not only observed in the classical target cells for $1,25(OH)_2D$ but also in the skin, promyelocytes, lymphocytes, colon cells, pituitary cells, and ovarian cells [11]. The function of vitamin D in these tissues has not yet been fully elucidated. The active vitamin D metabolite decreases cell proliferation, and this is applied in practice for the treatment of psoriasis [12]. It is a potent immunomodulator and may play a role in the prevention of autoimmune diseases such as multiple sclerosis and diabetes mellitus type 1 [10]. It has also been implicated in the defense against tuberculosis and other respiratory infections, insulin release and insulin sensitivity, and emotional and cognitive disorders.

CLINICAL PICTURE

The causes of rickets and osteomalacia are summarized in Table 75.1. The clinical picture of rickets is characterized by decreased longitudinal growth, widening of the epiphyseal zones, and painful swelling around these zones [30]. The bowing of the tubular bones is due to poor mineralization of the growing skeleton. Special features include the rachitic rosary caused by swelling of the cartilage of the ribs. Rachitic children do not grow well and exhibit slowed developmental milestones such as walking. The clinical features of osteomalacia include bone pain, muscular weakness, and difficulty with walking. The muscular weakness is preferential to the proximal muscles around shoulder and pelvic girdle. It is manifest with standing up from a chair or stair climbing. When serum calcium is very low in patients with rickets or osteomalacia, symptoms of low serum calcium level may prevail such as tetany and convulsions. Fractures may occur because the quantity of mineralized bone in osteomalacia is low, similar to that in osteoporosis.

LABORATORY

Vitamin D deficiency is diagnosed by measuring serum 25(OH)D. Rickets and osteomalacia are associated with a serum 25(OH)D lower than 25 nmol/l, and often lower than 12.5 nmol/l [15, 31]. Characteristic laboratory findings include a low serum calcium and phosphate concentration or overt hypophosphatemia and an increased level of alkaline phosphatase. The serum concentration of PTH is usually increased (secondary hyperparathyroidism). The serum concentration of $1,25(OH)_2D$ is not helpful as it is normal in most patients with vitamin D deficiency [13, 15]. When serum 25(OH)D is very low, the serum $1,25(OH)_2D$ level may be low due to substrate deficiency [2, 15, 32]. The urinary excretion of calcium over a period of 24 hours is low to very low in patients with vitamin D deficiency due to low calcium absorption from the gut and enhanced tubular reabsorption of calcium due to secondary hyperparathyroidism.

RADIOLOGY

Radiological pictures of patients with rickets show decreased mineralization around the epiphysis, indistinct bone margins and less contrast. The number of ossification centers is decreased. Treatment is followed by rapid improvement (Fig. 75.1).

In osteomalacia, the radiographs show less contrast and are less sharp as if the patient had moved during the X-ray [33]. The classical sign of osteomalacia is the pseudofracture, also named Looser zone. It is a radiolucent line through one cortical plate, often with sclerosis at the margins (Fig. 75.2). The pseudofractures are visible on bone scintigraphy as hot spots.

The assessment of bone mineral density (BMD) by dual X-ray absorptiometry may reveal low values compatible with osteopenia (T-score -1 to -2.5) or osteoporosis (T-score below -2.5). It indicates that the amount of mineralized bone in patients with osteomalacia is low and can be similar to that in patients with osteoporosis [33]. The amount of nonmineralized bone (osteoid tissue) may be high, leading to large and fast increases of BMD (up to 50%) when proper therapy has been instituted.

BONE HISTOLOGY

A transiliac bone biopsy after tetracycline double labeling provides a certain diagnosis of osteomalacia or can exclude it. The biopsy should be included in methylmethacrylate without prior decalcification. Sections should be stained with Goldner or von Kossa. Unstained

Fig. 75.2. Pseudofracture (arrow) in the left os ilium in a patient with osteomalacia.

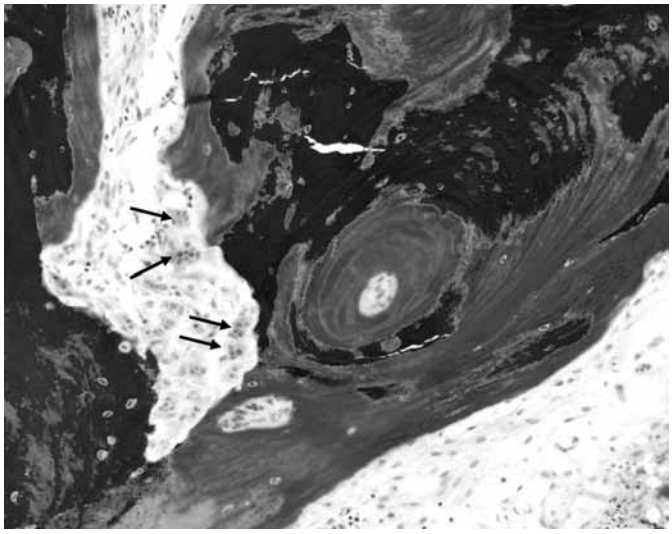

Fig. 75.3. Osteomalacia in a patient with celiac disease. Goldner stain, mineralized bone is black, osteoid tissue is gray. Besides thick osteoid seams, increased bone resorption by multinucleated osteoclasts (arrows) is visible.

sections should be made for tetracycline fluorescence. Typically for osteomalacia, the nonmineralized bone matrix (osteoid) comprises more than 5% of the bone (Fig. 75.3) (osteoid volume more than 5%, usually more than 10%). The osteoid surface is extended, more than 70%, and osteoid seams are thick, more than 15 µm or more than 4 lamellae [1]. Bone resorption is usually increased due to secondary hyperparathyroidism. Howship's (resorption) lacunae are visible with many multinucleated osteoclasts (Fig. 75.3). In frank osteomalacia, double tetracycline labels are not visible, but labeling may appear diffuse and of low intensity. The mineralization index, including osteoid thickness, osteoid volume, mineralization rate and bone formation rate, may be helpful [34].

TREATMENT OF VITAMIN D DEFICIENCY

The symptoms of rickets and osteomalacia may disappear with remarkably low doses of vitamin D_3 (e.g., 800–1,200 IU/day, 20–30 µg/day) unless intestinal absorption is impaired as in celiac disease [35]. However, a higher initial dose (vitamin D_3 2,000 IU/day, 50 µg/day) may be prescribed to bring serum 25(OH)D in the sufficient range (greater than 50 nmol/l or greater than 20 ng/ml) within a few weeks. For maintenance, infants and small children may require as little as 400 IU (10 µg) of vitamin D_3 per day. Adults require 600 to 800 IU (15–20 µg) per day as a maintenance dose. Either vitamin D_3 (cholecalciferol) or D_2 (ergocalciferol) may be prescribed, but vitamin D_2 is less effective [36]. A calcium supplement should always be added. It can be prescribed as calcium carbonate, citrate or glubionate. A dose of 1,000 mg elemental calcium per day in children with rickets and 1,500–2,000 mg per day in adults with osteomalacia is necessary. A special problem is rickets or osteomalacia in patients with celiac disease. A gluten-free diet is essential, but higher doses of vitamin D and calcium may be required, and serum 25(OH)D should be regularly assessed.

Following treatment of severe vitamin D deficiency, serum calcium and phosphate quickly rise into the normal range. The alkaline phosphatase may initially increase but then falls, within weeks to months to normal levels. At the same time, the urinary excretion of calcium increases to the normal range.

The radiological changes of rickets may heal very rapidly. Ossification centers may become visible within weeks, and healing within a few months is the rule (Fig. 75.1). Pseudofractures in adults may heal more slowly and complete disappearance may take more than one year.

Recently, the required doses of vitamin D and the appropriate level of 25(OH)D have been discussed at international meetings and in scientific papers [14, 16, 17, 37]. The required dose depends on the baseline serum 25(OH)D level, the desired level, and the dosing interval. When the baseline serum 25(OH)D is around 20 nmol/l, a dose of 400 IU/day leads to a mean serum 25(OH)D of 55 nmol/l, and a dose of 800 IU/day to 70 nmol/l after 3 months [38]. In general, 800 IU/day (20 µg/day) is a sufficient dose to obtain a serum 25(OH)D level over 50 nmol/l (20 ng/ml) in most people. The Institute of Medicine has defined the required serum 25(OH)D level at 50 nmol/l [19]. When the desired 25(OH)D level is set at 75 nmol/l much higher vitamin D doses are required [39].

PREVENTION OF FALLS AND FRACTURES

The pathway from vitamin D deficiency to falls and fractures is shown in Fig. 75.4.

In a meta-analysis of randomized controlled trials, it was found that a vitamin D dose higher than 400 IU/day

(10 µg/day) with or without calcium reduced the risk of hip fracture by 18% and any nonvertebral fracture by 20% versus calcium or placebo [40]. In a Cochrane review, only the combination of vitamin D with calcium reduced hip fractures [pooled relative risk (RR) of 8 trials = 0.84, 95% CI: 0.73 to 0.96], and the authors concluded that vitamin D and calcium decrease hip fracture risk in frail institutionalized older people [41]. Another meta-analysis also showed that the addition of calcium to vitamin D is essential for its preventive effect on fractures [42].

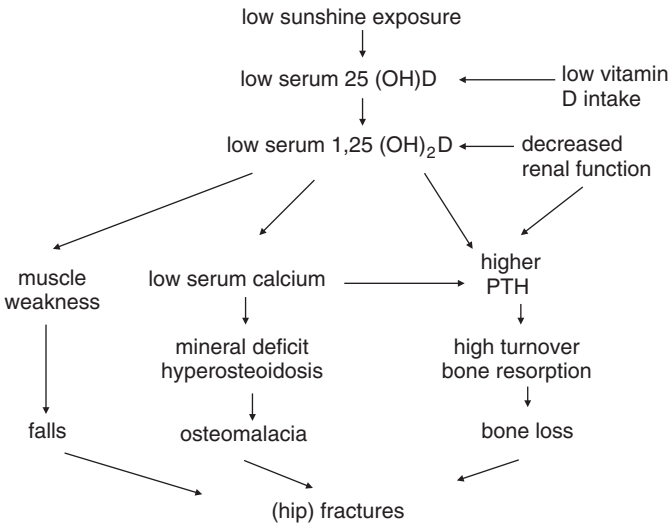

Fig. 75.4. The pathway from vitamin D deficiency to falls and fractures.

Mild to moderate vitamin D deficiency is also associated with reduced muscle strength, impaired physical performance and falls [3–5, 43]. Vitamin D supplementation in combination with calcium may reduce the risk of falls. A meta-analysis showed that vitamin D_3 700–1,000 IU/day reduced fall risk by 19% compared with placebo (pooled RR from 7 trials = 0.81, 95% CI: 0.71–0.92) [44]. The positive effect on falls was confirmed in a recent meta-analysis [45]. While in most trials daily vitamin D doses were used, the effect of a yearly dose of 500,000 IU was compared with a placebo in an Australian study. The incidence of falls and fractures was higher in the vitamin D group than in the placebo group hazard ratio [HR 1.16 CI: 1.05–1.28 and 1.26 CI: 0.99–1.59, respectively]. This indicates that very high doses of vitamin D leading to very high serum 25(OH)D levels (greater than 120 nmol/l) may have adverse effects and that the curve may be U-shaped [46].

GUIDELINES FOR VITAMIN D INTAKE

In Table 75.3, the official recommendations for dietary intake in the U.S. as established by the Institute of Medicine [19] are presented and compared with other guidelines of the Endocrine Society [47], the European Commission (http://ec.europa.eu/food/fs/sc/scf/out157_en.pdf), and The Netherlands [48]. When comparing the recommendations of the Institute of Medicine with those of the Endocrine Society [19, 47], one may conclude that the required level of serum 25(OH)D and the daily requirement of vitamin D are still debated. Some experts

[b]RDA = Recommend Dietary Allowance
[c]Daily requirement
[d]Individual European countries often have more detailed recommendations
[e]Infants from 4 weeks onwards; 6–11 months 10–25 µg/day; 1–3 years 10 µg/day:
Scientific Committee on Food of the European Commission (http://ec.europe.eu/food/fs/sc/scf/out157_en.pdf)
[f]The standing Committee of European Doctors now recommends 15–20 µg/day for older persons; see: www.cpme.eu (2009/179 final)
[g]Adequate intake
[h]20 µg is also recommended for persons having osteoporosis and residents of homes for the elderly and nursing homes

believe that the required levels should be higher. In a recent nursing home study, it was shown that an intake of 600 IU (15 µg) daily reduced the percentage of persons having a serum 25(OH)D below 50 nmol/l from 100% to 10.9% within 4 months [49]. A dose of 800 IU (20 µg) should be sufficient in most people. The latter dose is supported by a meta-analysis on fracture prevention [40]. The Institute of Medicine defined the tolerable upper intake level of vitamin D as 4,000 IU (100 µg) per day for adults, including pregnant and lactating women [19]; the Endocrine Society defined the tolerable upper intake level of vitamin D of 10,000 IU (250 µg) for adults, including pregnant and lactating women aged 19 years and older [47]; the European Commission defined the tolerable upper intake as 2,000 IU (50 µg) for adults, including pregnant and lactating women (http://ec.europa.eu/food/fs/sc/scsf/out157_en.pdf). For children and adolescents, lower tolerable upper intake levels were defined.

However, long-term use of lower doses may also lead to adverse effects as was shown in the Women's Health Initiative, in which significantly more kidney stones occurred in the group receiving 1,000 mg calcium and 400 IU (10 µg) vitamin D daily as compared to a placebo for a period of 7 years (HR = 1.17; 95% CI: 1.02–1.34) [50]. No significant differences in mortality, cardiovascular disease, cancer, and gastrointestinal symptoms were observed.

As discussed above, the Australian trial comparing vitamin D 500,000 IU once per year with placebo resulted in very high serum 25(OH)D (greater than 120 nmol/l) and more falls and fractures in the first 3 months after dosing [46].

RICKETS CAUSED BY IMPAIRED 1α-HYDROXYLATION OR BY A DEFECTIVE VITAMIN D RECEPTOR

The observation that some forms of rickets could not be cured by regular doses of vitamin D led to the discovery of rare inherited abnormalities of vitamin D metabolism or the vitamin D receptor. These inborn errors of metabolism have been confirmed by several mouse knockout models [11, 51].

Pseudovitamin D deficiency rickets (vitamin D–dependent rickets type I, OMIM #264700)

After the discovery of $1,25(OH)_2D$, it became apparent that some patients with congenital rickets had very low serum concentrations of $1,25(OH)_2D$ that did not increase after vitamin D supplementation [52]. It turned out that these patients did not have 1α-hydroxylase activity. Inactivating mutations of the 1α-hydroxylase gene were identified in affected children [53]. The disease is autosomal recessive.

Clinical features

Patients with pseudovitamin D deficiency rickets present soon after birth with rickets and signs of hypocalcemia, tetany, or convulsions. Laboratory investigations show low serum concentrations of calcium and phosphate and elevated alkaline phosphatase. Serum 25(OH)D is within normal range, but serum $1,25(OH)_2D$ is very low or undetectable [13]. Radiologic examination and bone biopsy show features indistinguishable from nutritional rickets.

Treatment

The patients should be treated with $1,25(OH)_2D$ (calcitriol 0.5–1 µg/day) or 1α-hydroxyvitamin D (alphacalcidol 0.5–1.5 µg/day) to restore serum $1,25(OH)_2D$ to normal levels. This leads to cure of rickets within a few months with normalization of serum calcium, phosphate, and alkaline phosphatase. Another marker of adequate therapy is serum PTH, which should be within reference limits. Overtreatment results in hypercalciuria, hypercalcemia, urolithiasis, and nephrocalcinosis. Serum calcium, serum creatinine, and the urinary excretion of calcium over a period of 24 hours should be checked at regular intervals: in children every month and when stable every 3 months, in adults every 3–6 months. Patients and parents should be instructed on signs and symptoms of underdosage, i.e., hypocalcemia (numbness, pins and needles, tetany) and overdosage, i.e., hypercalcemia (thirst, polyuria, nausea, headache). The requirement of calcitriol or alphacalcidol increases in pregnancy 50% to 100% and frequent monitoring is necessary [54]. Therapy should be continued for life, and accidental discontinuation will lead to hypocalcemia within a few days, later followed by signs of rickets or osteomalacia within weeks to months.

Hereditary vitamin D resistant rickets (vitamin D–dependent rickets type 2, OMIM #277440)

True resistance to $1,25(OH)_2D$ was discovered as some children with congenital rickets did not respond to treatment with calcitriol [55]. In fact, these children had a high serum $1,25(OH)_2D$, leading to the suspicion of a (post)receptor defect. After cloning of the vitamin D receptor (VDR), mutations have been identified at the DNA binding domain, the $1,25(OH)_2D$ binding domain, and other domains [56]. Hereditary vitamin D–resistant rickets is an autosomal recessive disease.

Clinical features

Affected children born to normal heterozygote parents present early in life with rickets and signs of hypocalcemia, including tetany and convulsions. The first kindreds had alopecia, but later the disease was recognized in children without alopecia. The degree of hormone resistance, i.e., hypocalcemia, may also vary. Laboratory examination shows low serum calcium and serum phosphate and a high alkaline phosphatase level. Serum PTH is increased and serum $1,25(OH)_2D$ is elevated [13]. The

latter is caused by stimulation of the renal 1α-hydroxylase by the increased PTH level.

Radiological examination shows the signs of rickets with widened epiphyseal zones and unsharp radiolucent bones. Pseudofractures may be present.

Treatment

The success of treatment is variable and depends on the degree of hormone resistance. When some VDR function is present, a pharmacologic rather than physiologic dose of calcitriol or alphacalcidol can improve calcium absorption and heal the rickets. In case of complete resistance, active vitamin D metabolites are ineffective. Such severely affected individuals can be treated with calcium infusion that overcomes the defective calcium absorption [57]. Rickets can be cured by calcium infusion, and this confirms that mineralization depends on the presence of adequate calcium and phosphate concentrations rather than on the action of $1,25(OH)_2D$. As calcium absorption from the intestine also has a passive component by diffusion—which is independent of vitamin D—very high doses of oral calcium can be effective as well.

Vitamin D intoxication

Vitamin D intoxication is caused by increased ingestion of vitamin D or one of its active metabolites, e.g., alphacalcidol or calcitriol. In case of intoxication by regular vitamin D, the pathogenesis is not completely clear. The serum 25(OH)D concentration is increased over 200 nmol/l up until 1,500 nmol/l, but the serum $1,25(OH)_2D$ level usually is normal [13]. Several mechanisms have been proposed. The high amount of 25(OH)D could act on the vitamin D receptor. More probably, the high serum 25(OH)D could compete with $1,25(OH)_2D$ for binding places of vitamin D binding globulin, thereby increasing the bioavailable (free) serum $1,25(OH)_2D$ levels. In addition, extrarenal activation of 25(OH)D by local 1α-hydroxylase in intestine and bone tissue may contribute to the hypercalcemia.

Clinical features

The patient presents with signs and symptoms of hypercalcemia, i.e., thirst, polyuria, nausea, headache. The cause may be obvious, either supplementation with high doses of vitamin D, or a somewhat high dose of active metabolite. Less obvious causes may be an over-the-counter supplement or table sugar to which vitamin D has been added [58, 59] The patient may appear dehydrated, even confused. Laboratory examination shows hypercalcemia, normal, or increased serum phosphate, increased serum creatinine or BUN, a very high 25(OH)D level, a normal $1,25(OH)_2D$ level, and suppressed serum PTH.

Treatment

The patient should be rehydrated with saline, and corticosteroids may be given to decrease the formation of $1,25(OH)_2D$. The half-life of 25(OH)D is around 25 days, so a complete cure may take some time. Calcium intake should be restricted as long as hypercalcemia is present.

Intoxication with active metabolites

Intoxication with alphacalcidol or calcitriol may appear quickly, but, when recognized, also disappears soon with appropriate measures as the half-life is short, about 7 hours. Treatment should consist of dose reduction or temporary arrest of the active metabolite, rehydration, and restriction of oral calcium intake.

Increased endogenous production of $1,25(OH)_2D$

Endogenous intoxication with calcitriol occurs in the patient with granulomatous disorders or lymphoproliferative diseases when committed macrophages contain 1α-hydroxylase, thus permitting the inappropriate conversion of 25(OH)D into $1,25(OH)_2D$. The latter has been reported from patients with sarcoidosis, tuberculosis, rheumatoid arthritis, Hodgkin's disease, and non-Hodgkin's lymphoma [60–62]. Whereas the renal formation of $1,25(OH)_2D$ is tightly regulated by feedback control, the extrarenal production in these diseases is not. The production of $1,25(OH)_2D$ depends on the amount of substrate i.e., 25(OH)D, and a positive correlation between serum 25(OH)D and $1,25(OH)_2D$ is observed in these disorders, while it is not in normal circumstances [13]. The treatment consists of management of the hypercalcemia and hypercalciuria, and treatment of the underlying disease. Glucocorticoids decrease the hydroxylation of 25(OH)D into $1,25(OH)_2D$ and may help to correct the hypercalcemia.

DEFINITION

Vitamin D deficiency, insufficiency, and sufficiency are categories used to describe the nutritional status of vitamin D and are defined by the level of serum 25 hydroxyvitamin D (25OHD). The term vitamin D "deficiency" applies to the most severe depletion of vitamin D in the body. It is characterized by intestinal malabsorption of calcium and phosphorus, hypocalcaemia, low 1,25 dihydroxyvitamin D, secondary hyperparathyroidism, and demineralization of bone. Unmineralized bone that accumulates as an excessive amount of osteoid tissue is described as osteomalacia in adults and rickets in children. Vitamin D "insufficiency" has less pronounced secondary hyperparathyroidism but increased bone loss and osteoporosis. Probably the changes in serum vitamin D are a continuum with insufficiency and osteoporosis at one end of the spectrum and severe deficiency and osteomalacia at the other end.

WHAT SERUM 25OHD LEVEL IS CLINICALLY IMPORTANT?

Controversy has arisen over the level of serum 25OHD that defines vitamin D insufficiency and deficiency. In 2011, the Institute of Medicine (IOM) defined insufficiency as less than 20ng/ml [1], however. In 2011 the Endocrine Society (ES) defined it as 20–29ng/ml [2]. These differences are summarized in Fig. 76.1.

One clear biochemical difference between the categories of vitamin D deficiency and insufficiency is serum 1,25 dihydroxyvitamin D because its level decreases when serum 25OHD declines to less than 10–12 ng/ml, provided renal function is normal [3].

BACKGROUND

The best-known consequences of severe vitamin D deficiency are rickets in children and osteomalacia in adults. First described in Northern Europe, it was noted that rickets occurred in as many as 60% of cases at postmortem at the end of the winter and early spring when vitamin D depletion was most extreme [4]. It was originally referred to as the "English disease." Several factors caused this problem: lack of sunlight in the northern latitudes, reduced ultraviolet light because of cloud cover, pollution from smoke due to industrial and coal fired heating in homes, and poor nutrition. In 1921 Hess was amongst the first to show that sunlight and ultraviolet light could cure rickets in children [5]. Supplementation of infant foods eradicated childhood rickets in Northern Europe. However, in certain populations such as Asian immigrants or even in the Middle Eastern coun-

tries that have cultural habits such as purdah and the wearing of the burkah that covers all the body and face, rickets and osteomalacia still can occur, although diet may also be a contributing factor [6, 7]. In North America rickets occurs occasionally in African-American children who only breast feed and in whom maternal levels of 25OHD during pregnancy and lactation are low [8]. Low levels of serum 25OHD are found in high-risk groups such as elderly subjects in nursing homes who have low sunlight exposure [9]. In an elderly population in England, bone biopsies of high-risk patients showed that the incidence of osteomalacia was approximately 4% [10], and in Spain low levels of serum 25OHD less than 6 ng/ml were associated with a finding of osteomalacia in bone biopsies [11]. Several other diseases that can lower serum 25OHD levels are malabsorption syndromes, bypass surgery, liver disease, chronic kidney disease, and drugs such as corticosteroids, phenytoin, ketoconazole, cholestyramine; these can result in osteomalacia [12]. Serum 25OHD levels are also influenced by certain genes. Recent genome-wide screening identified shown four genes associated with serum 25OHD levels, and a combination of three of these genes was able to predict low levels of serum 25OHD [13].

PATHOPHYSIOLOGY

Severe vitamin D deficiency causes malabsorption of calcium and phosphorus from the diet, secondary hyperparathyroidism and defective mineralization of bone leading to osteoporosis and osteomalacia (Fig. 76.2). The increase in serum parathyroid hormone (PTH) that occurs with low serum 25OHD is quite variable [14]. It is more commonly elevated when serum 25OHD levels are less than 15 ng/ml; however, in 30–50% of subjects serum PTH can be low even when serum 25OHD levels are below 15 ng/ml [15]. In elderly subjects, the age-related decrease in absorption of calcium and a low calcium intake may contribute to secondary hyperparathyroidism [16, 17]. At any stage, depending on the level of 25OHD, the sequence can be interrupted. This would occur particularly in summer when sunlight increases serum 25OHD, and mineralization of osteoid occurs partially or completely; thus osteomalacia fluctuates with season [18]. Theoretically a high calcium and phosphorus intake

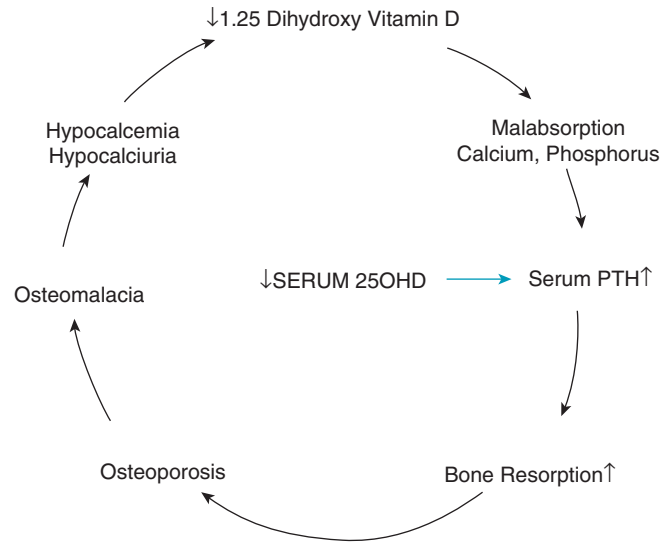

Fig. 76.2. Low serum 25 hydroxyvitamin D (25OHD) stimulates secondary hyperparathyroidism and bone resorption leading to osteoporosis . If 25OHD deficiency is severe < 10 ng/ml (25 nmol/L) it leads to both osteoporosis and osteomalacia.

can prevent demineralization and osteomalacia but in many patients with osteomalacia nutrition is also poor.

Diagnosis of osteomalacia can only be truly confirmed by bone biopsy, although in children there are characteristic radiologic changes that show irregularity of the metaphysis of bone and softening of the bone that leads to bowing of the legs, a finding that alerts parents and physician. However, the biochemical results of low ionized calcium, hypophosphatemia, and low serum 25OHD makes the diagnosis very likely [19]. In elderly people in Europe with osteoporotic hip fractures, histological evidence of osteomalacia was found in 20–30% [18, 20], though another study found a much lower incidence of 12% in the elderly, even though many had very low levels of serum 25OHD [21]. A recent study of bone biopsies in sudden death cases in Germany found that 25% of cases had evidence of osteomalacia based on the criteria of an osteoid volume greater than 2% [21]. This figure of 2% may be low, and others suggest the upper range should be 3% [22]. Ninety-nine percent of these cases occurred when serum 25OHD was 0–20 ng/ml and the other 1% when serum 25OHD was between 20 and 30ng/ml. Of interest was the finding that in many cases with no detectable serum 25OHD in the blood, there was no evidence of osteomalacia, which suggests that other factors contribute to osteomalacia besides vitamin D.

CAUSES

The two major natural sources of vitamin D are sunlight and diet. Sunlight is the major contributor because normal diets have such a small content of vitamin D.

Table 76.1. Mean Diet and Total Vitamin D Intake and Mean Serum 25OHD for the United States, 2005–2006, (NHANES 2005–6)

	Vitamin D Intake (IU/day)		
Age Group (years)	Diet Alone[a]	Total Intake[b]	Mean Serum 25OHD ng/ml (±SE)[c]
Males			
14–18 yrs	244 ± 16	276 ± 20	24 ± 0.6
19–30	204 ± 12	264 ± 16	23 ± 0.5
31–50	216 ± 12	316 ± 12	24 ± 0.4
51–70	204 ± 12	352 ± 16	24 ± 0.5
>70	224 ± 16	428 ± 28	24 ± 0.4
Female			
14–18 yrs	152 ± 8	200 ± 20	24 ± 0.7
19–30	144 ± 12	232 ± 12	25 ± 0.8
31–50	176 ± 12	308 ± 20	23 ± 0.5
51–70	156 ± 16	404 ± 40	23 ± 0.4
>70	180 ± 8	400 ± 20	23 ± 0.4

NOTE: IU = International Units; SE = standard error. [a]Date are mean ± SE for foods only. [b]Date are mean ± SE for total intake: foods and dietary supplements. [c]Date are mean ± SE.

The amount of vitamin D generated by sunlight (UV-B) depends on latitude, season, time of day, and time of exposure. There is a marked seasonal variation in serum 25OHD. Levels increase between May to September by about 10 ng/ml in summer at a latitude of 40 degrees [23] but only 4 ng/ml at a higher latitude of 55 degrees [24]. As discussed earlier, factors that also decrease UV exposure are sunscreen and darker skin color [25, 26]. A typical diet averages between 100 and 200 IU daily (Table 76.1) but will be higher in areas where fish consumption is higher (300–400 IU/day). In North America, dairy products are fortified with vitamin D; milk has 400 IU added to a quart (approximately 1,000 ml), and cow's milk naturally has about 50 IU. Many people take supplements after age 50, and the average vitamin D intake increases to approximately 400 IU/day (Table 76.1) [1].

The **prevalence** of vitamin D deficiency, insufficiency, and sufficiency varies according to the distance from the equator and therefore the amount of sunlight exposure. In Northern Europe and Canada (latitude >50 degrees) summer seasons are shorter because they are further from the equator, and cloud cover also limits ultraviolet exposure. Recent results from the NHANES study in North America show that 8% of 25OHD values are <10 ng/ml and 24% are between 10 and 20 ng/ml [27].

Assessment of vitamin D status. Vitamin D is absorbed quickly from the diet or from skin, it has a short half-life of 24 hours, and serum levels range from 0 to 100 ng/ml. Vitamin D is transported to the liver and converted to 25OHD that has a half-life of about 3 weeks; levels vary between 10 and 50 ng/ml with a strong seasonal change. From the liver, 25OHD is transported to the kidney and converted to 1,25 dihydroxyvitamin D that has a half-life of about 4 hours and measures 25–50 pg/ml. Because of its longer half-life, serum 25OHD has become the optimal measurement for assessment of nutritional status. Today there are several techniques that are satisfactory for measurement of serum 25OHD such as radioimmunoassay, high performance liquid chromotogaphy, and tandem mass spectroscopy. All methodologies have potential errors but they are continually improving. Generally, if well performed and combined with quality controls, one can be confident of the measurement's accuracy. Although one-third of Caucasians have serum 25OHD levels less than 20 ng/ml, such low values may not have the same implications for people with darker skin color. For example, African-Americans have much lower levels of serum 25OHD than Caucasians [26], but their bone mass is higher and they have fewer fractures; so how should low vitamin D status be classified in people of color? Biological markers or clinical diseases associated with deficiency/insufficiency other than bone have yet to be identified for these groups.

FRACTURES

Most evidence-based data suggest that a serum 25OHD above 20 ng/ml is sufficient for skeletal health. This conclusion is based on five large studies totaling 6,562 subjects that show a significant increase in hip fractures in women and men with serum 25OHD below 20 ng/ml (reviewed in Ref. 28). The evidence linking clinical nonvertebral fractures to low serum 25OHD is different between men and women and ethnicity. In men, non-hip fractures are increased only in those with serum 25OHD below 20 ng/ml [29]. In women, non-hip fractures are significantly decreased in groups with higher serum 25OHD of 20–30 ng/ml and greater than 30ng/ml compared to less than 20 ng/ml in Caucasian women. However, the opposite is found in African-American and Asian women—fracture events are more common in the groups with serum 25OHD above 20 ng/ml compared to below 20 ng/ml [30]. These are relatively small case control studies and the accuracy of reporting fractures is approximately 80%, so larger studies are needed to confirm these results. Further support for the importance of a low serum 25OHD is the finding that bone resorption markers were increased only in women with a serum 25OHD less than 20 ng/ml [14] and a study in men showing an increased rate of bone loss in those groups with serum 25OHD less than 20 ng/ml compared to higher serum 25OHD above 20 ng/ml [31].

Effect of vitamin D on fractures

The studies are difficult to interpret because none of the individual studies have a dose response design; doses vary from 300 to 1,000 IU/day, and few studies are placebo controlled. There are actually only five studies of vitamin

D alone where the primary outcome was fractures and taken together the results were not significant. Most of the trials usually compare a combination of vitamin D plus calcium compared to a calcium control group or placebo. This has led to various meta-analyses of fracture studies; most use the same data set, and the difference lies in the inclusion criteria used for that particular analysis. The most comprehensive analyses are in the AHRQ-Tufts report that analyzed 17 trials [32]. A reasonable summary of the results show that addition of vitamin and calcium compared to calcium or placebo (14 trials) reduces fractures by 10% (nonsignificant) but a comparison of vitamin D plus calcium compared only to placebo (8 trials) significantly reduces fractures by 13%. In institutionalized patients the reduction in fractures was higher at 31%. Evidence that links a serum 25OHD threshold to treatment with vitamin D in fracture studies is not clear. This is usually because in half the studies the baseline serum 25OHD level is above 20 ng/ml, and efficacy does not seem any different between studies where the baseline starts above or below 20 ng/ml. A study would have to start at a much lower serum 25OHD levels and then exceed 20 ng/ml to address this question. Another issue is that almost all studies are single dose, so a threshold dose cannot be defined. Furthermore, meta-analyses that try to define a threshold response based on serum 25OHD are challenging because it means combining serum 25OHD values from studies and assays performed over a 20-year period between 1992 and 2009 when external independent standards were not used in assays.

BONE MINERAL DENSITY (BMD)

With regard to peak bone mass in young adults, a cross-sectional study from NHANES that included all ages showed an increase in BMD and higher serum 25OHD in groups with 25OHD above 19 ng/ml with an overall gain of about 4% in Caucasians, 1.5% in Hispanics, and 1.5% in African-Americans [33]. But in a cross-sectional study of 7,000 older women with a mean age of approximately 65 years, BMD was significantly lower only in the group with serum 25OHD less than 10 ng/ml compared to groups below 20 ng/ml or above 20 ng/ml [34]. With regard to older women there was only fair evidence to support a link between low serum 25OHD and BMD or change in BMD, with nine studies showing no correlation and 10 showing a correlation [32]. Subsequently, the MrOs study showed increased bone loss in the hip only in the groups with serum 25OHD less than 20 ng/ml [31]

Bone biopsies

As discussed earlier in a study of 675 sudden death autopsies where a bone biopsy and serum 25OHD was measured, the criteria used for osteomalacia was an osteoid volume greater than 2%. Twenty-five percent of the biopsies had osteomalacia, all associated with serum 25OHD below 30 ng/ml; however, in 99% of the samples, serum 25OHD was below 20 ng/ml [21].

Nonskeletal effects

Vitamin D insufficiency and serum parathyroid hormone (PTH)

Many studies have shown that serum PTH is inversely related to serum 25OHD, and that with the increase in serum 25OHD there is a decrease in serum PTH that usually reaches a plateau. In the Endocrine Society guidelines, the statement is made that serum PTH reaches a plateau at a threshold of 30 ng/ml, but this is supported by only three references. In a recent review of 79 studies from the literature [14], the level of serum 25OHD at which serum PTH reached a plateau varied from 12 to 50 ng/ml, with most values being less than 30 ng/ml. In seven studies there was no threshold: thus results do not support a serum 25OHD threshold of 30 ng/ml (Fig. 76.3).

Vitamin D insufficiency and calcium absorption

As vitamin D levels decline, secondary hyperparathyroidism increases and stimulates 1,25 dihydroxyvitamin D production in the kidney, but after age 75 years, as renal function declines, the production of 1,25 dihydroxyvitamin D also declines [35]. There is also a separate age-related decrease in calcium absorption that

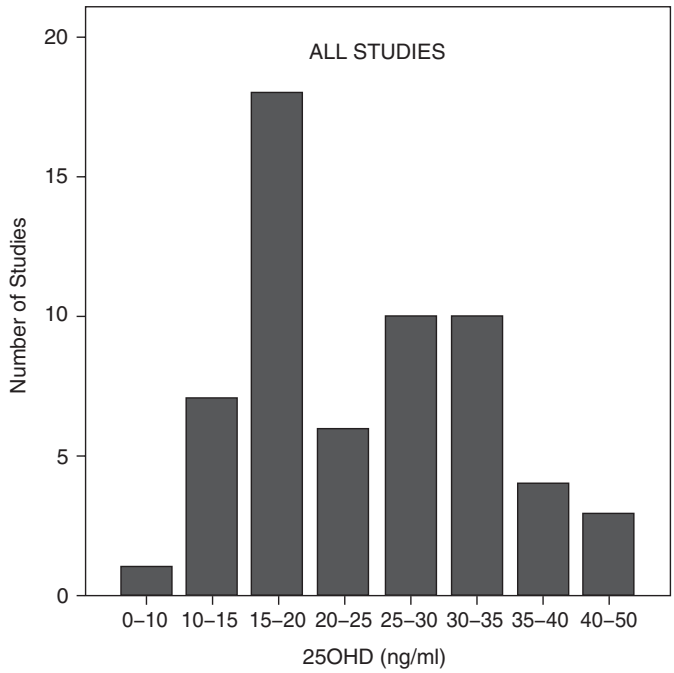

Fig. 76.3. Review of studies showing different levels of serum 25OHD when serum PTH shows a plateau.

occurs a decade earlier [16, 17], and this probably accounts for the intestinal resistance to vitamin D [36]. Renal production of 1,25(OH)$_2$D also can be impaired by serum 25OHD deficiency, and this has been said to occur at a serum 25OHD level of 12 ng/ml by limiting the supply of 25OHD substrate [3, 37]. The most convincing data on calcium absorption support a serum 25OHD threshold of 5–10ng/ml for normal calcium absorption [37].

Physical function

There is cross-sectional data showing an association between physical function and serum 25OHD. An analysis from 4,100 subjects in the NHANES study showed a relationship between serum 25OHD and two physical performance tests: a timed walking test over 8 feet and the timed rise [38]. The major improvement in physical function occurred between the reference group (lowest quintile) with a serum 25OHD between 2 and 18 ng/ml and the second quintile with a serum 25OHD between 19 and 23 ng/ml; higher serum 25OHD was not associated with further improvements in physical performance. In a 3-year longitudinal study of 1,234 subjects in Northern Europe, physical performance was significantly worse in subjects with serum 25OHD below 20 ng/ml [39]. Prospective studies on the effect of vitamin D and calcium on physical performance tests such as quadriceps strength, grip strength, timed rise, timed walk, and timed up and go between studies have been inconsistent [40].

Frailty

A study has associated greater frailty with serum 25OHD over a 6-year follow-up in older women [41]. The odds ratio for developing frailty was 1.46 (1.19–1.42) if serum 25OHD was below 15 ng/ml; 1.24 (0.99–1.54) if values were 15–20 ng/ ml, and 1.32 if serum 25OHD was above 30 ng/ml—the referent was a serum 25OHD of 20–30 ng/ml. Similarly in men, frailty was more likely to occur in men with a serum 25OHD below 20 ng/ml [42].

Falls

In a meta-regression analysis, the IOM was unable to show a significant effect of vitamin D on falls or any significant threshold effect [1].

Association studies with low serum 25OHD

Most tissues in the body have a vitamin D receptor and have the ability to synthesize 1,25(OH)2D from 25OHD in local cells. This has raised questions about the effect of low serum 25OHD on nonskeletal disease. It is very difficult to prove what level of vitamin D deficiency or insufficiency reduces extra renal synthesis. There have been a number of studies that showed a cross-sectional association with several disease such as diabetes and cancer, but due to lack of any clinical trials on the efficacy of vitamin D it is not possible yet to draw any conclusions.

Screening

The recent evidence-based IOM report suggests that a serum 25OHD below 20 ng/ml defines vitamin D insufficiency [1]. The Endocrine Society guidelines recommend that the target level should be 30 ng/ml, and they also recommend that large groups of the normal population undergo screening, including all African-Americans, all Hispanics, all pregnant women, all obese people above 30 kg/m^2 [2]. An estimate shows that if these screening guidelines were adopted, about 50 million people in the United States would need to be screened. Conservatively, the initial cost would be $15 billion dollars without taking into account physician charges and follow-up tests. It seems difficult to justify screening these groups since there are no studies that demonstrate improvement in disease outcomes in older people with osteoporosis and a serum 25OHD below 20 ng/ml.

Certain high risk groups can be identified, particularly the elderly who are institutionalized in nursing homes, those who avoid sunlight exposure, as well as medical conditions such as chronic renal disease, liver disease, malabsorption syndromes, medications known to interfere with vitamin D metabolism, anticonvulsants, corticosteroids, antifungals, and HIV drugs. For these groups screening makes sense.

Management of vitamin D deficiency and insufficiency

Because many elderly people with low vitamin D below 20 ng/ml have increased serum PTH, they also have decreased calcium absorption and a low calcium intake so treatment with a combination of vitamin D and calcium is optimal. Based on the data reviewed above, the minimum target for treatment is to exceed a serum 25OHD of 20 ng/ml; whether it should be 30 ng/ml is arguable pending better data.

It has been suggested that serum 25OHD increases by 0.7 to 1 ng/ml for every 100 IU administered [2]. However, a recent dose response study shows that this is a simplification because the dose response is not linear but quadratic, and the increase is actually four times larger per 100 IU when serum 25OHD levels are less than 20 ng/ml [43]. Vitamin D$_3$, 600–800 IU/day, will increase almost all subjects to a serum 25OHD greater than 20 ng/ml and 1600–2000 IU/day will increase all subjects to a serum 25OHD greater than 30 ng/ml. It is advisable to add a calcium supplement if the diet calcium cannot be increased. How much calcium should be added? Probably the total calcium intake should be between 800 and 1,000 mg daily. However, a calcium intake of 600–800mg/day may be all that is needed if the patient is on antiresorptive drugs, since net bone resorption is close to zero and there is no need for calcium supplementation unless calcium intake is less than 600mg/day.

If the end point is serum 25OHD, then daily doses of 1,000 IU of vitamin D$_2$ (ergocalciferol) are not different from vitamin D$_3$ in the effect on serum 25OHD [44]. Monthly doses of 50,000 IU of vitamin D$_2$ produce a

serum 25OHD level that is about 5 ng/ml lower than on 50,000 D_3 because D_2 has a shorter half-life; however, levels are adequate [45] and there is no evidence that a slightly higher serum level on D_3 translates to better clinical efficacy since there are no studies. There is no evidence that the initial treatment of people with vitamin D insufficiency (serum 25OHD less than 20ng/ml) with large doses of vitamin D 50,000 IU weekly for 8 weeks as proposed is any more effective than daily vitamin D. In fact, a study that compared an average of 1,500 IU/day given on a daily, weekly, or monthly dosing schedule showed no difference in final levels of serum 25OHD after 5–8 weeks [46]. In other words, there is no urgent need to increase serum 25OHD with large weekly doses.

Calcitriol (1,25-dihydroxyvitamin D) may be a better choice in the elderly with a low glomerular filtration rate (GFR) less than 40 mls/min because they have of impaired conversion of 25OHD to 1,25-dihydroxyvitamin D [34]. Lower GFR is associated with worse physical performance and more falls [47, 48].

Calcitriol has a rapid onset of action and a half-life of 4–6 hours. It is available in doses of 0.25 and 0.5 micrograms, and the usual dose is 0.25 mcg twice daily. If used, the calcium intake should be restricted to 600–800 mg daily because of a higher incidence of hypercalcemia and hypercalciuria [49].

The main natural sources of vitamin D are diet and sunlight. The natural food sources of vitamin D are fatty fish, cod, salmon, and eggs. In North America, many foods, especially dairy products and cereals, are fortified with vitamin D. Milk is fortified with 400 IU per quart (~ liter) as is orange juice and yogurt. Because all foods and liquids are labeled with the vitamin D content, it is easy to estimate the intake of vitamin D.

Sunlight

For many people, only wintertime supplementation with vitamin D is necessary because in winter the lowest levels of serum 25OHD are from January to March, and levels increase to normal by mid-summer. The mild secondary hyperparathyroidism of winter returns to normal in summer [30]. In Northern Europe, the sunny season is 2 months shorter so that the increase in serum 25OHD is less. Even short exposure to UV-B light increases serum 25OHD efficiently. In North America, serum 25OHD levels increase by about 10 ng/ml, which is equivalent to a dose of 800–1,000 IU vitamin D daily. Sunscreen will block most of the UV effect [32]. In summary, for people who are normally active and outside in the summer, low levels of serum 25OHD occur only for 4–6 months of the year and a low dose of vitamin D 600–800 IU could be used in winter months to avoid vitamin D insufficiency. For those who avoid direct sunlight in summer the dose should be increased to 800 IU.

Safety

There are no safety data on vitamin D alone. The IOM recommended 600–800IU daily for older people. It also recommended a tolerable upper limit of 4000 IU/day; however, this was not a recommended intake but a guide to avoid toxicity. Although the IOM guidelines for people over 50 years suggest a calcium intake of 1,200 mg/day and vitamin D 800–1,000 IU/day there is no discussion of safety mainly because of the lack of data on different doses [1]. Yet vitamin D 400 IU/day and a supplement of calcium carbonate 1000 mg/day were shown to increase the incidence of kidney stones by 17% over 7 years in the Women's Health Initiative study of 36,000 women [50]. There is little other data on long-term toxicity but mortality data from the NHANES study showed an increase in all cause mortality once serum 25OHD exceeded approximately 50 ng/ml [1] so a conservative use of vitamin D and calcium is prudent pending further results.

SUMMARY

Vitamin D deficiency and insufficiency is an important clinical problem in all parts of the world. Even using a conservative definition of a serum 25OHD of below 20ng/ml, the studies show that one-third of Caucasian have low levels especially during winter. Screening of high-risk groups for low serum 25OHD and then treatment with vitamin D 600–800 IU and calcium 500–750 mg daily can reduce fractures. At this time there are no prospective data on prevention of nonskeletal diseases potentially linked to vitamin D insufficiency; only clinical trials can provide an answer.

DEFINITION

The chronic kidney disease–mineral bone disorder (CKD–MBD), is a term coined by the organization Kidney Disease: Improving Global Outcomes (KDIGO) in 2006 [1, 2] for the syndrome associated with chronic kidney diseases (CKDs) in which disorders of mineral metabolism and renal osteodystrophy are key contributors to the excess mortality observed in CKD [3–5]. Secondly, the skeletal remodeling disorders caused by CKD contribute directly to the heterotopic mineralization, especially vascular calcification, and the disordered mineral metabolism that accompany CKD [6, 7]. Thirdly, CKD or renal injury impairs skeletal anabolism decreasing osteoblast function and bone formation rates [7, 8]. As a result of recent advances, a multiorgan system has been defined involving the kidney, skeleton, parathyroid glands, fat and the cardiovasculature that fails in CKD (see Fig. 77.1).

PATHOBIOLOGY

Abnormalities of bone in the CKD–MBD are seen after a relatively mild reduction in the glomerular filtration rate (creatinine clearances between 40 and 70 ml/min, (stage 2 CKD) [9, 10]. In addition, elevated PTH levels and elevated fibroblast growth factor-23 (FGF23) levels are observed before detectable changes in the serum phosphorus, calcitriol, or calcium [11, 12]. The early increase in FGF23 in CKD [12, 13] makes it a powerful biomarker indicating that renal injury has affected osteocytic secretion [13]. If hyperparathyroidism is prevented, the prevalence of a low turnover osteodystrophy, the adynamic bone disorder increases, further demonstrating the effects of kidney injury on the skeleton [8]. By end-stage kidney disease (ESKD), skeletal histologic pathology is found in virtually all patients [14]. The pandemic of CKD and ESKD and the role of the CKD–MBD in the associated mortality, make the syndrome a major health issue for Americans and all developed societies [5, 15, 16].

Pathogenesis

Renal injuries produce circulating signals that affect skeletal osteocytes (see Fig. 77.1) [17]. The resulting stimulation of FGF23 and sclerostin production yield an inhibition to skeletal remodeling that becomes a background as adaptive hyperparathyroidism maintains and even increases remodeling rates. In addition to FGF23, the increases in Dickkopf 1 and sclerostin powerful inhibitors of Wnt signaling in early CKD represent biomarker evidence of skeletal inhibition produced by renal injury. The loss of skeletal anabolism in CKD occurs in the presence of normal parathyroid hormone (PTH), vitamin D, Ca, and PO4 levels, but it is not usually observed as the adynamic bone disorder because disturbed homeostasis in these factors stimulate PTH secretion. The sustained increase in PTH levels produced through adaptation to CKD increase remodeling rates and eventually produce an unwanted high turnover disorder of skeletal remodeling, osteitis fibrosa, (see below).

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

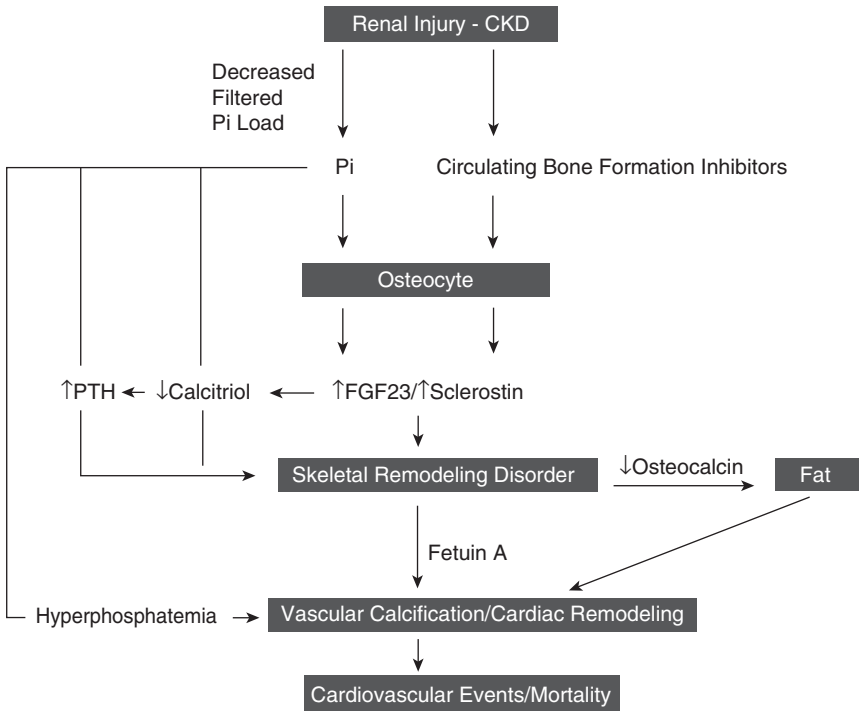

Fig. 77.1. A multiorgan system "wired" together in part by circulating communications is activated in chronic kidney disease. Renal injury increases the circulating levels of inhibitors of bone formation such as Dickkopf-1 and the soluble frizzled related protein family. Renal injury also decreases the filtered load of Pi, and this disturbance, though not sufficient to detectably change serum Pi, stimulates secretion of FGF23 by osteocytes. Through changes in FGF23, sclerostin, PTH, and calcitriol (among others), a skeletal remodeling disorder evolves, which in turn contributes to vascular calcification, cardiac remodeling and cardiovascular morbidity/mortality. Direct connections between each organ have been partially defined in the case of kidney–bone and kidney–heart communications. The contribution of the skeleton and the kidney to hyperphosphatemia, the role of hyperphosphatemia in causing vascular calcification, and the effects of vascular calcification on the heart have been established.

Pathogenetic factors in the CKD–MBD

Fibroblast growth factor 23

Fibroblast growth factor 23 (FGF23) is the original phosphatonin (phosphate excretion regulating hormone) discovered in studies of autosomal dominant hypophosphatemic rickets and oncogenic osteomalacia [18, 19]. FGF23 levels are stimulated by mild renal injury and progressively rise during the course of CKD [20, 21] due to increased secretion, loss of feedback inhibition, and decreased catabolism by the diseased kidney. FGF23 is produced by osteocytes and osteoblasts, and it represents direct bone–kidney and bone–parathyroid connections in the multiorgan system involved in the CKD–MBD (not shown in Fig. 77.1). FGF23 signaling through FGF receptors requires the coreceptor function of α-Klotho [22]. Klotho has limited tissue distribution and thus,defines the tissue targets of FGF23 as a hormone. The off-target actions of FGF23 are associated with CKD (discussed below) and perhaps with anomalous expression of Klotho (also discussed below). The principal tissue targets of FGF23 are the proximal and distal renal tubules, the parathyroid glands and the brain. FGF23 suppresses PTH secretion, and PTH gene expression through FGFR/Klotho signaling [23]. In late CKD, the very high levels of FGF23 may permit anomalous FGF receptor activation independent of Klotho and result in FGF23 stimulated toxic reactions such as cardiac myocyte hypertrophy [24].

Klotho

Klotho was originally identified as an aging suppressor, and its gene product is a single-pass transmembrane protein that can be shed through membrane-anchored proteases [25]. Secreted Klotho functions in an endocrine fashion as an enzyme or possibly as a hormone [26]. Klotho is highly expressed in the renal distal tubule, but its major actions as a FGF23 coreceptor are in the proximal tubule [27], where FGF23/Klotho regulate the activity of NaPi2a and NaPi2c, CYP27B1 (the 1α-hydroxylase) and CYP24A1 (the 24 hydroxylase), the parathyroid gland, and the brain. Recent studies suggest that Klotho is expressed in the arteries of humans and that this renders them an FGF23 target tissue[28]. Klotho deficiency in CKD is associated with vascular calcification [26, 28], and rescue by transgenic overexpression impaired phosphate stimulated vascular calcification.

Hyperphosphatemia

As renal injury decreases nephron number, phosphate excretion is maintained by reductions in the fraction of filtered phosphate reabsorbed by the remaining nephrons under the influence of FGF23 and PTH. The increase in phosphate excretion per remaining nephron maintains phosphate homeostasis at the cost of higher PTH and FGF23 levels. In stages IV and V CKD, when renal injury is severe enough that the glomerular filtration rate reaches levels of less than 30% of normal, hyperphosphatemia develops due to decreased renal excretion despite high PTH and FGF23 levels [29]. Studies demonstrate that the failure of calcium and phosphorous deposition into the skeleton or excess resorption of the skeleton also contribute to abnormal serum phosphorus and calcium levels in CKD and ESKD [7, 30]. Hyperphosphatemia decreases serum calcium through physicochemical

complexation and suppresses 1α-hydroxylase activity, which results in further lowering of circulating calcitriol levels (Fig. 77.1). Moreover, a direct stimulatory effect of phosphorus on parathyroid gland cells, independent of calcium and calcitriol, produces increased secretion and nodular hyperplasia of parathyroid gland cells (Fig. 77.1) [31, 32]. A direct stimulatory effect of Pi, perhaps in the exchangeable Pi pool, regulates osteocyte FGF23 secretion. Finally, hyperphosphatemia is a signaling mechanism for induction of heterotopic mineralization of the vasculature in CKD and ESKD (Fig. 77.1) [33–35].

Calcitriol deficiency

The physiologic actions of FGF23 from the osteocyte include inhibition of proximal tubular CYP27B1, 25OH vitamin D 1α hydroxylase, and stimulation of CYP24A1, vitamin D 24-hydroxylase, decreasing calcitriol production, increasing catabolism and producing vitamin D deficiency in early CKD (Fig. 77.1). As CKD advances, the functioning nephron mass is decreased, and this, combined with an increased phosphate load in the remaining nephrons and increased FGF23 levels, results in calcitriol deficiency [36]. Calcitriol deficiency, in turn, decreases intestinal calcium absorption and leads to hypocalcemia. Calcitriol deficiency in cases of advanced kidney failure in turn diminishes tissue levels of vitamin D receptors (VDRs), in particular, the VDR of parathyroid gland cells [37]. Because the chief cell VDR suppresses the expression of pre-pro-PTH mRNA, lower circulating calcitriol levels together with a low number of VDRs in patients with ESKD result in stimulation of both synthesis and secretion of PTH [38].

Hypocalcemia

As CKD progresses, hypocalcemia develops due to decreased intestinal calcium absorption. Low blood levels of ionized calcium stimulate PTH secretion, whereas high calcium concentrations suppress it. The action of calcium on parathyroid gland chief cells is mediated through a calcium sensor; a G-protein coupled plasma membrane receptor (CASR) expressed in chief cells, kidney tubular epithelia, and widely throughout the body at lower levels [39, 40]. The short-term stimulation of PTH secretion induced by low calcium is due to exocytosis of PTH packaged in granules, and longer-term stimulation results from an increase in the number of cells that secrete PTH. More prolonged hypocalcemia induces changes in intracellular PTH degradation and mobilization of a secondary storage pool. Within days or weeks of the onset of hypocalcemia, pre-pro-PTH mRNA expression is stimulated. This effect is exerted through a negative calcium response element located in the upstream flanking region of the gene for PTH. Expression of the calcium receptor has been shown to be suppressed by calcitriol deficiency and stimulated by calcitriol administration, suggesting an additional regulatory mechanism of the active vitamin D metabolite on PTH production. The decreased number of calcium-sensing receptors with low circulating calcitriol may, at least in part, explain the relative insensitivity of parathyroid gland cells to calcium in patients undergoing dialysis.

Calcium balance is deranged in CKD as expected from the discussion above, but often it is affected by medical therapy aimed at phosphate binding or by the use of calcium supplements, surprisingly to the positive side. In CKD, there is little ability to adjust calcium excretion through the kidney for unknown reasons, and the result of increased intake and inadequately regulated absorption is positive balance. This is a major factor in the stimulation of vascular calcification highly prevalent in CKD.

Hyperparathyroidism

All of the mechanisms discussed above result in increased production of PTH and nodular hyperplasia of the parathyroid glands in CKD. The size of the parathyroid glands progressively increases during CKD and, in dialyzed patients, paralleling serum PTH levels. This increase in gland size is mainly due to diffuse cellular hyperplasia. Monoclonal chief cell growth also develops, resulting in the formation of nodules. Nodular hyperplastic glands have less vitamin D receptor and calcium-sensing receptors compared to diffusely hyperplastic glands, promoting parathyroid gland resistance to calcitriol and calcium. Sustained elevation in PTH levels, while adaptive to maintain osteoblast surfaces, produces an abnormal phenotype of osteoblast function and osteocyte stimulation with relatively less type 1 collagen and more receptor activator of nuclear factor-κB ligand (RANKL) production than anabolic osteoblasts. A key component of the RANKL stimulation is osteocytic in origin. This leads to a high turnover osteodystrophy, PTH receptor desensitization, and excess bone resorption.

Hypogonadism

Patients with ESKD have various states of gonadal dysfunction. Estrogen and testosterone deficiency significantly contribute to renal osteodystrophy (ROD) pathogenesis.

Other factors

Inflammatory mediators, acidosis, aluminum, leptin, and retained catabolites are all potentially critical factors in CKD–MBD that have not been well studied, or have been clinically eliminated (space prevents further description of their roles). Some patients with CKD are treated with glucocorticoids, which have an impact on bone metabolism. Patients maintained on chronic dialysis have retention of β2-microglobulin. Additionally, alterations in growth factors and other hormones involved in the regulation of bone remodeling may be disordered in CKD/ESRD, thus affecting bone remodeling and contributing to the development of ROD.

Table 77.1. Pathology and Diagnosis of Bone Turnover in CKD

I. Predominant hyperparathyroidism, high-turnover ROD
   a. Intact PTH >500 pg/ml
   b. Elevated alkaline phosphatase or bone-specific alkaline phosphatase
   c. Sclerostin levels elevated but may be less than in the ABD
II. Low-turnover disease
   a. Adynamic bone disorder (ABD)
      1. Intact PTH <100 pg/ml
      2. Normal alkaline phosphatase or bone-specific alkaline phosphatase
      3. Low osteocalcin
      4. Elevated sclerostin, especially early in CKD before stage V
   b. Osteomalacia
      1. Intact PTH <100 pg/ml
      2. Normal alkaline phosphatase or bone-specific alkaline phosphatase
      3. Low osteocalcin
      4. Elevated Al^{+3}
III. Mixed uremic osteodystrophy
   a. PTH >300 pg/ml
   b. Elevated Al^{+3}
IV. Unknown
   a. PTH > 100 < 500 pg/ml

ROD, renal osteodystrophy, refers to the skeletal pathology component of the CKD–MBD.

Pathology of CKD–MBD (also referred to as ROD)

Renal osteodystrophy (ROD) is a term for the skeletal pathology component of the CKD–MBD syndrome, and this specific definition replaces the previous use of the term in a broader context, which is now specified by the new syndrome term, CKD–MBD . ROD is not a uniform disorder. Depending on the relative contribution of the different pathogenic factors discussed above and their treatment, various pathologic patterns of bone remodeling are expressed in CKD and ESKD. See Table 77.1 for the pathology and diagnosis of bone turnover in CKD.

Predominant hyperparathyroid bone disease, high turnover ROD, osteitis fibrosa

Sustained excess parathyroid hormone results in increased bone turnover. Osteoclasts, osteoblasts, and osteocytes are found in abundance. Disturbed osteoblastic activity results in a disorderly production of collagen, which results in formation of woven bone. Accumulation of fibroblastic osteoprogenitors not in the osteoblastic differentiation program results in collagen deposition (fibrosis) in the peritrabecular and marrow space. The nonmineralized component of bone, osteoid, is increased, and the normal three-dimensional architecture of the osteoid is frequently lost. Osteoid seams no longer exhibit their usual birefringence under polarized light; instead, a disorderly arrangement of woven osteoid and woven bone with a typical crisscross pattern under polarized light is seen. The mineral apposition rate and number of actively mineralizing sites are increased, as documented under fluorescent light after the administration of time-spaced fluorescent (tetracycline) markers.

Low-turnover bone disease, adynamic bone disorder

Low-turnover uremic osteodystrophy is the other end of the spectrum of renal osteodystrophy. The histologic hallmark of these disorders is a profound decrease in bone turnover, due to a low number of active remodeling sites, suppression of bone formation, and resorption. Bone resorption is not as decreased as formation. The result is a low turnover osteopenic condition. The majority of trabecular bone is covered by lining cells, with few osteoclasts and osteoblasts. Bone structure is predominantly lamellar. The extent of mineralizing surfaces is markedly reduced. Usually only a few thin, single tetracycline labels are observed. Two subgroups can be identified in this type of renal osteodystrophy, depending on the cause of events leading to a decline in osteoblast activity: adynamic bone disorder (ABD) and low turnover osteomalacia from Al^{+3} intoxication, bisphosphonate administration, or other factors.

Low-turnover osteomalacia is characterized by an accumulation of unmineralized matrix in which a diminution in mineralization precedes or is more pronounced than the inhibition of collagen deposition. Unmineralized bone represents a sizable fraction of trabecular bone volume. The increased lamellar osteoid volume is due to the presence of wide osteoid seams that cover a large portion of the trabecular surface. The occasional presence of woven bone buried within the trabeculae indicates past high bone turnover. When osteoclasts are present, they are usually seen within trabecular bone or at the small fraction of trabecular surface left without osteoid coating.

Mixed uremic osteodystrophy, high turnover ROD plus a mineralization defect

Mixed uremic osteodystrophy is caused primarily by hyperparathyroidism and defective mineralization with or without increased bone formation. These features may coexist in varying degrees in different patients. Increased numbers of heterogeneous remodeling sites can be seen. The number of osteoclasts is usually increased. Because active foci with numerous cells, woven osteoid seams, and peritrabecular fibrosis coexist next to lamellar sites with a more reduced activity, greater production of lamellar or woven osteoid causes an accumulation of osteoid with normal or increased thickness of osteoid

seams. Whereas active mineralizing surfaces increase in woven bone with a higher mineralization rate and diffuse labeling, mineralization surfaces may be reduced in lamellar bone with a decreased mineral apposition rate.

Associated features

Osteoporosis and osteosclerosis

With progressive loss of renal function, cancellous bone volume may be increased along with a loss of cortical bone, but this is in part due to deposition of woven immature collagen fibrils instead of lamellar fibrils. Thus, bone strength suffers despite the increase in mass detected by dual energy X-ray absorptiometry (DXA). Patients undergoing chronic dialysis might have a loss or gain in bone volume depending on bone balance. When the bone balance is positive, osteosclerosis may be observed when osteoblasts are active in depositing new bone (especially woven), thus superseding bone resorption. This is rare in the 21st century due to improved therapy of secondary hyperparathyroidism.

In the case of negative bone balance, bone loss occurs in cortical and cancellous bone and is more rapid when bone turnover is high. In those cases, bone densitometry will detect osteopenia or osteoporosis. The prevalence of osteoporosis in the population with CKD exceeds the prevalence in the general population [41–43]. Osteoporosis is observed in CKD before dialysis is required for end-stage kidney failure [44]. When bone turnover is high, as in secondary hyperparathyroidism with osteitis fibrosa, bone resorption rates are in excess of bone formation, and osteopenia progressing to osteoporosis may result. When bone turnover is low, although both bone formation rates and bone resorption may be reduced, resorption is in excess and loss of bone mass occurs. Thus, osteoporosis may be observed with either high turnover [44–47] or low turnover [48] forms of osteodystrophy. When bone resorption exceeds bone formation rates in CKD, positive phosphorus and calcium balance results in hyperphosphatemia and hypercalcemia without an increase in skeletal mineral deposition, but with a stimulation of heterotopic mineralization, especially of the vasculature. The failure of the skeleton to absorb positive phosphate balance in CKD is an important stimulus to heterotopic mineralization, and links the skeleton and osteoporosis in CKD to cardiovascular events and mortality [35]. From the above discussion, it is apparent that four forms of osteoporosis complicate the CKD–MBD: due to high turnover ROD, due to low turnover ROD, osteoporosis preexistent to renal disease, and osteoporosis due to gonadal hormone deficiency.

Bone aluminum, iron, lanthanum, bisphosphonate accumulation

These substances accumulate in bone at the mineralization front, at the cement lines, or diffusely. The extent of stainable aluminum at the mineralization front correlates with histologic abnormalities in mineralization. Aluminum deposition is most severe in cases of low-turnover osteomalacia. However, it can be observed in all histologic forms of renal osteodystrophy. In patients in whom an increased aluminum burden develops, bone mineralization and bone turnover progressively decrease. These abnormalities are reversed with the removal of the aluminum. Iron also accumulates at the mineralization front and can cause low turnover forms of ROD similar to aluminum, although much less is known about iron intoxication than aluminum. Lanthanum has recently been added as a rare earth ion administered to CKD and ESKD patients as a phosphate binder. It is poorly absorbed, and its levels in bone are much less than aluminum. It has proven not to have long-term toxic effects. Five-year data suggest that the levels of skeletal lanthanum accumulation remain below those with any biologic or toxic effects. Lanthanum disappearance from bone deposits is slow, but not as slow as bisphosphonate disappearance. Bisphosphonates are drugs used in the treatment of osteoporosis and hypercalcemia. There are increasing instances of bisphosphonate use in patients with CKD and ESKD, especially for treatment of vascular calcification and calciphylaxis. However, the nature of the bone remodeling abnormalities in CKD, especially with woven bone formation and mineralization defects, lend a high level of risk to skeletal deposition of a substance that once deposited may not be removed. Such a risk of long-term retention of an active drug inhibiting bone turnover is now being recognized with use of bisphosphonates in osteogenesis imperfecta, and the rare side effect of the drugs in osteonecrosis of the jaw and atypical femoral fractures [49]. The risk of these side effects is obviously increased in CKD, appropriately limiting their use to emergent situations.

Clinical manifestations

Patients with mild to moderate kidney insufficiency are rarely symptomatic due to ROD and its skeletal pathology. However, fracture risk is increased more than twofold above age-matched cohorts without CKD. Stimulation of vascular calcification in the setting of disordered skeletal remodeling is a life-threatening complication of the CKD–MBD . It produces vascular stiffness, which in CKD causes an increase in systolic blood pressure, a widening of the pulse pressure and an increase in pulse wave velocity. All of these lead to cardiac hypertrophy, heart failure, and cardiovascular mortality.

The pathogenesis of vascular calcification in CKD is complex, and pathologically is of two types: neointimal and arterial medial. Atherosclerotic neointimal calcification is multifactorial, but it involves activation of an osteoblastic differentiation program in cells of the neointima of atherosclerotic plaques. The skeleton contributes to the pathogenesis of vascular calcification. Signals deriving from the skeleton are direct causes of the vascular mineralization. One such signal is hyperphosphatemia [35]. Diffuse calcification of arterial tunica media

is referred to as Mönckeberg's sclerosis. CKD is the most common cause of Mönckeberg's sclerosis, especially when it complicates diabetes mellitus.

Heterotopic mineralization, calciphylaxis, and tumoral calcinosis

Heterotopic tissue calcification may occur in the eyes and manifest as band keratopathy in the sclera or induce an inflammatory response known as the "red eye syndrome" in the conjunctiva. Calcium deposits are also found in the lungs and lead to restrictive lung disease. Deposits in the myocardium might cause arrhythmias, annular calcifications, valvular calcification, or myocardial dysfunction. Calcification of the kidney may contribute to progression of kidney failure. Most soft tissue calcifications are attributed to the increased calcium phosphate product contributed to by renal osteodystrophy and excess bone resorption. The syndrome of calciphylaxis is characterized by vascular calcification in the tunica media of peripheral arteries. These calcifications induce painful violaceous skin lesions that progress to ischemic necrosis. This syndrome is associated with serious complications and often death.

Tumoral calcinosis is a form of soft tissue calcification that involves the periarticular tissues. Calcium deposits may grow to enormous size and interfere with the function of adjacent joints and organs. Although this type of calcification is usually associated with high calcium phosphate products, its exact pathogenesis is poorly understood. The recent discoveries of three single gene mutations in FGF23, Klotho, and GALNT3 that cause inherited tumoral calcinosis shed light on the role of hyperphosphatemia in its pathogenesis [50–52]. The role of GALNT3 in hyperphosphatemia is associated with enzymatic degradation of FGF23.

Bone pain, fractures, and skeletal deformities

Symptoms of ROD related to the skeleton appear in patients with advanced kidney failure. Clinical manifestations are preceded, however, by an abnormal biochemical profile that should alert the physician and prompt steps to prevent more severe complications. When symptoms related to the skeleton occur, they are usually insidious, subtle, nonspecific, and slowly progressive.

Bone pain is usually vague, ill defined, and deep seated. It may be diffuse or localized in the lower part of the back, hips, knees, or legs. Weight bearing and changes in position commonly aggravate it. Bone pain may progress slowly to the degree that patients are completely incapacitated. Bone pain in patients with ESKD usually does not cause physical signs; however, local tenderness may be apparent with pressure. Occasionally, pain can occur suddenly at one joint of the lower extremities and mimic acute arthritis or periarthritis not relieved by heat or massage. A sharp chest pain may indicate rib fracture. Spontaneous fractures or fractures after minimal trauma may also occur in vertebrae (crush fractures) and in tubular bones.

Bone pain and bone fractures can be observed in all patients with ESKD independent of the underlying histologic bone disease, especially when osteoporosis is present [41]. However, low-turnover osteomalacia and aluminum-related bone disease are associated with the most severe bone pain and the highest incidence of fractures and incapacity.

Skeletal deformities can be observed in children and adults. Most children with ESKD have growth retardation, and bone deformities may develop from vitamin D deficiency (rickets) or secondary hyperparathyroidism. In rickets, bowing of the long bones is seen, especially the tibiae and femora, with typical genu valgum that becomes more severe with adolescence. Long-standing secondary hyperparathyroidism in children may be responsible for slipped epiphyses secondary to impaired transformation of growth cartilage into regular metaphyseal spongiosa. This complication most commonly affects the hips and becomes obvious in preadolescence. It causes limping but is usually painless. When the radius and ulna are involved, ulnar deviation of the hands, and local swelling may occur. In adults, skeletal deformities can be observed in cases of severe osteomalacia or osteoporosis and include lumbar scoliosis, thoracic kyphosis, and recurrent rib fractures.

The diagnosis and treatment of the CKD–MBD are covered in Chapter 78, and this discussion concludes with recall of the data leading to Fig. 77.1. Renal injury disturbs the complex physiology of bone and mineral metabolism, promotes vascular calcification, and compromises cardic function. In addition, the effects of kidney disease on the skeleton contribute through the bone–cardiovascular axes to the major effect of kidney injury to stimulate cardiovascular disease and produce the high mortality rates associated with kidney disease.

INTRODUCTION

Loss of glomerular filtration and other renal functions in chronic kidney disease leads to complex abnormalities of mineral homeostasis, referred to as mineral and bone disorder (CKD–MBD) [1, 2], that include biochemical abnormalities [i.e., elevations in serum fibroblast growth factor 23 (FGF23) and parathyroid hormone (PTH), reductions in 25(OH) and $1,25(OH)_2$ vitamin D concentrations, hyperphosphatemia, hypocalcemia], metabolic bone disease, extraskeletal calcification, and increased cardiovascular and all cause mortality [3]. The discovery of the phosphaturic and vitamin D regulatory hormone FGF23 has provided new insights into the pathogenesis of secondary hyperparathyroidism [4]. A heightened interest in CKD–MBD has arisen because of compelling, but not incontrovertible, evidence that elevations of serum FGF23, PTH, and phosphorus, along with reductions in 25(OH)D and $1,25(OH)_2D$, contribute to derangements of immune and cardiovascular functions leading to the observed increases in morbidity and mortality associated with CKD. Moreover, new therapeutic approaches and bundling of payments for management of ESRD have created an opportunity to reconsider the optimal therapeutic approaches to treat disordered mineral metabolism in CKD.

PHYSIOLOGY

Understanding the pathophysiology of abnormal mineral metabolism is a prerequisite for making informed decisions regarding therapies. Three hormones (PTH, FGF23, and $1,25(OH)_2D$) and four organ systems [parathyroid gland (PTG), bone, small intestines, and kidney] are involved in regulation mineral homeostasis.

PTH, the key calcemic hormone, is produced and secreted by PTG and is responsible for the tight minute-to-minute regulation of serum ionized calcium levels through stimulation of calcium reabsorption in distal tubule [5], calcium efflux from bone due to increased osteoclastic bone resorption [6], and conversion of 25(OH) D to $1,25(OH)_2D$ through the simulation of Cyp27b1 activity in the proximal tubule of the kidney [7]. $1,25(OH)_2D$ stimulates calcium and phosphate absorption through the gut. The principal factor regulating PTH secretion is extracellular calcium acting through the G-protein coupled calcium-sensing receptor (CasR) located in chief cells in the parathyroid gland. $1,25(OH)_2D$, acting through classical vitamin D receptor (VDR) nuclear pathways [8], and hyperphosphatemia through unknown mechanisms [9], respectively, inhibit and stimulate PTH production. Mouse genetic studies that compare the effects of ablation of CasR [10] and VDR in the PTG on

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

hyperparathyroidism [11], however, suggest that hypocalcemia through CasR is the dominant over $1,25(OH)_2D$ VDR pathway in the development of hyperparathyroidism. FGF23 is purported to suppress PTH in animal studies [12], but PTH is elevated in the presence of elevated FGF23 in CKD, possibly due to downregulation of the FGFR1/Klotho coreceptor for FGF2 in the PTG in CKD [13]. Actions of PTH to increase serum calcium also results in enhanced phosphorus release from the bone and increased gastrointestinal phosphate absorption through $1,25(OH)_2D$ effects [7]. The phosphaturic actions of PTH by downregulating sodium phosphate cotransporters in the proximal tubule of the kidney increases phosphate excretion, thereby avoiding a positive phosphate balance [14].

Native vitamin D is a secosteroid that is available in the diet, cholecalciferol (vitamin D_3, from animal and ergocalciferol (vitamin D_2) from plant sources, respectively) and is produced endogenously by the conversion of 7-dehydrocholesterol by exposure UV light. Vitamin D is stored in fat and circulates bound to vitamin D binding proteins (DBPs). Vitamin D metabolism involves both systemic and intracrine pathways. In the systemic pathway, vitamin D undergoes two key hydroxylation steps to form active $1,25(OH)_2D$. Both vitamin D_2 and vitamin D_3 are metabolized in the liver by a group of 25-hydroxylase (including CYP27A) to form 25(OH)D and $25OHD_3$, respectively. This hydroxylation step in the liver is substrate dependent and is not thought to be regulated by hormones or alterations in calcium or phosphate. The major site of regulation is in the conversion of 25(OH)D to the active $1,25(OH)_2D$ by 1α-hydroxylase (Cyp27b1) in the kidneys, where 25(OH)D and DBPs are reabsorbed in the proximal nephron from tubular fluids by a megalin-dependent mechanism. 25(OH)D undergoes hydroxylation of the carbon atom located at position 1 of the A ring of 25-hydroxyvitamin D in the mitochondria of epithelial cells. The kidney is the major source of circulating $1,25(OH)_2D$ and its production is stimulated by PTH and decreased by phosphate and FGF23. In addition, 25(OH)D and $1,25(OH)_2D$ are catabolized by 24 α-hydroxylase (Cyp24) to inactive metabolites, a step that stimulated by FGF-23 and $1,25(OH)_2D$ itself [15].

In the intracrine pathway, 25(OH)D is also converted to $1,25(OH)_2D$ and catabolized by Cyp24 in extrarenal tissues, such as monocytes and macrophages, where it has been shown to be important regulator of the innate immune response. Antigen stimulation is required for the intracrine production of $1,25(OH)_2D$ and extrarenal tissues do not contribute to the circulating $1,25(OH)_2D$. Other local/intractine functions of $1,25(OH)_2D$ have been demonstrated, including effects on cardiovascular function through the regulatory effects on the renin–angiotensen system and may also have effects to prevent certain types of cancers. These extrarenal effects have been used as the biological basis for current recommendations to provide vitamin D supplementation to CKD patients.

FGF23 is a bone-derived hormone that is mainly produced by osteocytes and osteoblast. In the kidneys, FGF23 acts as phosphaturic and vitamin D–regulatory hormone by increasing renal phosphate (P) excretion through inhibition of sodium-dependent phosphate reabsorption and decreases $1,25(OH)_2D$ production through the downregulation of CYP27b1 gene and the upregulation of CYP 24 gene expression and activity [16]. Physiologically, FGF23 participates in a bone–kidney axis to prevent vitamin D toxicity, where $1,25(OH)_2D$ stimulates FGF23 production, which, in turn, targets the kidney to suppress $1,25(OH)_2D$ synthesis and increase its degradation. Another putative function of FGF23 may be to coordinate bone formation and mineralization with renal handling of phosphate. Impaired mineralization and/or bone formation leads to alteration in intrinsic matrix derived factors that stimulate FGF23 release to match bone phosphate buffering capacity with renal phosphate handling. The link between bone mineralization and FGF23 expression in bone is supported by inactivating mutations of Phex, Dmp1, and Ank, which regulate various aspects of extracellular matrix mineralization [17]. The main systemic stimulators for FGF23 secretion are increased serum $1,25(OH)_2D$ levels, dietary phosphorus intake [16] and PTH. $1,25(OH)_2D$ binds the vitamin D response element in the promoter region of the FGF23 gene in osteocytes and directly increases FGF23 gene transcription [12]. In contrast, alterations of dietary phosphate have failed to show a consistent effect to increase increased FGF23 secretion [18], or have small effects on serum FGF23 concentrations, suggesting that phosphate itself may not directly regulate FGF23. PTH effects are also variable, with some studies showing that PTH stimulates, while others show that PTH inhibits FGF23 expression in bone. These discrepancies of PTH effects on FGF23 are likely due to differential anabolic and catabolic effects of PTH on bone that are dependent on the dose and frequency of PTH administration and to interactions between these direct PTH and $1,25(OH)_2D$ on FGF23 gene transcription [4, 12].In addition to its role in regulating phosphate and vitamin D metabolism, FGF23 is associated with adverse cardiovascular events, metabolic syndrome, and mortality in both CKD and the general population through mechanisms that remain to be elucidated [19–21].

PATHOGENESIS

New insights into the regulation of mineral homeostasis derived from understanding the regulation and function of FGF23 have challenged some of the traditional views of the pathogenesis of secondary hyperparathyroidism as well as the mechanism and significance of reduced circulating 25(OH)D and $1,25(OH)_2D$ in CKD. Traditionally, secondary hyperparathyroidism in CKD has been viewed as vitamin D deficient state, where decreased glomerular filtration rate (e-GFR) and functioning nephron mass results in diminished 1-α hydroxylase enzyme (Cyp27b1) in the proximal tubule leading to

Table 78.1. Target Levels for Calcium, Phosphorus, and Parathyroid Hormone

		KDOQI	KDIGO
Calcium	CKD stage 3-5	Normal range	Normal range
	CKD 5D	Normal range but preferably 8.4–9.5 mg /dL	Normal range
Phosphorus	CKD stage 3-4	2.7–4.6 mg/dL	Normal range
	CKD stage 5	3.5–5.5 mg/dL	Normal range
	CKD stage 5D	3.5–5.5 mg/dL	Toward normal range
Intact PTH	CKD stage 3	35–70 pg/mL	Optimal level is unknown
	CKD stage 4	70–110 pg/mL	Optimal level is unknown
	CKD stage 5	200–300 pg/mL	Optimal level is unknown
	CKD stage 5D	200–300 pg/mL	2–9 times above upper limit

Ca: calcium; CKD: chronic kidney disease; GFR: glomerular filtration rate; KDOQI: Kidney/Dialysis Outcomes Quality Initiative; P: phosphorus; PTH: parathyroid hormone.
Modified from National Kidney Foundation DOQI™ Kidney Disease Outcomes Quality Initiative. 2004. *Am J Kidney Dis* 43: S1–S201; and the National Kidney Foundation and Kidney Disease: Improving Global Outcomes (KDIGO).

decreased $1,25(OH)_2D$ production and phosphate retention due to impaired phosphate clearance. The resulting reduction in $1,25(OH)_2D$, hypocalcemia, and hyperphosphatemia results in the stimulation of PTH release from the parathyroid gland, which undergoes hypertrophy and hyperplasia, characteristic of secondary hyperparathyroidism. In the integrated view of the FGF23–PTH–vitamin D endocrine axis in CKD, initial secretion of FGF23 by the bone triggered by unknown stimuli is the inciting event leading to secondary hyperparathyroidism in CKD. Increments in serum FGF23 concentrations suppress Cyp27b1-mediated $1,25(OH)_2D$ production and enhances Cyp24-mediated $1,25(OH)_2D$ catabolism leading to reduced circulating $1,25(OH)_2D$. In addition, FGF23 inhibits renal phosphate reabsorption to compensate for phosphate retention due to the reduced GFR in people with CKD [4]. Although FGF23 has been shown to suppress PTH production in healthy individuals, in CKD, FGFR1, and Klotho are downregulated in PTG, thus PTH is increased [4]. As CKD progresses, increased PTH stimulates bone remodeling and efflux of calcium and phosphorus from the bone and a further increase FGF23 production. In addition, PTH stimulates the production of 1, $25(OH)_2D$ production [12], offsetting the effects of FGF23 to suppress $1,25(OH)_2D$. The interactions between FGF23–PTH–vitamin D favor net phosphate loss while maintaining calcium homeostasis [4].

DIAGNOSIS

Biochemical determinations of PTH, 25(OH)D, calcium, and phosphate are used to define and monitor CKD–MBD. While assessment of serum FGF23 may be useful, it is currently not routinely used in the assessment of CKD–MBD. In addition, while bone markers, such as bone-specific alkaline phosphatase, osteocalcin, procollagen C-terminal propeptide (PICP) and procollagen N-terminal propeptide (PINP), radiographic characterization of bone density and soft-tissue calcifications, and histological assessment of bone structure, formation, and resorption are informative, these analytical tools are not commonly being used in the diagnosis and management of CKD–MBD. The biochemical targets representing optimal management of CKD–MBD are not known, and recent efforts to establish guidelines have produced disparate recommendations.

Clinical practice guidelines for bone metabolism and disease in CKD stages 3 to 5 have been developed by the National Kidney Foundation – Kidney Disease: Outcomes Quality Initiative (KDOQI) in 2003 [22] and Kidney Disease: Improving Global Outcomes (KDIGO) in 2009 [2] (Table 78.1). The differences between the two guidelines reflect uncertainty regarding the importance of biochemical measurements in predicting outcomes. KDOQI guidelines are supported by data from observational studies that serum phosphorus concentrations less than 3.5 and above 5.5 mg/dl are associated with increased mortality, and calcium concentration greater than 9.5 mg/dl and high calcium phosphorus products greater than 55 are associated with increased vascular calcifications. PTH values between 150 and 300 pg/ml are associated with "normal" bone remodeling. The difficulty in achieving these targets in end-stage renal disease (ESRD) patients, the variability in PTH assays in predicting bone remodeling, and lack of evidence from randomized controlled trials to support the safety, efficacy, and survival advantage of attaining these biochemical ranges have lead to alternative recommendations. In this regard, KDIGO differs from KDOQI in that decision making needs to be based on a trend rather than a single laboratory value, In addition, KDIGO raises the upper limit of serum calcium to that in the general population and recommends achieving phosphate control also toward the normal range of 2.5 to 4.5 mg/dl.

PTH is a measure of PTG activity; however, it correlates poorly with indices of bone turnover. There is lack of consensus on the optimal PTH range in the dialysis patient, as reflected by different recommended PTH ranges in different guidelines. For example, the KDOQI goals for serum laboratory values for PTH in ESRD is 150–300 pg/ml, whereas in KDIGO, the upper limit of PTH in ESRD is 600 pg/ml (and upward changes in PTH levels are an indication for treatment below this limit). In contrast, the Japanese Society for Dialysis Therapy sets the PTH range to 60–180 pg/mL in ESRD patients, a upper limit roughly twofold greater than the upper normal limit in the general population. These variable recommendations are due in part to the variability in different PTH assays and differing assessments of the risks of lower PTH on bone metabolism and soft-tissue calcifications. Too liberal of an upper limit is likely to increase the risk of progressive parathyroid disease leading to tertiary hyperparathyroidism and parathyroidectomy, whereas too low of a limit might increase the risk of adynamic bone disease. The observation that serum levels of PTH greater than 600 pg/ml are associated with an increased risk of death and cardiovascular events in CKD [23] has influenced the establishment of a broader range of PTH levels.

Currently, other than bone biopsies, there is no diagnostic test that identifies the different subtypes of bone diseases in CKD, although it is not clear that such information is clinically important or can be used to direct therapy, which is typically directed at preventing progressive elevations in PTH, avoiding hypercalcemia, and minimizing the severity of hyperphosphatemia. Biomarkers of bone formation (bone-specific alkaline phosphatase, osteocalcin) and bone resorption (urinary collagen breakdown products, TRAP5b), do not predict bone histology in uremic bone disease as they do in assessing bone turnover in patients with osteoporosis.

Serum FGF23 concentrations progressively increases during CKD, reaching over 1,000-fold above normal in ESRD patients [24]. Observational studies showed that elevated FGF23 is associated with refractory hypreparathyrodism (HPTH), progression of renal failure, left ventricular hypertrophy, and vascular calcifications and increased mortality [19–21, 24]. The factors leading to increased FGF23 in CKD is not clear, but use of active vitamin D analogues results in increased FGF23 levels [16], whereas calcimemitics are associated with decreased FGF23 levels [25]. FGF23 levels are also high in patients with secondary HPTH, and parathyroidectomy results in lowering of circulating FGF23 levels. FGF23 levels are not currently used in clinical practice.

The best biochemical index of vitamin D nutrition is considered to be 25(OH)D. Low 25(OH) levels are highly prevalent in CDK. Definitions for vitamin D insufficiency (25(OH)D concentration of 20 to 30 ng/mL), and deficiency (25(OH)D level less than 20 ng/mL) are the same in CKD as the general population [26].

Skeletal X-rays are insensitive measures of bone density but can detect vascular calcifications. Measurement of bone mineral density (BMD) by dual-energy X-ray absorptiometry (DXA) scanning is limited in CKD patients, since BMD correlates poorly with osteopenia and fracture risk because of the effects of secondary HPTH to cause extraskeletal calcifications, osteosclerosis, and osteomalacia. Thus, it is an insensitive tool to evaluate bone mass in CKD patients [27].

TREATMENT OF CKD–MBD

Therapeutic goals

The goals of therapy of CKD–MBD are: (1) to attain neutral phosphorus balance without causing protein malnutrition, (2) to control PTH levels in a range that prevents the progression of secondary to tertiary HPTH while maintaining normal bone health, and (3) to provide adequate vitamin D supplementation to optimize biological effects of this hormone that are not necessarily related to mineral metabolism. Since hyperphosphatemia, vascular calcifications, and elevated FGF23 are associated with increased cardiovascular disease and mortality in CKD, a desirable outcome of management would also be to reduce the contribution of CKD–MBD to the increased morbidity and mortality. Although retrospective evaluations of large databases establish a positive association with vitamin D usage and improved survival, there are no perspective studies demonstrating that any specific treatment paradigm results in a reduction in mortality. Recent prospective trials, however, have compared protocols that use progressive titration of active vitamin D analogues to use of protocols with fixed vitamin D replacement and suppression of PTH using escalating doses of cinacalcet. Most of these trials demonstrate a greater ability of the cinacalcet-based regimens when used in combination with lower doses of active vitamin D analogues to more effectively suppress PTH without elevating serum phosphate levels [28, 29]. However, neither prospective trials that attempt to establish a salutary effect of use of activate vitamin D analogues to suppress the renin–angiotensin system and prevent left ventricular hypertrophy (LVH) nor the use of cinacalect to reduce vascular calcification and cardiovascular mortality have been positive. Consequently, at the present time there are no prospective clinical trials to define the optimal therapy for CKD–MBD. Therefore, combined pharmacological therapy that targets multiple molecular components of the disorder pathways, including phosphate binders, nutritional vitamin D and active vitamin D analogues, and calcimimetics, is the current standard of care. Treatment considerations depend on the stage of CKD, the mechanism of action of the various therapeutic agents, potential toxicities associated with various treatments, and cost/reimbursement of the various therapies.

Achieving neutral phosphate balance

CKD patients are at increased risk of positive phosphate balance and hyperphosphatemia because the amount of

phosphate absorbed from dietary intake in the setting of concomitant active vitamin D therapy exceeds the amount that can be bound by phosphate binders and removed by the standard 4-hour thrice weekly dialysis regimen. Phosphate is absorbed in the small intestines by passive diffusion and by active transport mediated by the sodium-dependent phosphate transporter Napi2b, a step that is stimulated by the use of active vitamin D analogues. In addition, though not contributing to a net positive phosphate balance, increased phosphate efflux from bone under the effects of excessive PTH levels can contribute to hyperphosphatemia. Based on the potential sources of hyperphosphemia and methods to limit phosphate absorption and removal, there are multiple steps to controlling serum phosphate concentrations, including (1) dietary phosphate restriction; (2) administration of oral agents phosphate binders to prevent gastrointestinal phosphate absorption; (3) minimizing active phosphate transport in the small intestines by reducing doses of active vitamin D analogues or use of niacin; (4) reducing PTH levels to decrease bone efflux of phosphate; and (5) increasing dialysis duration and/or frequency to increase phosphate removal.

Dietary phosphate restriction

Dietary phosphate restriction to 800–1000 mg per day is difficult to achieve because of variable phosphate content of processed foods and patient compliance with complex dietary regimens. In addition, recent studies suggest that dietary phosphate restriction may be associated with poorer indices of nutritional status and adverse outcomes, and is not associated with survival benefits [30]. Avoidance of high dietary phosphate (as in dairy products, certain vegetables, many processed foods, and colas) and intake of high biologic value sources of protein (such as meat and eggs) are part of standard nutritional counseling. Dietary counseling of patients with CKD also should include the source of protein from which the phosphate is derived as there is some evidence that vegetarian protein diet leads to lower serum phosphorus levels and decreased FGF23 levels in comparison to meat protein diet [31]. In stage CKD-5D, the recommended protein intake is 1.2 (hemodialysis) and 1.3 g/kg/day (peritoneal dialysis), which provides at least 1,000 mg per day of phosphorus.

The use of phosphate binders

Given the difficulty of achieving dietary phosphate restriction, the risk of protein malnutrition and the low compliance rate associated with phosphate restriction, phosphate binders are the mainstay of therapy. Both cation- and resin-based binders act by forming poorly soluble complexes with phosphate in the intestinal lumen that is poorly absorbed and are maximally effective when they are ingested with meals. However, the low compliance rate associated with the requirement of high bill burdens, gastrointestinal side effects that are associated with some binders, and interactions between binders and other medications limit their effectiveness in preventing hyperphosphatemia. The currently available phosphate binders include the following.

Calcium-based binders

Calcium-based binders include calcium carbonate, which contains 500 mg of elemental calcium in a 1,250-mg tablet, and calcium acetate (Phoslo), which has 169 mg of elemental calcium in a 667-mg tablet. Calcium citrate should be avoided since citrate augments aluminum and calcium absorption from the gastrointestinal tract [32]. Although calcium acetate has a greater binding capacity for phosphate than calcium carbonate *in vitro*, potentially allowing a lower dose to be used, the incidence of hypercalcemia is similar with these two forms of therapy, possibly due to the greater bioavailability of calcium in the acetate preparation [33]. Calcium-based binders are inexpensive, effective phosphate binders when used in large doses in advanced cases of CKD. Calcium-based phosphate binders should be taken with meals to bind dietary phosphate. Vitamin D analogues can stimulate active calcium transport in the small intestines and the concomitant use of calcium binders can lead to increased risk of hypercalcemia and positive calcium balance [34]. The K/DOQI guidelines recommend that the total daily calcium intake be limited to 2,000 mg/day (500 mg calcium from diet, 1,500 mg calcium binders). On the basis of the binding characteristics of calcium, 1,500 mg elemental calcium in calcium acetate binds 238 mg phosphate per day; in contrast, 1,500 mg per day elemental calcium in calcium carbonate binds 166 mg of phosphorus per day.

Phosphate-binding resins

Sevelamer is a non-absorbed polymer that is available in the forms of sevelamer carbonate and sevelamer hydroclauric acid (HCL). Sevalmer selectively binds phosphorus in the gut, but its low affinity for phosphate (i.e., 800 mg of sevelamer binds 64 mg of phosphate) necessitates a large pill burden to achieve phosphate control [35]. In a prospective trial of hemodialysis patients, sevelamer achieved similar phosphate control but resulted in less hypercalcemia and progressive coronary and aortic calcification compared to treatment with calcium containing phosphate binders [36]. The most common side effects of sevelamer are gastrointestinal and its ability to bind other drugs such as furosemide, tacrolimus, L-thyroxine, and quininolones. Sevelamer HCL has the potential to provide an acid load due to the exchange of bicarbonate for chloride on the polymer, which contributes to a lowering of the serum bicarbonate levels in treated patients. Sevelamer's binding of short fatty acids in the large intestines also has a lipid lowering effects that may be beneficial [36].

Bivalent and trivalent cation binders

Lanthanum salts. The capacity of lanthanum to bind phosphate *in vitro* is similar to that of aluminium

hydroxide, and it is greater than that of calcium acetate, calcium carbonate, and sevelamer [37, 38]. In general, adherence with lanthanum is better than sevalmer and calcium-containing phosphate binders because of the lower pills burden. Each 1,000 mg of elemental lanthanum binds approximately 130 mg of phosphate. Lanthanum accumulates in the bone, but to date there has been no bone toxicity demonstrated. Long-term treatment with lanthanum carbonate had no effect on bone mineralization or remodeling in a 3-year follow-up study [39].

Aluminium salts. Aluminium salts have the greatest phosphate-binding capacity per weight. However, the use of aluminium salts is associated with a risk of aluminum toxicity, which is manifested by osteomalacia, encephalopathy, and anemia. Aluminum contaminated dialysate and concomitant use of calcium citrate, which increases aluminum GI absorption [32], confound the precise assessment of the risk of low dose oral aluminum containing phosphate binders. When used, the duration of treatment is typically limited to periods of 1 to 2 months for one course only. and the doses kept as low as possible.

Iron and magnesium salts. Magnesium hydroxide and carbonate have been used phosphate binders. However, because of the risk for hypermagnesemia and adverse GI side effects, oral magnesium binders have not gained widespread clinical use as phosphate binders.

Fermagate contains magnesium and ferric iron held in an insoluble hydrotalcite structure with carbonate groups, which are exchanged for phosphate. In a phase II trial, 1 g given three times daily before meals was associated with reduced serum phosphate levels, but a higher dose (6 g per day) was associated with adverse GI events [40].

Although there are differences in these various phosphate binders with regard to efficacy, potential for calcium loading, and costs, there are no definitive controlled trials that favor the use of one phosphorus binder over the other. The risk of vascular calcifications and hypercalcemia from the use of calcium-based binders, especially with the current use of vitamin D analogues in the management of hyperparathydosim in CKD, however, has led to a greater use of non-calcium-containing phosphorus binders. However, there is no solid evidence to support this practice. In a CARE–1 study [41], calcium acetate was more effective in lowering serum phosphorus and PTH levels than sevelamer hydrochloride, but in the Treat to Goal study [42], the change in the magnitude of coronary artery and aorta calcifications was less in patients treated with sevelamer hydrochloride. Similarly, the large open–labeled Dialysis Clinical Outcomes Revisited trial (DCOR) trial [43], found a beneficial effect of sevelamer on vascular calcifications but no mortality benefit. In a recent meta-analysis of all available trials that studied various forms of phosphorus binders, there was no comparative superiority of non-calcium-binding agents over calcium-containing phosphate binders for important patient-level outcomes, including as all-cause mortality and cardiovascular end points, hospitalizations, and end-of-treatment serum calcium–phosphorus product levels [44]. Sevelamer is associated with reduced and calcium binders with an increased risk of hypercalcemia, whereas calcium binders are more effective in suppressing serum PTH [42]. The salutary effect of sevelamer to reduce vascular calcification may be due to its lipid-lowering effects. In a CARE-2 study [36], 203 prevalent hyperphosphatemic hemodialysis patients were randomized to receive calcium acetate plus atorvastatin or sevelamer without atorvastatin for 12 months. There was no difference in the progression of calcification between the two groups, providing that serum lipids were kept within the same range [36]. Because of the associated risk of hypercalcemia, non-calcium phosphate binders are typically used in combination with vitamin D analogues, whereas calcium binders offer potential advantages with cincalcet therapy, which is associated with reductions in serum calcium. Intestingly, the use of non-calcium-containing phosphate binders has not been universally associated with reduced vascular calcifications.

Minimizing active phosphate transport in the small intestines by reducing doses of vitamin D analogues or use of niacin

All vitamin D analogues have the potential to increase serum phosphorus through enhancement of the active transport of phosphorus in the small intestines by the sodium-dependent phosphate transporter Napi2b. Vitamin D analogues increase serum calcium and phosphate [23, 45], and protocols that use less active vitamin D analogues, including those using cinacalcet, improved phosphate control [28, 46]. Therefore, a reduction of active vitamin D analogues dose can result in reductions in serum phosphate concentrations.

Niacin has a direct inhibitory effect on active transport-mediated phosphorus absorption in the mammalian small intestine [47] and has been shown to decrease serum phosphorus levels [48] in patients with end stage renal disease.

Suppressing PTH to lower serum phosphate

Bone is an underappreciated source contributing to serum phosphorus concentrations in CKD patients due to increased phosphate efflux from bone caused by excessive PTH-dependent increase in bone turnover [49]. Indirect evidence for the contribution of bone to serum phosphorus levels is derived from association between elevated serum phosphorus and PTH levels, the decrease in serum phosphorus levels after parathyroidectomy, and the reductions in serum phosphate in subjects treated with cinacalcet to lower PTH [28, 29]. In addition, whereas PTH infusions lower serum phosphate in patients with normal renal function, it increases serum phosphate in patients with ESRD. The contribution of bone remodeling to serum phosphate is typically in the range of 0.5 to 1.5 mg/dl.

Frequent daily dialysis

A 4–hour standard dialysis treatment removes approximately 900 mg of phosphate [50]. Thrice 4-hour weekly dialysis removes roughly 2.7 gm of phosphorus per week [50], which is insufficient to prevent a positive phosphate balance, especially in the presence of increased gastrointestinal phosphate absorption due active vitamin D analogue therapy, unless efforts to limit phosphate absorption are initiated. Recent studies found that the total weekly phosphorus removal with nocturnal hemodialysis six times per week is more than twice that removed by thrice weekly in in-center hemodialysis [51]. Indeed, nocturnal dialysis performed six times per week results in lowering of the serum phosphate and discontinuation of phosphate binder therapy compared to patients on standard thrice-weekly hamodialysis. Although the addition of an extra dialysis session would be predicted to lower serum phosphate, there are limited data at present to support this, possibly due to the fact that the other steps to control phosphate were not initiated.

Control PTH levels within an acceptable range that prevents progressive HPT while maintaining normal bone and vascular health

The second goal for treating CKD–MBD is to reduce PTH levels. The rationale for reducing PTH are several, including prevention of parathyroid gland hyperplasia and need for parathyroidectomy, reduction in metabolic bone disease and fracture risk, better control of serum phosphate, and reduction in cardiovascular mortality. PTH levels in excess of 600 pg/ml are associated with increased mortality in patients on hemodialysis, whereas consistent maintenance of PTH in a range between 150 and 300 pg/ml is associated with reduced mortality [52]. This can be achieved by the use of either vitamin D analogues or calcimimetics. Of these approaches, targeting the CaSR in parathyroid glands with calcimimetics offers the most direct method for suppressing PTH. The use of vitamin D analogues to target the VDR is effective too, but recent data suggest that the VDR in the parathyroid gland is not essential for regulation of PTH production. The actions of vitamin D analogues on gastrointestinal calcium absorption, as well as effects on the PTH gene transcription, account for the suppression of PTH. There are two different treatment paradigms that can be used to suppress PTH: titration of active vitamin D analogues or titration of cinacalcet with fixed dose of vitamin D analogues.

Vitamin D analogues

Vitamin D analogues include $1,25(OH)_2D$, calcitriol, prodrug alfacalcidol, and the active vitamin D analogues: paricalcitol, doxercalciferol, falecalcitriol, and 22-oxacalcitriol. All vitamin D analogues have been shown to be effective in the treatment of secondary hypreparathyrodism (HPTH) in CKD-5 and dialysis patients. On the other hand, active vitamin D analogues are associated with increased circulating FGF23 levels [16]. The significance of this is not known, but elevated FGF23 is the strongest predictor of mortality in ESRD [19–21, 24].

There is no uniform agreement or clinical evidence to support the use of one type of vitamin D analogue, the frequency of administration, or dose. In the only prospective randomized trial that has directly compared the efficacy of calcitriol versus paricalcitol, both agents were comparable in their PTH suppressive effects [53]. Because of reimbursement issues and patient compliance, intermittent intravenous administration with hemodialysis is often used in the U.S., whereas the oral route of administration is the more common in other countries. It remains to be established if differences in the route and dose of administration are associated with better clinical outcomes and less toxicities.

The current recommendations are to administer active vitamin D sterols to CKD-5 or dialysis patients who have intact PTH greater than 300 pg/ml, provided their phosphorus is less than 5.5 and corrected calcium for albumin is less than 9.5 mg/dl. The bioequivalence of intravenous calcitriol, paricalcitol, and doxercalciferol are 0.5, 2.5, and 5 mg, respectively [54].

High doses of vitamin D analogues are associated with hypercalcemia and hyperphosphatemia. Although some of active vitamin D analogues may have less calcemic and phosphatemic effects than calcitriol because of fewer gastrointestinal effects on calcium and phosphorus absorption, clinical trials also show that all analogues have the potential to increase serum calcium and phosphate when administered in high doses to achieve target PTH levels recommended by the KDOQI [55], which are associated in observational studies with increased all-cause and cardiovascular mortality in dialysis patients [56]. Active vitamin D analogues are one of the main stimulators of FGF23 production [16], which has been shown in observational studies to be a powerful, independent predictor of mortality on hemodialysis. Observational studies have shown that active vitamin D analogues are associated with improved survival in both end-stage and predialysis CKD populations [57]. In one retrospective study, the use of active vitamin D analogues in chronic hemodialysis patients is associated with 2-year survival advantage and a lower risk of cardiovascular mortality compared to patients who did not receive active vitamin D therapy [57]. However, a meta-analysis in 2007 of 76 trials of 3,667, mostly dialysis patients, provided opposing evidence that vitamin D compounds do not reduce the risk of death or vascular calcification, and calcitriol increases the risk of hypercalcemia and hyperphosphatemia, while not consistently reducing PTH levels and newer analogues increases calcium levels, in comparison to placebo [55]. Calcitriol, by binding with its intracellular VDR in multiple tissues

can regulate cellular proliferation and differentiation, inflammation, immune system and endocrine system including renin–angiotensin system (RAS), insulin resistance and lipid metabolism [58].

Calcimimetic

It is known that calcium suppresses PTH secretion by its action on CasR. In a prospective trial of 52 dialysis patients, large doses of calcium (about five times the recommended doses of elemental calcium by KDOQI) was as effective as daily oral calcitriol and intermittent intravenous calcitriol in PTH suppression with less frequent hyperphosphatemia [59]. However, concerns of the risk of increased vascular calcifications with calcium loading limits the use of calcium binders. Calcimimetics are agents that allosterically increase the sensitivity of the CasR in the PTG to calcium and suppress PTH without increasing serum calcium or providing a calcium load. Cinacalcet is the most effective agent in suppressing PTH. It targets the CaSR in parathyroid chief cells and dose dependently suppresses both PTH gene transcription and secretion, leading to reductions in serum PTH levels that are proportional to the severity of secondary hyperparathyroidism [60]. Cinacalcet is only available in oral form. The initial dose of cinacalcet is 30 mg/day, and subsequent doses are titrated every 2 to 3 weeks in 30-mg increments until a maximum dose of 180 mg/day is achieved. The most common side effects of cincalcet use are nausea and vomiting, which are reported to be mitigated by taking the medication with meals. In addition, hypocalcemia is a prevalent side effect of cincalcet that requires close monitoring of serum calcium. Cinacalcet should only be used if serum calcium levels are greater than 8.4 mg/dl [60]. Cinacalcet has also been shown to be effective in reducing PTG volume in hemodialysis patients, suggesting that use of this treatment may alter the natural history of PTG hyperplasia [61]. In addition, cinacalcet reduces serum FGF23 and serum phosphate concentrations [25]. A recent analysis of the ACHIEVE trial showed that treatment with Cinacalcet plus low-dose calcitriol analogues resulted in lower FGF23 levels compared with a treatment regimen using calcitriol analogues alone in ESRD [25]. Cinacalcet can be used effectively to treat secondary hyperparathyroism with reductions in the doses of active vitamin D analogues and minimizes the risk of hypercalcemia. Ongoing clinical trials are assessing the effects of cinacalcet on mortality and other outcomes in hemodialysis patients, but *post hoc* analysis of phase III clinical trials suggest that cinacalcet may lead to reductions in the risk of parathyroidectomy, fracture, and cardiovascular hospitalization, along with improvements in self-reported physical function and diminished pain [62]. There is no evidence that any of these treatment regimens reduces preexisting vascular calcifications or improves mortality in patients with ESRD.

Two treatment paradigms: High dose vitamin D analogues versus cinacalcet and low dose vitamin D analogues for treating CKD–MBD in ESRD (CKD-5D)

The different effects of the two main medications to suppress PTH on serum calcium and phosphate have resulted in two distinct strategies to suppress PTH. One approach titrates active vitamin D analogues to suppress PTH with the potential side effects of increased serum calcium, phosphate (requiring increased doses of phosphate binders), and FGF23, but with observational data suggesting that use of vitamin D is associated with improved survival that is attributed to the importance of vitamin D in processes unrelated to its function to regulate mineral metabolism. The other approach titrates the dose on cinacalcet to suppress PTH through its actions on CasR in the PTG, and uses nutritional and/or active vitamin D analogues in low, physiological doses (e.g., 0.5 mg calcitirol) to reduce the risk of hypocalcemia and to provide the purported survival benefit of vitamin D therapy. Phosphate binders are used to control phosphate in both approaches. The differential effects of vitamin D analogues (raises) and cinacalcet (lowers) on serum phosphate in ESRD may reflect the effects of cinacalcet to suppress PTH-mediated phosphate efflux from bone and active vitamin D analogues actions to increase gastrointestinal absorption of phosphate.

These two approaches have been compared in the OPTIMA trial [29]: (OPen label, Randomized Study Using Cinacalcet To IMprove Achievement of KDOQI™ Targets in Patients With ESRD). Overall, in the cinacalcet-treated group, mean intact parathyroid hormone (iPTH) levels decreased 46%, whereas the mean PTH in the unrestricted conventional care did not change. The percentage of patients achieving the target phosphorus level was higher in the group treated with cinacalcet (63%) compared to the conventional care group (50%, P = 0.002). This study is limited due to enrollment of patients already proven to be resistant to conventional treatment with vitamin D analogues and the more limited use of vitamin D analogues due to hyperphosphatemia [29]. The ACHIEVE study [28] represents a comparative trial in ESRD patients with moderate hyperparathyroidism of escalating doses of paricalcitol compared to fixed doses of paricalcitol and escalating doses of cinacalcet. Although cinacalcet suppressed PTH to a greater degree than paricalcitol, and was associated with fewer hypercalcemic episodes, this study found no difference between paricalcitol and cinacalcet-based therapies in attaining the primary end point of suppressing PTH to a target range of 150–300 pg/ml (i.e., cinacalcet tended to over suppress PTH at the doses used).

At present there are insufficient data to support one treatment approach over another. Regardless of which paradigm is initiated, most patients will ultimately require combinations of calcium and non-calcium

phosphate binders, vitamin D analogues, and cinacalcet to optimally manage the biochemical abnormalities present in ESRD. Recognizing that there are no high-quality trials showing either net beneficial or harmful effects of any of these therapies, it seems reasonable to use these agents at doses that minimizes their recognized toxicities, namely, hypercalcemia and hyperphosphatemia with vitamin D analogues, and hypocalcemia and a tendency to oversuppress PTH with calcimimetics while taking advantage of their different molecular targets and biological actions (e.g., cinacalcet targets CasR and is a more potent suppressor of PTH, whereas vitamin D analogues target the widely expressed VDR, which has potential effects on both mineral homeostasis and other biological processes such as innate immunity and cardiovascular function).

TREATMENT OF CKD–MBD IN STAGE CKD 3-4

In earlier stages of CKD, the severity of the renal dysfunction, secondary HPTH, bone disease, and vascular calcifications are less severe than in ESRD patients, which provides the opportunity to initiate therapy early to prevent the progressive complications of CKD–MBD. Since hypocalcemia and hyperphosphatemia appear late in the course of CKD, it would seem logical to initiate therapy in CKD 3 (GFR < 60 ml/min per 1.73 m^2), when FGF23 and PTH levels first begin to increase. The initial treatment of CKD–MBD in CKD 3-4 is dietary phosphorus restriction. This approach is supported by evidence in animal models and human studies that phosphate restriction, in early stages of CKD can increase endogenous production of $1,25(OH)_2D$ and delay the development of secondary hyperparathyroidism [37]. Because CKD is associated with hypocaluria [38] and there is residual renal function, the use of calcium-based binders does not have the same risk as in ESRD, and they could be used in combination with dietary phosphate restriction. In the absence of hyperphosphatemia, however, monitoring the effectiveness of phosphate binder therapy might include assessment of urinary phosphate and calcium levels and assessment of PTH (since FGF23 measurements are currently used in clinical practice). At present, phosphate binders have not been approved for treatment of patients with impaired renal function and normal phosphate levels. Assessment for nutritional vitamin D deficiency by measurement of serum 25(OH) D levels and treatment of 25(OH)D deficiency is supported by evidence of modest reductions in iPTH levels with nonactivated vitamin D therapy in CKD patients. KDOQI guidelines suggest measurement of serum 25(OH) D levels in patients with stage 3 and 4 CKD who have increased iPTH levels; optimal levels should be greater than 30 ng/mL [22]. Vitamin D deficiency has also been shown to be associated with increased mortality and morbidity in the general population and in CKD patients. If calcium binders and phosphate restriction fail to achieve target PTH levels, then active vitamin D analogues can be used as a second line of therapy. There are no studies in CKD patients that show that the superiority of one vitamin D analogue over the other or compares the use of vitamin D analogues with treatment with calcium binders only. Cinacalcet is currently not approved for the treatment of secondary hyperparathyroidism in CKD 3-4 patients, and its use in this setting is associated with increased serum phosphate levels, requiring increase use of phosphate binders. The differences between vitamin D analogues and cinacalcet on serum phosphate levels in earlier stages of CKD may be due to their differential effects on circulating concentrations of FGF23.

PARATHYROIDECTOMY

The surgical correction remains the final, symptomatic therapy of the most severe forms of secondary hyperparathyroidism (sometimes called tertiary hyperparathyroidism), which cannot be controlled by medical management. Indications for parathyroidectomy in ESRD patients include symptomatic or severe hypercalcemia or hyperphosphatemia, symptomatic bone disease or spontaneous fracture, calciphylaxis, and persistent hyperparathyroidism for more than 1 year after transplantation. The monitoring of serum calcium, phosphorus, magnesium, and potassium levels in the immediate post parathyroidectomy course is necessary as these patients at risk of developing hungry bone syndrome characterized by symptomatic hypocalcemia, decreases in serum phosphate concentrations, and occasionally hyperkalemia. The changes in calcium and phosphate reflect increased uptake into bone due to the transition from bone resorption to formation.

Disorders of mineral homeostasis in children may present differently than in adults. This chapter outlines disorders of mineral metabolism that occur in children emphasizing the specific features of the age group.

DISORDERS OF CALCIUM HOMEOSTASIS

Hypocalcemia

Clinical presentation

In the newborn with acute hypocalcemia, jitteriness, hyperacusis, irritability, and limb-jerking may occur, with progression to generalized or focal clonic seizures. Laryngospasm may lead to a misdiagnosis of croup. Atrioventricular heart block occurs in prematures with hypocalcemia, and electrocardiograms should be performed in newborns with significant bradycardia [1]. Apnea, tachycardia, tachypnea, cyanosis, edema, and vomiting have been reported in newborns with hypocalcemia.

Transient hypocalcemia of the newborn

Early neonatal hypocalcemia occurs during the first 3 days of life and is seen in prematures, infants of diabetic mothers, and asphyxiated infants. The premature infant has an exaggerated postnatal depression in circulating calcium, such that total calcium levels may drop below 7.0 mg/dl, but the proportional drop in ionized calcium is less. Parathyroid hormone (PTH) insufficiency may contribute to early neonatal hypocalcemia in prematures; a delay in the phosphaturic action of PTH and resultant hyperphosphatemia may further decrease serum calcium.

Late neonatal hypocalcemia presents as tetany between 5 and 10 days of life, occurs more frequently in term than in premature infants, and is usually not correlated with birth trauma or asphyxia. Late neonatal hypocalcemia is associated with maternal vitamin D insufficiency. An increased occurrence of late neonatal hypocalcemia in winter has been noted.

Hypocalcemia associated with magnesium (Mg) deficiency may present as late neonatal hypocalcemia. Severe hypomagnesemia (circulating levels of magnesium below 0.8 mg/dl) may occur in congenital defects of intestinal magnesium absorption or renal tubular reabsorption [2]. Hypocalcemia in this setting may be refractory to therapy unless magnesium levels are corrected.

Maternal hyperparathyroidism may result in neonatal hypocalcemia. Serum Pi is often greater than 8 mg/dl and symptoms may be exacerbated by high Pi intake. Maternal hypercalcemia results in increased calcium delivery to the fetus, thereby suppressing parathyroid gland responsivity. As a result, normal calcium levels are not maintained postpartum due to persistent parathyroid gland suppression.

Persistent hypocalcemia presenting in childhood

Hypoparathyroidism

Persistent hypocalcemia detected in childhood may be due to congenital hypoparathyroidism. Mutations in genes involved in parathyroid gland development, PTH processing, PTH secretion, PTH structure and PTH

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

resistance have been identified (see Chapter 72). The most frequently identified disorder of parathyroid gland developmental is the DiGeorge anomaly (OMIM #188400), which comprises hypoparathyroidism, T-cell incompetence due to a partial or absent thymus, and conotruncal heart defects (e.g., tetralogy of Fallot, truncus arteriosus) or aortic arch abnormalities. These structures are derived from the third and fourth pharyngeal pouches and are seen in association with microdeletions of chromosome 22q11.2 [3]. Cleft palate and facial dysmorphism may occur. Some present late in childhood due to mild parathyroid defects not apparent in infancy [4]. Deletion of *TBX1*, which encodes a T-box transcription factor, is sufficient to cause the cardiac, parathyroid, thymic, facial, and vellopharyngeal features of the syndrome; however, variability in phenotype with similar genetic defects occurs [5]. One recently reported case demonstrates a child with a deletion in this region inherited from the father, who had a compensating duplication of the region on the other chromosome and was therefore asymptomatic [6]. A similar phenotype identified as DiGeorge 2 syndrome has been attributed to a deletion of distal end of chromosome 10p [7] (601362); GATA3 may be the responsible gene for the hypoparathyroidism accompanying this deletion, which likely represents variants of the HDR (hypoparathyroidism, sensorineural deafness, renal dysplasia) syndrome (146255). Other genetic defects result in disrupted parathyroid gland development (146200, 307700) [e.g., loss of *TBCE* (241410 and 244460), or *GCM2* (603716)], abnormal PTH processing and molecular structure (*PTH*, 168450), abnormal PTH secretory dynamics (*CaSR*), and resistance to PTH action (*GNAS*, 103580). Individuals with classic PTH resistance (pseudohypoparathyroidism), due to loss of function of the Gs alpha protein, often do not develop clinically evident hypocalcemia until a few years of age.

Acquired hypoparathyroidism in children is most commonly caused by autoimmune destruction of the glands [autoimmune polyendocrinopathy syndrome type 1 (APS1) (240300)]. Manifestations of APS1 include adrenal insufficiency, mucocutaneous candidiasis, and hypoparathyroidism; loss of function mutations in the *AIRES* gene, which encodes an autoimmune regulator with features of a transcription factor is often identified in such cases. Surgery for thyroid disorders may result in inadvertent removal of parathyroid tissue, resulting in acquired hypothyroidism, as can heavy metal deposition associated with thalassemia and Wilson's disease.

Vitamin D-related hypocalcemia

Vitamin D deficiency, increasingly reported in North America, is most commonly observed in African-American infants who are breastfed or have limited dietary intake of dairy products. Older age groups may be affected [8]. Rarely, inherited defects in vitamin D metabolism (mutations in *CYP1b*) or the receptor (*VDR*) cause vitamin D-related hypocalcemia. Dilated cardiomyopathy can accompany severe vitamin D-deficiency hypocalcemia in children and is reversible [9].

Other causes of hypocalcemia

Severe hypocalcemia has been induced in children when Pi enema preparations have been administered rectally or orally [10]. The Pi load can result in extreme hyperphosphatemia (up to 20 mg/dl), life-threatening hypocalcemia, and hypomagnesemia. Such preparations should never be administered to infants younger than 2 years of age. Hyperphosphatemia with rhabdomyolysis has resulted in hypocalcemia. Rotavirus infections may induce malabsorption-related hypocalcemia [11]. Ethylenediaminetetraacetic acid (EDTA) chelation therapy has resulted in acute hypocalcemia associated with fatality in a child with autism [12]. Hungry bone syndrome following treatment of severe rickets or after parathyroidectomy can result in transient, albeit severe, hypocalcemia [13].

Calcium malnutrition has been considered rare in North America; however, recent trends of decreased dietary intake of dairy products have resulted in an increasing incidence of this diagnosis in infants [14].

Infantile osteopetrosis may present with hypocalcemia due to impaired bone resorption; however, hypercalcemia may ensue with successful bone marrow transplant therapy and subsequent resorption of osteopetrotic bone [15]. Decreases in ionized calcium occur in infants who undergo exchange transfusions with citrated blood products or receive lipid infusions. Citrate and fatty acids may complex with ionized calcium, reducing the free calcium compartment in the serum and may result in symptoms of hypocalcemia. Alkalosis secondary to adjustments in ventilatory assistance may provoke a shift from ionized to protein-bound calcium. Prolonged pharmacologic inhibition of bone resorption, as with potent bisphosphonate therapy, may also precipitate hypocalcemia [16].

Treatment of hypocalcemia

In the neonate

Early neonatal hypocalcemia is usually treated when total serum calcium is below 6 mg/dl (1.25–1.50 mmol/L) (or ionized calcium below 3 mg/dl, 0.62–0.72 mmol/L) in prematures or below 7 mg/dl (1.75 mmol/L) in term infants. Therapy of acute tetany consists of intravenous (never intramuscular) calcium gluconate (10% solution) given slowly (<1 ml/min); 1 to 3 ml will usually arrest seizure activity. Doses should not exceed 20 mg of elemental Ca/kg body weight and may be repeated up to four times per 24 hours. After successful management of acute emergencies, maintenance therapy is achieved by intravenous administration of 20–50 mg of elemental Ca/kg body weight per 24 hours. Calcium glubionate is a commonly used oral supplement (most preparations provide 115 mg of elemental Ca/5 ml). Management of

late neonatal tetany should include low-phosphate formula such as Similac PM 60/40, in addition to calcium supplements. Therapy can usually be discontinued after several weeks.

The place of vitamin D in the management of transient hypocalcemia is less clear. A significant portion of intestinal calcium absorption in newborns occurs by facilitated diffusion and is not vitamin D dependent. Thus, vitamin D metabolites may not be as useful for the short-term management of transient hypocalcemia as added calcium. In persistent hypoparathyroidism, calcitriol is used in the long term. Four hundred to 800 units of vitamin D daily will prevent vitamin D deficiency in premature infants. Overt vitamin D deficiency rickets should respond within 4 weeks to 1,000–2,000 units of daily oral vitamin D. It is important to monitor the clinical response to pharmacologic vitamin D therapy in infants and small children because of the risk for hypervitaminosis D [17]. Such patients should receive at least 40 mg of elemental Ca/kg body weight/day.

In the older child

Calcium and active vitamin D metabolites are usually titrated to maintain serum calcium in an asymptomatic range without incurring hypercalciuria. In hypoparathyroidism, a target serum calcium of 7.5–9.0 mg/dl is recommended, as higher serum calcium levels are more likely to result in hypercalciuria. In *autosomal dominant hypocalcemia*, due to activating mutations in the calcium-sensing receptor (CaSR), thiazide diuretics can be helpful if symptomatic hypocalcemia coexists with hypercalciuria. Hypercalciuria is not typically observed in patients with pseudohypoparathyroidism type 1a when serum calcium is maintained in the usual normal range.

Disorders of hypercalcemia

Infants are usually asymptomatic with mild to moderate hypercalcemia (11.0–12.5 mg/dL). More severe hypercalcemia may lead to failure to thrive, poor feeding, hypotonia, vomiting, seizures, lethargy, polyuria, dehydration, and hypertension. Hypercalcemia is discussed in detail elsewhere in the *Primer*. Syndromes with specific childhood features are described below.

Severe neonatal hyperparathyroidism (SNHP, 239200) presents in the first few days of life. Serum calcium levels may reach 30 mg/dL. Serum Pi is low, and serum PTH is elevated. Nephrocalcinosis may be present on ultrasonagraphic examination. SNHP is a rare autosomal recessive disorder due to homozygous CaSR loss-of-function mutations [18], occurring in families with *familial hypocalciuric hypercalcemia* (FHH, 145980); SNHP is life threatening, usually requiring emergency extirpation of the parathyroid glands.

In *Williams syndrome* (194050) hypercalcemia may occur in the neonatal period. Growth failure, a characteristic facies, cardiovascular abnormalities (usually supravalvular aortic stenosis or peripheral pulmonic stenosis), delayed psychomotor development, and selective mental deficiency may be present. A deletion of the elastin gene is often found in Williams syndrome. Hypercalcemia usually subsides spontaneously by 1 year of age but may rarely persist for longer. Treatment has traditionally consisted of a vitamin D-free, low-calcium diet, and in severe settings, corticosteroids; pamidronate can be used, with fewer potential complications than glucocorticoids [19].

Subcutaneous fat necrosis is a self-limited disorder of infancy presenting with hypercalcemia and erythematous or violacious skin. Affected areas contain mononuclear cell infiltrates, often coexistent with calcification. Pamidronate is useful when significant hypercalcemia is unresponsive to dietary calcium and vitamin D restriction.

In *vitamin D intoxication*, increased circulating 25-OHD levels occur, but $1,25(OH)_2D$ levels are usually low. *Vitamin A intoxication* may result in bone pain, hypercalcemia, headache, pseudotumor cerebri, and an exfoliative erythematous rash. Alopecia and ear discharge may be present. Hypercalcemia is mediated by increased bone resorption. In order to establish the diagnosis of vitamin A intoxication, serum retinyl ester levels should be determined.

Other conditions in children in which hypercalcemia may be manifest include *Down syndrome*, *skeletal dysplasias* (such as *Jansen's*, 156400), *hypophosphatasia* (241500, 241510), SHORT syndrome [**S**hort stature, **H**yperextensibility of joints and/or hernia (inguinal), **O**cular depression, **R**ieger anomaly, and **T**eething delay) (OMIM) [20], and *osteogenesis imperfecta* (120150 and others). Endogenous overproduction of $1,25(OH)_2D$ occurs in granulomatous diseases, such as *cat-scratch disease*. Inflammatory disorders may generate hypercalcemia via increased bone resorption as in *Crohn's disease*. Other causes include those commonly encountered in adults: immobilization, malignancy, and acquired hyperparathyroidism. Iatrogenic causes include parenteral nutrition, dialysis, and drugs (e.g., thiazides and antifungals) [21].

Idiopathic infantile hypercalcemia has been recently attributed to loss of function mutations in CYP24A1, the vitamin D 24 hydroxylase, invoking impaired catabolism of $1,25(OH)_2D$ as a mechanism for this syndrome [22, 23]. Phosphate losses or inadequate supply results in hypophosphatemia, accompanied by hypercalcemia, typical of the breastfed premature infant (and the inadequacy of breast milk phosphate to meet increased skeletal demands).

Treatment of hypercalcemia

Management of acute hypercalcemia consists of administration of intravenous saline. Furosemide (1 mg/kg) may be given intravenously at 6- to 8-hour intervals. Bisphosphonate therapy for unremitting hypercalcemia in children has become widely accepted [19]. Pamidronate has been highly successful in the management of hypercalcemia.

DISORDERS OF PHOSPHATE HOMEOSTASIS

Disorders of hypophosphatemia

Serum Pi is relatively higher in young children compared to adults. Unfortunately, lapses in diagnosis of childhood hypophosphatemia occur because this clinical difference is not always recognized (see Table 79.1).

Etiology of hypophosphatemia in children

Hypophosphatemia may result from decreased Pi supply, excessive renal losses, or intracellular/extracellular compartmental movement of Pi. "Supply" problems result from dietary deficiency or limited intestinal absorption of Pi. Reduced dietary intake occurs in breastfed premature infants, as human milk is relatively low in Pi content. Fortifiers have been developed to restore mineral content to human milk; these may result in hypercalcemia, so monitoring may be indicated when used. Rickets due to inadequate dietary Pi can be treated with 20–25 mg of elemental phosphorus/kg body weight/day, given orally in three or four divided doses.

Hypophosphatemia secondary to renal losses is encountered clinically in the setting of several primary Pi wasting disorders, of which *X-linked hypophosphatemia* (XLH, 307800) is the most common [24]. XLH may be suspected in the setting of a family history, but affected adult members may never have been correctly diagnosed. XLH typically presents in the second or third year of life, with progressive leg bowing. The progression of bowing over a 6-month period in a child over 18 months old requires further investigation. Children may be incorrectly diagnosed with other disorders (typically metaphyseal dysplasias). The delay in a correct diagnosis of XLH may result in the child missing early medical therapy, which has beneficial effects on growth and leg alignment. Circulating fibroblast growth factor 23 (FGF23) is elevated in XLH, and mediates renal Pi wasting. Additionally, FGF23 decreases 25-OHD 1-hydroxylase (*CYP27B1*) message synthesis, limiting $1,25(OH)_2D$ production, despite hypophosphatemia. Medical treatment consists of the administration of Pi in conjunction with $1,25(OH)_2D_3$ (calcitriol). Doses vary and require adjustment based on clinical monitoring. The range of doses for both Pi and calcitriol on a per weight basis are extremely wide; doses for calcitriol are usually 20–50 ng/kg/day, usually given in two divided doses, and phosphorus, 0.25–2 gms/day in three to five divided doses. A detailed compendium of treatment guidelines for XLH is available [25]. Autonomous hyperparathyroidism and/or vitamin D intoxication may complicate the therapy, so monitoring is suggested at 3- to 4-month intervals in children with measurement of serum calcium, Pi, alkaline phosphatase, and urinary calcium and creatinine excretion; circulating PTH should be measured at least twice yearly. Accurate height measurements and assessment of the bow defect should be performed at all visits. Radiographs of the epiphyses of the distal femur and proximal tibia are obtained every 2 years or more frequently if bow deformities fail to correct, or if progressive skeletal disease is grossly evident. Therapy in adulthood is variably recommended, dependent upon symptomatology. Pi should never be given as monotherapy in XLH, but always with calcitriol.

Soft-tissue calcification of the renal medullary pyramids (nephrocalcinosis) may occur secondary to the mineral load that this treatment provides and can be detected with sonograms. Most compliant patients demonstrate nephrocalcinosis within 3–4 years of beginning therapy, but significant clinical sequelae in patients with mild nephrocalcinosis are not generally observed. Calcification of the entheses are described in the third decade, but not thought to be associated with treatment.

Several other hypophosphatemic disorders are described in which elevated FGF23 occurs, including *tumor-induced osteomalacia* (due to neoplastic overproduction of FGF23) (see Chapter 74), *autosomal dominant hypophosphatemic rickets* (193100) due to mutations that disrupt proteolytic cleavage of FGF23) [26], and in *fibrous dysplasia/McCune Albright syndrome* (174800) [27]. Most recently, *autosomal recessive hypophosphatemic rickets* (ARHR, 241520), due to mutations in dentin matrix protein 1 (DMP1), or ARHR2 (613312), due to mutations in ectonucleotide pyrophosphatase/phophodiesterase 1 (ENPP1) have been described [28–30]. In that PHEX, FGF23, and DMP1 are products of the osteocyte, a central role for this cell in regulation of mineralization has been speculated. This group of disorders is discussed in detail in Chapter 79. Finally, this constellation of biochemical findings in concert with parathyroid hyperplasia have been seen in the setting of overexpression of klotho (612089) [31].

Renal Pi losses occur in *hereditary hypophosphatemic rickets with hypercalciuria* (HHRH, 241530) secondary

Table 79.1. Normative Values in mg/dL (mmol/L) for Serum Phosphate by Age

Age (y)	Mean	2.5th Percentile	97.5th Percentile
0–0.5	6.7 (2.15)	5.8 (1.88)	7.5 (2.42)

Source: Brodehl J, Gellissen K, Weber HP. 1982. Postnatal development of tubular phosphate reabsorption. *Clin Nephrol* 17(4): 163–71.

to mutations in the renal NaPi (2c) cotransporter (*SLC34A3*) [32]. In contrast to XLH and other FGF23-mediated disorders, circulating $1,25(OH)_2D$ is elevated in HHRH; hypercalciuria is common and renal stones may occur. Osteoporosis may develop. HHRH is treated with oral phosphate, without vitamin D metabolites. Generalized tubular dysfunction (*Fanconi syndrome*, 134600) may occur in conditions such as *cystinosis*, *Lowe's syndrome*, and *Wilson's disease*. Finally, hypophosphatemia may occur in *Dent's disease* (300009), an X-linked recessive disorder due to mutations in *CLCN5*, which encodes a renal tubular chloride channel.

Intracellular/extracellular shifts

Acute hypophosphatemia may occur with acute movement from the extracellular space to intracellular compartments. This is typically seen with correction of diabetic ketoacidosis when insulin-induced intracellular Pi uptake can acutely decrease serum Pi. Another such setting is in the refeeding syndrome, as with nutritional rehabilitation of anorexia nervosa. Pi levels reach a nadir within a week of refeeding; slow oral feeds minimize the severity of this phenomenon. Targeting a minimum 4-day weight gain between 0.36 kg and 0.55 kg has been recommended to reduce complications of refeeding in anorexic adolescents. [33].

Hyperphosphatemia

Increases in serum Pi above age-appropriate ranges are uncommon in children with normal renal function. A massive exogenous phosphate load may occur with use of phosphate-containing enemas resulting in hyperphosphatemia and hypernatremia. Such acute elevations in circulating Pi are often accompanied by a reciprocal decrease in serum calcium, precipitating tetany and seizures. When serum Pi and/or calcium concentrations are sufficiently elevated to result in chronic elevations in the calcium × Pi product (in children, higher than $60\,mg^2/dl^2$ is often quoted as undesirable), there is a risk of soft tissue calcification, involving blood vessels, renal parenchyma, skin, cornea, and joints. Serum Pi may increase with rapid lysis of bulky tumors (tumor lysis syndrome). Hyperphosphatemia is a biochemical hallmark of hypoparathyroidism and pseudohypoparathyroidism, accompanied by hypocalcemia. Hyperphosphatemia is observed in chronic kidney disease, where progressive loss of nephrons results in limited capacity to reabsorb Pi. A primary disorder of renal Pi excretion, *hyperphosphatemic tumoral calcinosis* (HTC, 211900), can result from loss-of-function mutations in FGF23 [34], *GALNT3*, which encodes an enzyme that initiates O-glycosylation of FGF23, an important step in its secretion and/or trafficking [35], or Klotho, a membrane protein necessary for FGF23 signaling through fibroblast growth factor receptors (FGFRs) [36]. As expected from the impaired FGF23 activity, HTC has the converse biochemical phenotype of XLH [hyperphosphatemia due to an increased tubular maximum threshold for Pi reabsorption and increased circulating $1,25(OH)_2D$].

DISORDERS OF MAGNESIUM

Disorders of hypomagnesemia

Familial hypomagnesemia with secondary hypocalcemia (602014) is an autosomal recessive disease due to mutations in the TRPM6 ion channel, resulting in electrolyte abnormalities in the newborn period [37]. This syndrome presents at several weeks of age with tetany or seizures. Hypocalcemia may be refractory to therapy unless magnesium levels are corrected. Mutations in a renal tubular paracellular transport protein, paracellin, of the claudin family, and encoded by *CLDN16*, may also cause hypomagnesemia, hypocalcemia, and hypercalciuria (248250) [38]. CLDN19, another member of the claudin family, has been implicated as causal to heritable hypomagnesemia (248190) [39]. *Gitelman's syndrome* (263800) is an autosomal recessive disorder of magnesium and potassium wasting with metabolic alkalosis and hypocalciuria, due to mutations in the gene encoding a thiazide-sensitive Na–Cl cotransporter (*SLC12A3*) [2]. Recently, individuals with mutations in HNF1B, known to be important in renal development, have been shown to manifest hypomagnesemia due to renal tubular wasting [40]. Hypomagnesemia may accompany renal losses due to the tubulopathy observed with the use of drugs: chemotherapeutic agents, aminoglycosides, and cyclosporine are typical culprits in children. Refeeding syndrome, which may result in hypophosphatemia and hypokalemia, may also involve hypomagnesemia [41]. Low serum magnesium levels may also accompany hypoparathyroidism.

Treatment of hypomagnesemia

For acute symptomatic hypomagnesemia, magnesium sulfate is given intravenously using cardiac monitoring or intramuscular as a 50% solution at a dose of 0.1–0.2 ml/kg. One or two doses may treat transient hypomagnesemia; a dose may be repeated after 12 to 24 hours. Patients with primary defects in magnesium metabolism require long-term oral magnesium supplements; it is best to give these in several divided doses through the day as to avoid diarrhea. We begin oral supplementation at 5 mg of elemental Mg/kg body weight/day. A variety of salts are available for oral use, we have had limited complications with magnesium oxide.

Hypermagnesemia

Hypermagnesemia is unusual in pediatrics but may occur transiently after fetal exposure to maternal magnesium infusions used in the management of eclampsia/

preeclampsia, or with excessive use of cathartic preparations [42]. Severe hypermagnesemia can result in apnea, respiratory depression, and cardiac arrhythmias. Hypocalcemia may also result from hypermagnesemia.

SKELETAL MANIFESTATIONS OF DISORDERS OF CALCIUM AND PHOSPHATE

The typical skeletal abnormality in the growing child with a paucity of available calcium or Pi is rickets. The use of the term "rickets" in clinical settings generally refers to the growth plate cartilage abnormalities observed in the long bones. Rickets is manifest by radiographic findings such as widened metaphyses, irregular or "frayed" metaphyseal edges, and "cupped" metaphyseal deformations (Fig. 79.1).

Rickets is usually accompanied by *osteomalacia* in bone tissue. The histologic correlate of the radiographic findings at the growth plate is the expansion of the hypertrophic zone of chondrocytes [43]. Weight-bearing on the undermineralized skeleton results in characteristic bowing. A child with overt rickets may have minimal leg deformity prior to walking; however, enlarged wrists or costochondral junctions ("rachitic rosary") are typical. An osteomalacic skull (craniotabes) may be present.

Deficiency, or *nutritional rickets* refers to restricted vitamin D stores, which may result from limited intake and/or limited sunlight exposure. Dietary calcium deficiency can result in a similar clinical picture, and some children have a mixed deficiency of calcium and vitamin D [14]. Treatment is accomplished by provision of adequate vitamin D, traditionally suggested as 2,000 units daily, and providing adequate dietary calcium. Clinical and biochemical findings observed in certain inherited conditions mimic severe nutritional rickets. Mutations in encoding 1 alpha-hydroxylase (*CYP27B1*) (*1-alpha hydroxylase deficiency, or vitamin D-dependent rickets, type 1*) (264700), or the vitamin D receptor (VDR) (*hereditary vitamin D resistance*, or *vitamin D-dependent rickets, type 2*) (277440) are well described. Mutations in a vitamin D 25-hydroxylase enzyme have been described as well (60081) [44]. Therapy with calcitriol is generally recommended for these conditions, although hereditary vitamin D resistance may require exceptionally high dosages of this metabolite and is sometimes completely unresponsive to calcitriol. Provision of intravenous calcium has been useful in such settings, with gradual progression to enteral calcium treatment [45].

X-linked hypophosphatemia, XLH, is discussed above in the section on hypophosphatemia and in Chapter 79.

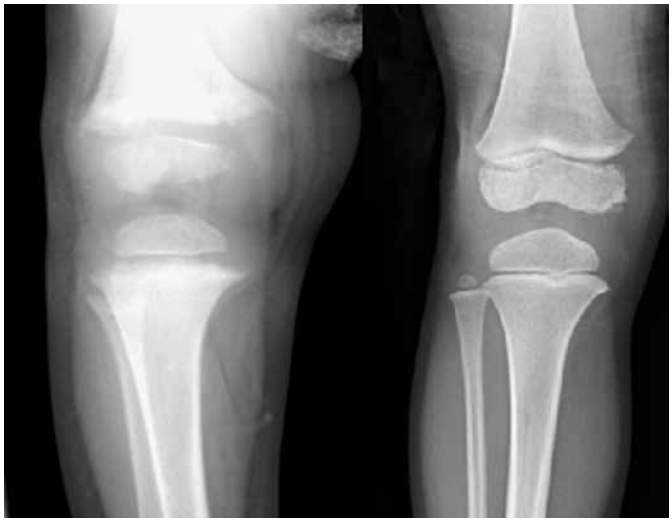

Fig. 79.1. Left: Radiograph of the right knee in an infant with vitamin D-deficiency rickets. Classic epiphyseal deformities are seen, with metaphyseal flaring and frayed edges of the metaphyseal-growth plate junction. Right: A normal knee is shown for comparison.

Paget's disease of bone is a localized disorder of bone remodeling. The process is initiated by increases in osteoclast-mediated bone resorption, with subsequent compensatory increases in new bone formation, resulting in a disorganized mosaic of woven and lamellar bone at affected skeletal sites. This structural change produces bone that is expanded in size, less compact, more vascular, and more susceptible to deformity or fracture than is normal bone [1]. Clinical signs and symptoms will vary from one patient to the next depending on the number and location of affected skeletal sites, as well as on the degree and extent of the abnormal bone turnover. It is believed that most patients are asymptomatic, but a substantial minority may experience a variety of symptoms, including bone pain, secondary arthritic problems, bone deformity, excessive warmth over bone from hypervascularity, fracture and a variety of neurological complications caused in most instances by compression of neural tissues adjacent to pagetic bone.

ETIOLOGY

Although Paget's disease is the second most common bone disease after osteoporosis, the factors involved in its pathogenesis are just beginning to be clarified. Both genetic and environmental factors have been implicated in the pathophysiology of Paget's disease. Paget's disease occurs commonly in families and can be transmitted vertically in an autosomal dominant pattern. Fifteen to 30% of Paget's disease patients have positive family histories of the disorder [2–4], and familial aggregation studies in a U.S. population [5] suggest that the risk of a first-degree relative of a pagetic subject developing the condition is seven times greater than is the risk for someone who does not have an affected relative.

Multiple genetic loci have been linked to familial Paget's disease, and three genes have been identified. Recent genome-wide association studies have identified several susceptibility loci for Paget's disease. These include variants in the *CSF-1* gene, the *RANK* gene, *PML* gene, and three other genes [6, 7]. An insertion mutation in the *RANK* gene has been reported [8], but this mutation is rarely found in patients with familial Paget's disease [9].

The most frequent mutations linked to Paget's disease are in a gene on 5q35-QTER, which encodes an ubiquitin binding protein, sequestasome-1 (SQSTM1/p62) [10]. Mutations in SQSTM1 occur in 30% of patients with familial Paget's disease with the P392L mutation being the most frequent [11]. Mutations in the SQSTM1 gene have been associated with the severity of Paget's disease. Mutation carriers had an earlier age of onset and more commonly required surgery and bisphosphonate therapy [12]. Sequestasome-1 plays an important role in the nuclear factor-κB (NFκB) signaling pathway. Patients with SQSTM1 mutations can have a variable clinical phenotype, including no evidence of Paget's disease in at least one or two individuals, and no gene dose effect can

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

be seen between heterozygotes and homozygotes individuals. Recent studies have reported that the P392L mutation in p62 is either a predisposing mutation for Paget's disease or can result in Paget's disease in experimental animal models [13, 14]. Human osteoclast precursors transfected with the $p62^{P392L}$ do not form osteoclasts characteristic of Paget's disease, and transgenic mice with the $p62^{P392L}$ mutation targeted to the osteoclast lineage develop progressive osteopenia and not Paget's disease. However, mice in which the normal p62 gene has been replaced with $p62^{P392L}$ either do not develop Paget's disease [13] or develop pagetic-like lesions predominantly in their femurs [14].

There is a restricted geographic distribution for the occurrence of Paget's disease: It is most common in Europe, North America, Australia, and New Zealand in persons of Anglo-Saxon descent and is extremely uncommon in Asia, Africa, and Scandinavia.

Some recent studies have reported an apparent decline in the frequency and severity of Paget's disease in both Great Britain and New Zealand [15, 16]. The basis for this decline is unknown, but the changes are too rapid to be explained by genetic factors and cannot be explained by migration patterns of persons with a predisposition to Paget's disease.

For more than 30 years, studies have suggested that Paget's disease may result from a chronic paramyxoviral infection. This is based on ultrastructural studies by Rebel and coworkers [17] who demonstrated that nuclear and, less commonly, cytoplasmic inclusions that were similar to nucleocapsids from paramyxoviruses were present in osteoclasts from Paget's disease patients. Mills and Singer [18] also reported that the measles virus nucleocapsid antigen was present in osteoclasts from patients with Paget's disease, but not from patients with other bone diseases. In some specimens, both measles virus and respiratory syncytial virus nucleocapsid proteins were demonstrated by immunocytochemistry on serial sections. Gordon and colleagues [19], using *in situ* hybridization studies, found canine distemper virus nucleocapsid protein in 11 of 25 Paget's disease patients, and Mee and coworkers [20], using highly sensitive *in situ* polymerase chain reaction (PCR) techniques, found that osteoclasts from 12 of 12 English patients with Paget's disease expressed canine distemper virus nucleocapsid transcripts.

Kurihara et al. [21] provided evidence for a pathophysiologic role for the measles virus in the abnormal osteoclast activity in Paget's disease both *in vitro* and *in vivo*. Transfection of the measles virus nucleocapsid gene into normal human osteoclast precursors resulted in formation of osteoclasts that expressed many of the abnormal characteristics of pagetic osteoclasts. However, other workers have been unable to confirm the presence of measles virus or CDV in pagetic osteoclasts [22]. Kurihara et al. also targeted the measles virus nucleocapsid gene to cells in the osteoclast lineage in transgenic mice and found that 29% of these mice developed localized bone lesions that are similar to lesions seen in patients with Paget's disease [23]. More recently, these investigators reported that mice expressing the MVNP gene and the $p62^{P392L}$ mutation develop exuberant pagetic lesions [24]. They further demonstrated that many of the effects of MVNP seen in these mice were moderated by IL-6 [24].

Among the many questions that still remain to be explained to understand the contributions of environmental and genetic factors to Paget's disease are: (1) Since paramyxoviral infections such as measles virus occur worldwide, why does Paget's disease have a very restricted geographic distribution? (2) How does the virus persist in osteoclasts in patients who are immunocompetent for such long periods of time, since measles virus infections generally occur in children rather than adults, and Paget's disease is usually diagnosed in patients over the age of 55? (3) Why does Paget's disease remain so highly localized in patients after diagnosis? (4) What is the explanation for the variable phenotypic presentation of patients with familial Paget's disease, especially that some of these patients who carry the mutated gene do not have Paget's disease even though they are over 70 years of age?

PATHOLOGY

The initiating lesion in Paget's disease is an increase in bone resorption due to an abnormality in the osteoclasts found at affected sites. Pagetic osteoclasts are more numerous than normal and contain substantially more nuclei than do normal osteoclasts, with up to 100 nuclei per cell. In response to the increase in bone resorption, numerous osteoblasts are recruited to pagetic sites where active and rapid new bone formation occurs. It is generally believed that the osteoblasts are intrinsically normal [25, 26].

In the earliest phases of Paget's disease, increased bone resorption dominates, and lytic changes are seen on radiographs. After this, there is a combination of increased resorption and relatively tightly coupled new-bone formation, produced by the large numbers of osteoblasts present at these sites. During this phase, and presumably because of the accelerated nature of the process, the new bone that is made is abnormal. Newly deposited collagen fibers are laid down in a haphazard rather than a linear fashion, creating more primitive woven bone. The end product is the so-called mosaic pattern of woven bone plus irregular sections of lamellar bone linked in a disorganized way by numerous cement lines representing the extent of previous areas of bone resorption. The bone marrow becomes infiltrated by excessive fibrous connective tissue and by an increased number of blood vessels, explaining the hypervascular state of the bone. Bone matrix is typically normally mineralized, and tetracycline labeling shows increased calcification rates. It is not unusual, however, to find areas of pagetic biopsies in which widened osteoid seams are apparent, perhaps reflecting inadequate calcium/phosphorus products in

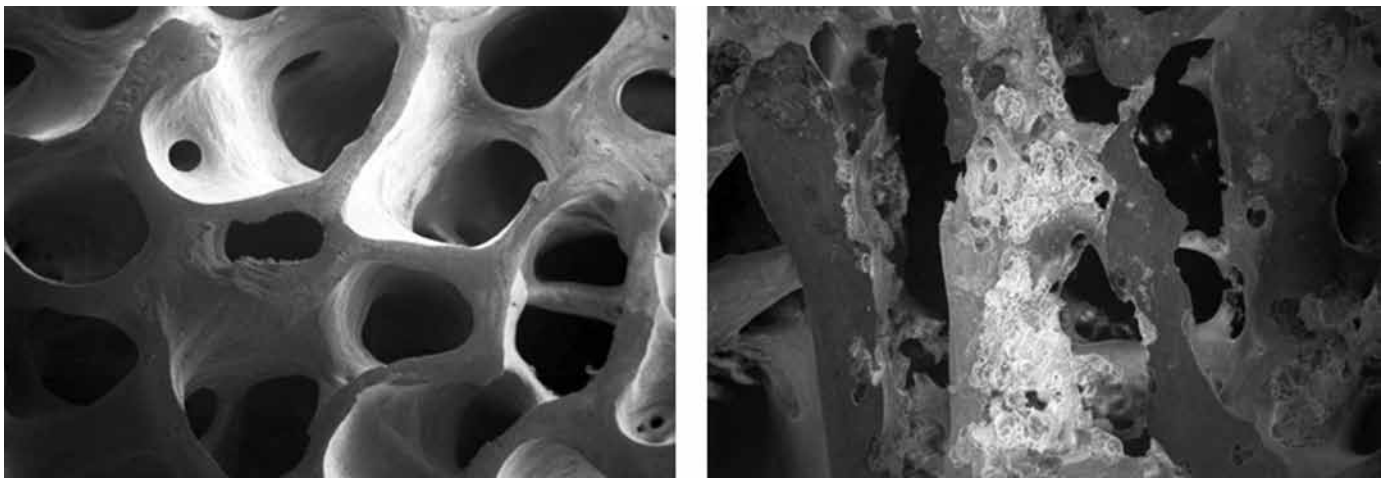

Fig. 80.1. Scanning electron micrographs with sections of normal bone (left) and pagetic bone (right). Both samples were taken from the iliac crest. The normal bone shows the trabecular plates and marrow spaces to be well preserved, whereas the pagetic bone has completely lost this architectural appearance. Extensive pitting of the pagetic bone is apparent, due to dramatically increased osteoclastic bone resorption. (Photographs courtesy of Dr. David Dempster; reproduced from Siris ES, Canfield RE. 1995. Paget's disease of bone. In: Becker KL (ed.) *Principles and Practice of Endocrinology and Metabolism, 2nd Ed.* Philadelphia: JB Lippincott. pp. 585–594. Used with permission.)

localized areas where rapid bone turnover heightens mineral demands.

In time, the hypercellularity at a locus of affected bone may diminish, leaving the end product of a sclerotic, pagetic mosaic without evidence of active bone turnover, so-called burned-out Paget's disease. Typically, all phases of the pagetic process can be seen at the same time at different sites in a particular subject. The chaotic architectural changes that occur in pagetic bone contribute to the loss of structural integrity. Figure 80.1 compares the appearances of normal and of pagetic bone by scanning electron microscopy.

BIOCHEMICAL INDICES IN PAGET'S DISEASE

Measurements of biochemical markers of bone turnover are useful clinically in the assessment of the extent and severity of disease in the untreated state and for monitoring the response to treatment [27]. Increases in serum or urine levels of biomarkers of bone resorption such as the C- and N-terminal telopeptides of collagen, CTX and NTX, reflect the increases in osteoclast mediated bone resorption. Secondary increases in osteoblastic activity are associated with elevated levels of bone formation markers including serum total alkaline phosphatase (SAP), bone specific alkaline phosphatase and procollagen type-1 N-terminal propeptide (P1NP). In untreated patients, the values of serum CTX or urine NTX and SAP rise in proportion to each other, reflecting the preserved coupling of resorption and formation. The magnitude of the increase in markers offers an estimate of the extent or severity of the abnormal bone turnover, with higher levels reflecting a more active, ongoing localized metabolic process. Active monostotic disease may have lower SAP values than polyostotic disease. Lower values (e.g., less than 3 times the upper limit of normal) may indicate fewer pagetic sites or a lesser degree of increased bone turnover at affected sites. However, mild elevations in a patient with limited and highly localized disease (e.g., the proximal tibia) may still be associated with symptoms and clear progression of disease at that site. Even a so-called normal SAP (e.g., at the upper limit of the normal range) may not truly be normal for the pagetic patient. To be confident that the SAP reflects quiescent disease, a result in the middle of the normal range is probably required.

Potent bisphosphonates are capable of normalizing the biochemical markers, an indication of a remission of the bone-remodeling abnormality, in a majority of patients and bringing the markers to near normal in most others so that monitoring the markers is helpful in assessing treatment effects. CTX or NTX may become normal in days to a few weeks after bisphosphonate therapy is initiated. It is often adequate, however, to monitor SAP alone, with a baseline measure pretreatment, a post-treatment test 1 to 3 months after treatment is completed and at 6–12-month intervals thereafter to determine duration of the effect of that treatment course.

Serum calcium is typically normal in untreated Paget's disease, but secondary hyperparathyroidism and transient decreases in serum calcium can occur in some patients who are being treated with potent bisphosphonates. This results from the early suppression of bone resorption in the setting of not yet reduced new-bone formation [28]. As restoration of coupling occurs with

time, parathyroid hormone (PTH) levels fall. The problem can be largely avoided by being certain that such patients are and remain replete in both calcium and vitamin D.

CLINICAL FEATURES

Paget's disease affects both men and women, with most series describing a slight male predominance. It is rarely observed to occur in individuals younger than age 25 years and thought to develop as a clinical entity after the age of 40 in most instances. It is most commonly diagnosed in people over the age of 50. In a survey of over 800 selected patients in the U.S., 600 of whom had symptoms, the average age at diagnosis was 58 years [29]. It seems likely that many patients have the disorder for a period of time before any diagnosis is made, especially because it is often an incidental finding.

Paget's disease may be monostotic, affecting only a single bone or portion of a bone (Fig. 80.2), or may be polyostotic, involving two or more bones. Sites of disease are often asymmetric. Clinical observation suggests that in most instances, sites affected with Paget's disease when the diagnosis is made are the only ones that will show pagetic change over time. Although progression of disease within a given bone may occur, the sudden appearance of new sites of involvement years after the initial diagnosis is uncommon.

The most common sites of involvement include the pelvis, femur, spine, skull, and tibia. The humerus, clavicle, scapula, ribs, and facial bones are less commonly involved, and the hands and feet are only rarely affected. It is believed that most patients with Paget's disease are asymptomatic and that the disorder is most often diagnosed when an elevated SAP is noted on routine screening or when a radiograph taken for an unrelated problem reveals typical skeletal changes. The development of symptoms or complications of Paget's disease is influenced by the particular areas of involvement, the interrelationship between affected bone and adjacent structures, the extent of metabolic activity, and presence or absence of disease progression within an affected site.

Fig. 80.2. Radiograph of a humerus showing typical pagetic change in the distal half, with cortical thickening, expansion, and mixed areas of lucency and sclerosis, contrasted with normal bone in the proximal half.

Signs and symptoms

Bone pain from a site of pagetic involvement, experienced either at rest or with motion, is probably the most common symptom. Pagetic bone associated with a high turnover state has an increased vascularity, leading to a sensation of warmth of the skin overlying bone (e.g., skull or tibia) that some patients perceive as an unpleasant sensation. Small transverse lucencies along the expanded cortices of involved weight-bearing bones or advancing, lytic, blade-of-grass lesions sometimes cause pain.

A bowing deformity of the femur or tibia can cause clinical problems. A bowed limb is typically shortened, resulting in specific gait abnormalities that can lead to abnormal mechanical stresses. Clinically severe secondary arthritis can occur at joints adjacent to pagetic bone (e.g., the hip, knee, or ankle).

Back pain may result from enlarged pagetic vertebrae. Vertebral compression fractures can occur since the bone is of suboptimal quality. Lumbar spinal stenosis with neural impingement may arise, producing radicular pain and possibly motor impairment. Degenerative changes in the spine that are unrelated to Paget's disease may also contribute to a patient's symptoms. Kyphosis may occur, or there may be a forward tilt of the upper back, particularly when a compression fracture or spinal stenosis is present. Paget's disease in the thoracic spine may rarely cause direct spinal cord compression with motor and sensory changes. Several cases of apparent direct cord compression have been documented to have resulted

from a vascular steal syndrome, whereby hypervascular pagetic bone "steals" blood from the neural tissue [30].

Paget's disease of the skull may be asymptomatic, but common complaints in up to one-third of patients with diffuse skull involvement may include an increase in head size with or without frontal bossing or deformity, or headache, sometimes described as a band-like tightening around the head. Hearing loss may occur as a result of isolated or combined conductive or neurosensory abnormalities; cochlear damage from pagetic involvement of the temporal bone with loss of bone density in the cochlear capsule may be an important component [31]. Cranial nerve palsies (such as in nerves II, VI, and VII) occur rarely. With extensive skull involvement, a softening of the base of the skull may produce flattening and basilar invagination, so that the odontoid process begins to extend upward as the skull sinks downward upon it. Rarely basilar invagination can produce direct brainstem compression or an obstructive hydrocephalus and increased intracranial pressure caused by blockage of cerebrospinal fluid flow. Pagetic involvement of the facial bones may cause facial deformity, dental problems, and, rarely, narrowing of the airway.

Fracture through pagetic bone can occur, particularly in long bones with active areas of advancing lytic disease; the most common sites are the femoral shaft or subtrochanteric area [32]. Increased vascularity of high turnover pagetic bone (i.e., with a moderately increased SAP) may lead to substantial blood loss in the presence of fractures due to trauma. Fractures also may occur in the presence of areas of malignant degeneration, a rare complication of Paget's disease. Far more common are the small fissure fractures along the convex surfaces of bowed lower extremities, which may be asymptomatic, stable, and persistent for years, but sometimes a more extensive transverse lucent area extends medially from the cortex, typically with symptoms of discomfort, and may lead to a clinical fracture with time. These painful lesions warrant treatment and careful radiographic follow-up over time. Fracture through pagetic bone usually heals normally, although some groups have reported as high as a 10% rate of nonunion.

Neoplastic degeneration is a relatively rare event, occurring with an incidence of less than 1%. This lesion typically presents as severe new pain at a pagetic site and has a grave prognosis. The majority of the tumors are classified as osteogenic sarcomas, although both fibrosarcomas and chondrosarcomas are also seen. The most common site of sarcomatous change appears to be the pelvis, with the femur and humerus next in frequency [33]. Typically, osteosarcomas are osteolytic, although these lesions involve cells of osteoblastic lineage [34].

Benign giant-cell tumors also may occur in bone affected by Paget's disease. These may present as localized masses at the affected site. Radiographic evaluation may disclose lytic changes. Biopsy reveals clusters of large osteoclast-like cells, which some authors believe represent reparative granulomas [35]. These tumors usually show a remarkable sensitivity to high dose glucocorticoids, and the mass will shrink or even disappear after treatment with prednisone or dexamethasone [36], although some will grow back after treatment ends. Anecdotal evidence also suggests possible shrinkage of benign giant-cell tumors in pagetic bone with thalidomide.

DIAGNOSIS

When Paget's disease is suspected, the diagnostic evaluation should include a careful medical history, including family history of the condition and symptom history, and a focused physical examination. The physical exam should note the presence or absence of warmth, tenderness, or bone deformity in the skull, spine, pelvis, and extremities, as well as evidence of loss of range of motion at major joints or leg length discrepancy.

Laboratory tests include measurement of SAP and in some cases a marker of bone resorption, as described earlier. It is also reasonable to assure normalcy of serum calcium and 25-hydroxy-vitamin D. Radiographic studies (bone scans and conventional radiographs) complete the initial evaluation. Bone biopsy is not usually indicated, as the characteristic radiographic and laboratory findings are diagnostic in most instances.

Bone scans are the most sensitive means of identifying possible pagetic sites but are nonspecific, and also can be positive in nonpagetic areas that have degenerative changes or, more ominously, metastatic disease. Plain radiographs of bones noted to be positive on the bone scan provide the most specific information, because radiographic findings are usually characteristic to the point of being pathognomonic. Enlargement or expansion of bone, cortical thickening, coarsening of trabecular markings, and typical lytic and sclerotic changes may be found. Radiographs also show the condition of the joints adjacent to involved sites, identify fissure fractures, indicate the degree to which lytic or sclerotic lesions predominate, and demonstrate the presence or absence of deformity or fracture.

Repeated scans or radiographs are usually unnecessary in observing patients over time, unless new symptoms develop or current symptoms become significantly worse. The possibility of an impending fracture or, rarely, of sarcomatous change should be borne in mind in these situations. Although imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI) scans are not usually required in routine cases, a CT scan may be helpful in the assessment of a fracture where radiographs are not sufficient, and MRI scans are useful in assessing the possibility of sarcoma, giant-cell tumor, or metastatic disease at a site of Paget's disease. Anecdotal data suggest that positron emission tomography (PET) scans of sclerotic lesions in patients with Paget's disease may help distinguish pagetic lesions from bone metastases, as the former are likely to be minimally to non-metabolic as compared with marked hypermetabolic changes seen with bone metastases [37].

The characteristic X-ray and clinical features of Paget's disease usually eliminate problems with differential diagnosis. However, an older patient may occasionally present with severe bone pain, elevations of the serum alkaline phosphatase and urinary N-telopeptide, a positive bone scan, and less-than-characteristic radiographic areas of lytic or blastic change. Here the possibility of metastatic disease to bone or some other form of metabolic bone disease (e.g., osteomalacia with secondary hyperparathyroidism) must be considered. Old radiographs and laboratory tests are very helpful in this setting, as normal studies a year earlier would make a diagnosis of Paget's disease less likely. A similar dilemma occurs when someone with known and established Paget's disease develops multiple painful new sites; here, too, the likelihood of metastatic disease must be carefully considered, and bone biopsy for a tissue diagnosis may be indicated.

TREATMENT

Specific antipagetic therapy consists of those agents capable of suppressing the activity of pagetic osteoclasts. Currently approved agents available by prescription in the United States include six bisphosphonate compounds: orally administered etidronate, tiludronate, alendronate, and risedronate, and intravenously administered pamidronate and zoledronic acid; and parenterally administered synthetic salmon calcitonin. Several of these are discussed briefly below. A more detailed review of these agents including more information on dosing regimens, clinical trial results, and side effects has been published [38].

Other symptomatic treatments for Paget's disease, including analgesics, anti-inflammatory drugs, use of orthotics or canes, and selected orthopedic and neurosurgical interventions, have important roles in management in many patients.

Two logical indications for medical treatment of Paget's disease are to relieve symptoms and to prevent future complications. It has been shown that suppression of the pagetic process by any of the available agents can effectively ameliorate certain symptoms in the majority of patients. Bone aches or pain, excessive warmth over bone, headache due to skull involvement, low-back pain secondary to pagetic vertebral changes, and some syndromes of neural compression (e.g., radiculopathy and some examples of slowly progressive brainstem or spinal cord compression) are the most likely to be relieved. Pain due to a secondary arthritis from pagetic bone involving the spine, hip, knee, ankle, or shoulder may or may not respond to antipagetic treatment. Filling in of osteolytic blade-of-grass lesions in weight-bearing bones has been reported in some treated cases with either calcitonin or bisphosphonates. On the other hand, a bowed extremity or other bone deformity will not change after treatment, and clinical experience indicates that deafness is unlikely to improve, although limited studies suggest that progression of hearing loss may be slowed [39] or even, in one case with pamidronate, reversed [40].

A second indication for treatment is to prevent the development of late complications in those patients deemed to be at risk, based on their sites of involvement and evidence of active disease, as shown by elevated levels of bone turnover markers. Admittedly, it has not been proven that suppression of pagetic bone turnover will prevent future complications. However, there is a restoration of normal patterns of new bone deposition in biopsy specimens after suppression of pagetic activity. It is also clear that active, untreated disease can continue to undergo a persistent degree of abnormal bone turnover for many years, with the possibility of severe bone deformity over time. Indeed, substantial (e.g., 50%) but incomplete suppression of elevated indices of bone turnover with older and less effective therapies has been associated with disease progression [41]; with potent bisphosphonates, however, indices become normal after treatment for extended periods in the majority of patients and approach normal in most of the rest.

Some treatment guides recommend, therefore, that the presence of asymptomatic but active disease (i.e., SAP above normal) at sites where the potential for later problems or complications exists (e.g., weight-bearing bones, areas near major joints, vertebral bodies, extensively involved skull) is an indication for treatment [38]. The need for treatment in this setting may be particularly valid in patients who are younger, for whom many years of coexistence with the disorder is likely. However, even in the elderly, one can justify treatment if a degree of bone deformity is present that might create serious problems in the next few years. Others argue that the evidence does not support such use; in the PRISM clinical trial—with a median of only 3 years of observation—disease suppression with bisphosphonates failed to reduce short-term complications or improve quality of life [42].

Although controlled studies are not available to prove efficaciousness in this situation, the use of a potent bisphosphonate before elective surgery on metabolically active pagetic bone also is recommended [43]. The goal is to reduce the hypervascularity associated with moderately active disease (e.g., a threefold or more elevation in SAP) to minimize blood loss at operation.

Recommendations for the management of Paget's disease have been published as guideline or management documents by consensus panels in the U.S. [38], U.K. [44], and Canada [45].

Bisphosphonates

Studies with etidronate [46], tiludronate [47], alendronate [48], risedronate [49], pamidronate [50] and zoledronic acid (also referred to as zoledronate) [51] have all demonstrated the efficacy of these agents in suppressing the localized bone turnover abnormality and in improving

many symptoms in patients with Paget's disease, and all of them are available and approved for use in the United States.

In most instances, the drug of choice, based on the efficaciousness of the agent and patient preferences regarding an intravenous or an oral regimen, is intravenous zoledronate or oral risedronate. Generic alendronate, 40 mg per day for 6 months (with the potential to repeat after a drug-free interval) and generic pamidronate, with several possible dosing approaches based on the patient's status [38], are also available at lower cost but with less convenient dosing regimens. Etidronate (400 mg per day for 6 months with repeated 6-months-on, 6-months-off cycles as needed) and tiludronate (3 months of 400 mg per day) are much less frequently used as they are of lesser potency than the other four bisphosphonates and may typically reduce elevated bone turnover markers by about 50% rather than achieve biochemical remission in the majority of patients.

Risedronate is prescribed as a daily oral dose of 30 mg for 2 months—note that this is a different dosing regimen than that for osteoporosis. The pill is taken after an overnight fast upon arising each morning with 8 ounces of plain water. The patient must remain upright and take nothing else by mouth for 30 minutes, after which he or she should eat. A follow-up measurement of SAP 1 to 2 months after completing the course is useful; if the value is not yet normal or near normal, a third or fourth month of risedronate could be offered with a good likelihood of normalcy or near normalcy of indices thereafter. In the pivotal clinical trial 80% of the patients had achieved a normal SAP 6 months after initiation of 2 months of treatment, with a period of subsequent disease suppression of up to 18 months [49]. Periodic measurement of SAP (every 6–12 months) should be done, and re-treatment is suggested, if indicated, if and when SAP rises above normal or increases by more than 25% of the nadir value if full remission was not achieved.

Zoledronic acid at a dose of 5 mg is administered as a single 15-minute intravenous infusion. In the pivotal clinical trial comparing one 5 mg infusion of zoledronic acid with 2 months of 30 mg per day oral risedronate, a normal SAP was achieved by 89% of zoledronic acid subjects compared with 58% of risedronate subjects [51]. A period of biochemical remission after the first zoledronic acid infusion of up to 18 months following the end of the initial observation period of 6 months was also noted in this study population. In practice, if a patient has a very high SAP pretreatment that fails to come to normal or near normal by a few months after the infusion, a second infusion can be provided. For patients who enter a biochemical remission or near remission after one (or two) doses, 6- to 12-month follow-up SAP measurements are suggested. Once the SAP begins to rise above normal or more than 25% above nadir levels if remission was not achieved, and if treatment is again indicated based on symptoms or concerns about complications, another dose can be provided. Again, note that treating at variable intervals based on biochemical remission and relapse differs from the regimen that is used when zoledronic acid is given for osteoporosis.

Secondary resistance to the effects of a given bisphosphonate (failure to achieve remission or a similar reduction in turnover markers with repeated courses of treatment) has been noted anecdotally with etidronate and has been reported with pamidronate [52] in some patients. Changing treatment at that point to a different bisphosphonate appears to be effective [52].

It is important to emphasize the need for full repletion of both calcium and vitamin D prior to and during treatment with potent bisphosphonates to avoid hypocalcemia and secondary hyperparathyroidism. Calcium and vitamin D repletion should be maintained thereafter in these patients as a general principle.

Side effects with alendronate and risedronate include upper gastrointestinal symptoms consistent with esophageal irritation in a minority of individuals. Excessive doses of etidronate (e.g., more than 6 months without a drug-free interval before re-treating) can infrequently induce a transient mineralization defect and osteomalacia. The first-ever dose of either pamidronate or zoledronic acid in a patient who has not previously received a nitrogen containing bisphosphonate can be associated with a flu-like reaction for 1–2 days after treatment with fever, headache, myalgia and arthralgia, ameliorated by using acetaminophen or an nonsteroidal anti-inflammatory drug (NSAID); this reaction is unlikely to occur with subsequent doses. Finally, relatively rare cases of uveitis or iritis have been described with nitrogen containing bisphosphonates. In such patients, either etidronate or tiludronate can be given, as these compounds do not contain the nitrogen atom.

Osteonecrosis of the jaw has recently been described as a complication typically following dental extractions in patients receiving relatively high doses of potent bisphosphonates given primarily for management of bone metastases. At least seven patients with Paget's disease have also been reported to have had this complication, most of whom were given very high doses for prolonged periods of time outside the usual prescribing guidelines [53]. This topic is discussed in detail elsewhere in the *Primer*.

Calcitonin

Synthetic salmon calcitonin is available as a subcutaneous injection. It is less effective than the nitrogen containing bisphosphonates and is most useful in the rare patient who is intolerant of all bisphosphonates or if bisphosphonate therapy is contraindicated. The usual starting dose is 100 U (0.5 ml; the drug is available in a 2-ml vial), generally self-injected subcutaneously, initially on a daily basis. Symptomatic benefit may be apparent in a few weeks, and the biochemical benefit (typically about a 50% reduction from baseline in SAP) is usually seen after 3 to 6 months of treatment. After this period, many clinicians reduce the dose to 50 to100 U

every other day or three times weekly. Escape from the efficacy of salmon calcitonin may sometimes occur after a variable period of benefit. The main side effects of parenteral salmon calcitonin include, in a minority of patients, the development of nausea or queasiness, with or without flushing of the skin of the face and ears. Intranasal calcitonin is not indicated for use in Paget's disease, but anecdotal experience suggests it may relieve some symptoms and lower elevated bone turnover markers in patients with mild disease.

Other therapies

Analgesics such as acetaminophen, aspirin, and NSAIDs may be tried empirically with or without antipagetic therapy to relieve pain. In particular, pain from pagetic arthritis (i.e., osteoarthritis caused by deformed pagetic bone at a joint space) is often helped by some of these agents.

Surgery on pagetic bone [54] may be necessary in the setting of established or impending fracture. Elective joint replacement, more complex with Paget's disease than with typical osteoarthritis, is often very successful in relieving refractory pain. Rarely, osteotomy is performed to alter a bowing deformity in the tibia. Neurosurgical intervention is sometimes required in cases of spinal cord compression, spinal stenosis, or basilar invagination with neural compromise. Although medical management may be beneficial and adequate in some instances, all cases of serious neurological compromise require immediate neurological and neurosurgical consultation to allow the appropriate plan of management to be developed.

INTRODUCTION

The metastasis of cancer cells to the skeleton is a complication of malignancy that disrupts normal bone homeostasis and remodeling, weakens bone and results in pathological fractures [1]. New mechanisms of bone metastasis have been implicated that involve all steps of metastasis: escape of rogue cancer cells from the primary tumor, systemic embolization, adherence to bone marrow vascular endothelium, extravasation into the bone microenvironment, propagation within a hospitable environment, and interaction with osteoblasts and/or osteoclasts to adversely alter bone remodeling. This multistep program requires the cooperation of many cell types and genes, each having a unique role during metastasis. This was illustrated in a study to identify genes contributing to osteolysis in a breast cancer cell line [2]. No one gene was solely responsible, but the cooperation of the genes, each implicated in a critical step collectively contributed to the formation of bone metastasis.

MALIGNANT TRANSFORMATION

Metastasis begins with malignant transformation of individual cells with characteristics that allow survival outside the confines of the primary tumor. An early step is epithelial-to-mesenchymal transition (EMT), a neoplastic process of cellular dedifferentiation and enhanced migratory potential. The transcription factors Twist, Snail, and Slug participate in EMT with resultant downregulation of cell adhesion factors such as E-cadherin [3–6]. Also cooperating are proteases such as matrix metalloproteinases, urokinase, and cathepsins that dissolve the primary tumor basement membrane and encourage escape of malignant cells [7–9]. Cancer cells may also alter basement membrane composition and architecture to encourage further escape of malignant cells by regulating basement membrane laminins that bind integrin receptors on the cancer cells [10]. Cancer cells that successfully pass through the primary tumor basement membrane and invade surrounding vasculature are primed for systemic embolization to distant organs.

CANCER CELL HOMING AND ADHESION TO BONE

The traditional view that cancer cells home to organs that provide the right microenvironment is evolving with the proposed existence of a premetastatic niche, a concept where metastatic sites are preselected and groomed for the arrival of metastatic cancer cells. In one example, breast cancer-secreted osteopontin, acting as an endocrine factor, activates bone marrow-derived hematopoietic progenitor cells that are released into the circulation

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

and deposited at distant premetastatic sites [11]. Vascular endothelial growth factor receptor 1 may serve as a marker and identify these prometastatic hematopoietic progenitor cells [12]. The premetastatic niche concept also applies to bone metastasis. Heparanase, produced by primary breast cancers, promotes shedding of tumor syndecan-1 [13]. This proteoglycan enhances osteoclastogenesis and bone remodeling, altering the bone microenvironment and preparing for the arrival of metastatic cancer cells [14].

Cancer cells entering circulation survive in part through the assistance of platelets [15]. Platelets direct fibrin deposition onto circulating cancer cells, thereby offering protection from immune surveillance and enhancing the ability to adhere to disrupted vascular endothelium [16, 17]. Cancer cells also promote platelet aggregation and the release of platelet lysophosphatidic acid (LPA) [18]. LPA receptors on cancer cells enhance cellular proliferation and stimulate the production of osteolytic factors [18].

The high prevalence of bone metastasis in advanced breast and prostate cancers suggests that they possess a unique "address" that directs circulating cancer cells to bone. The chemokine receptor CXCR4 expressed on cancer cells has an important role in delivery to bone [2, 19, 20]. Its ligand, CXCL12 or stromal-cell-derived factor 1a, is present in tissues that represent common sites of metastasis, including bone marrow and therefore cooperates with CXCR4 in cancer homing to bone [20–22]. Integrins also have important and complementary functions [23]. The integrin αvβ3, which binds the RGD peptide sequence found on a variety of extracellular matrix proteins, is important in tumor cell homing [24, 25]. In animal models of bone metastasis, αvβ3 antagonists prevented invasion of cancer cells into bone [26]. The integrin α2β1 is a high-affinity type I collagen receptor that participates in prostate cancer homing to bone [27, 28]. Tumor secretion of osteopontin and bone sialoprotein, small integrin-binding proteins, also supports metastasis by promoting tumor cell invasion, extracellular matrix degradation and survival at metastatic sites [29]. An initial interaction of metastatic tumor cells with bone marrow megakaryocytes may limit the bone metastasis potential [30].

OSTEOLYTIC BONE DISEASE

Once tumor cells arrive in bone, a "vicious cycle" of reciprocal bone–cancer cell signals regulate osteolytic metastasis. The secretion of breast cancer parathyroid hormone-related protein (PTHrP), supported by the Hedgehog signaling target GLI2, into the metastatic microenvironment stimulates osteoclastic bone resorption and release of transforming growth factor-β (TGFβ) from the mineralized bone matrix, which in turn stimulates the cancer cells to produce even more PTHrP [31–33]. Activation of osteoclast Notch signaling by expression of Jagged1 ligand in breast cancer cells serves as a complementary mechanism to increase osteoclastogenesis and the subsequent release of bone-derived TGFβ [34]. TGFβ in combination with the bone metastatic hypoxic environment regulates other prometastatic factors that enhance bone metastasis such as interleukins-6, -8, and -11, tumor necrosis factor-α, vascular endothelial growth factor, and CXCR4, and as such represents a central target for bone metastases therapy [35–38].

RUNX2, a transcription factor that specifies osteoblast fate, is also expressed in breast cancer cells and promotes breast cancer cells to function as osteoblast surrogates to support osteoclast formation [39]. Osteoclastic resorption of bone releases high concentrations of ionized calcium during dissolution of the bone. Calcium activates the calcium-sensing receptor (CaSR) expressed by breast cancer cells [40] that regulates tumor secretion of PTHrP further increasing the osteolytic response to the tumor cells [41, 42].

Multiple myeloma is far less common than breast cancer but osteolytic bone lesions are a nearly universal feature in advanced cases. Although not typically characterized as a metastatic malignancy, multiple myeloma shares many of the molecular mechanisms of pathologic bone resorption with breast cancer bone metastasis. Myeloma cells secrete a complement of osteoclast activating factors that include macrophage inflammatory protein-1α [43], receptor activator of nuclear factor-κB ligand (RANKL) [44], and interleukins-3 and -6 [45, 46]. Osteolysis is further enhanced with the secretion of inhibitors of osteoblast formation that include dickkopf homolog 1 (DKK1), secreted frizzled-related protein 2 and interleukin-3 by myeloma cells [47–49]. Other malignancies that result in osteolytic bone disease with varying frequency include non-small-cell lung cancer, melanoma, non-Hodgkin lymphoma, thyroid cancer, and acute lymphoblastic leukemia [50–54].

OSTEOBLASTIC BONE DISEASE

Endothelin 1 (ET-1) is abundantly secreted by prostate cancers and is a principal factor of the osteoblastic response to metastasis [55]. ET-1 stimulates the osteoblast, via the endothelin A receptor (ETAR), through downregulation of the Wnt signaling inhibitor DKK1 to form pathological new bone [55, 56]. The Wnt signaling pathway is a key osteoblast regulatory pathway critical for normal osteoblast differentiation and function [57]. The formation of osteoblastic bone metastasis is likely dually dependent on the downregulation of microenvironment DKK1 secretion from osteoblasts via tumor-produced ET-1 and from prostate cancer cells themselves [56, 58]. Although bone morphogenetic proteins (BMPs) cooperating with Wnt proteins have been implicated in osteoblastic disease [59], BMP-7 has been shown in some studies to prevent bone metastases. This secreted factor inhibits bone metastasis by antagonizing TGFβ signaling

and reversing the epithelial-to-mesenchymal transition of cancer cells [60]. Platelet-derived growth factor may promote osteoblastic disease as well as invasive behavior of prostate epithelium [61]. A puzzling question has been the role of prostate-specific antigen (PSA) in osteoblastic metastasis. Despite convincing *in vitro* evidence that PSA has biological activity contributing to bone metastasis, *in vivo* studies demonstrating a clear causal relationship are lacking [62].

CONCLUSION

Metastatic cancer cells with an affinity to bone flourish within the bone microenvironment. These cells have the ability not only to proliferate in bone but to coax osteoblasts and osteoclasts to produce factors within the bone microenvironment that further stimulate cancer cell growth. Discovery of the molecular mechanisms that control bone metastasis has translated into therapeutic preclinical and clinical trials. Denosumab, the monoclonal antibody targeting RANKL, is now approved for preventing skeletal-related events in bone metastasis [63, 64]. Blockade of PTHrP and/or TGFβ to reduce bone metastasis has shown promise in preclinical models [31, 33, 39, 65–67]. ETAR blockade reduces the progression of osteoblastic lesions and may reduce mortality as well [68, 69].

Many unanswered questions remain regarding the pathophysiology and treatment of bone metastasis. Does accelerated bone turnover facilitate tumor growth in bone, as suggested in animal models [70, 71]? What controls tumor dormancy in bone? What is the role of angiogenesis? What is the benefit of preemptive bone targeted therapies to prevent bone metastasis and the role of combined therapies? Will inhibitors of cathepsin K be as effective as denosumab or bisphosphonates to treat metastatic bone disease? What are the most effective radiopharmaceutical therapies and pain therapies? The answer to many of these critical issues will surely lead to the identification of additional therapeutic targets. A combination of therapies, each targeting a specific metastatic step or signaling pathway, is a likely formula for a bone metastasis cure.

INTRODUCTION

Bone metastases are frequent complications of cancer, occurring in up to 80% of patients with advanced breast or prostate cancer and in approximately 15–30% of patients with carcinoma of the thyroid, lung, bladder, or kidney [1]. In addition, melanomas and multiple myeloma also readily metastasize to the skeleton. Bone metastases can be classified into osteolytic, osteoblastic, or a mixed phenotype. Once tumors metastasize to bone, the disease is incurable, and patients may experience several skeletal-related events such as severe bone pain, hypocalcaemia, nerve compression syndromes, and pathological fractures [2, 3]. This severely increases morbidity and diminishes the quality of life of the patients.

Imaging has become an indispensible tool in the diagnosis and treatment of skeletal metastasis both in the clinic and experimentally. Novel multimodality imaging approaches are emerging rapidly and will greatly facilitate experimental studies in preclinical models of metastatic bone disease (Fig. 82.1; Table 82.1).

CANCER IMAGING

In the clinic, imaging is traditionally used for detection and staging of the disease, monitoring of the response to therapy, and identifying the risk for pathologic fractures. However, functional and molecular imaging can also be used to study processes involved in tumor growth and metastasis, including angiogenesis and pharmacokinetics.

Preclinical imaging, using small animals, can be used to visualize and observe changes at the organ, tissue, cell, or molecular level (e.g., the location or the size of the tumor or the characteristics of the tumor or tumor-surrounding stroma).

Current imaging modalities can be classified into morphological/anatomical imaging techniques [ultrasound imaging, computed tomography (CT), and magnetic resonance imaging (MRI)] and molecular imaging techniques [positron emission tomography (PET), single photon emission computed tomography (SPECT), and optical imaging fluorescence (FLI) and bioluminescence imaging (BLI)]. For imaging metastatic bone disease in the clinic, several modalities are used, each with their own advantages and drawbacks. To detect and stage the disease, Tc^{99m} methylene diphosphonate (Tc^{99m}MDP) bone scintigraphy is mainly used, supported by plain film radiography or SPECT. Bone scintigraphy can be followed by MRI, CT, or even PET/SPECT. For preclinical imaging, several of the imaging modalities are adapted for small animal studies. In addition to these, optical imaging is widely used in small animals to study the pathogenesis and experimental treatment of metastatic bone disease.

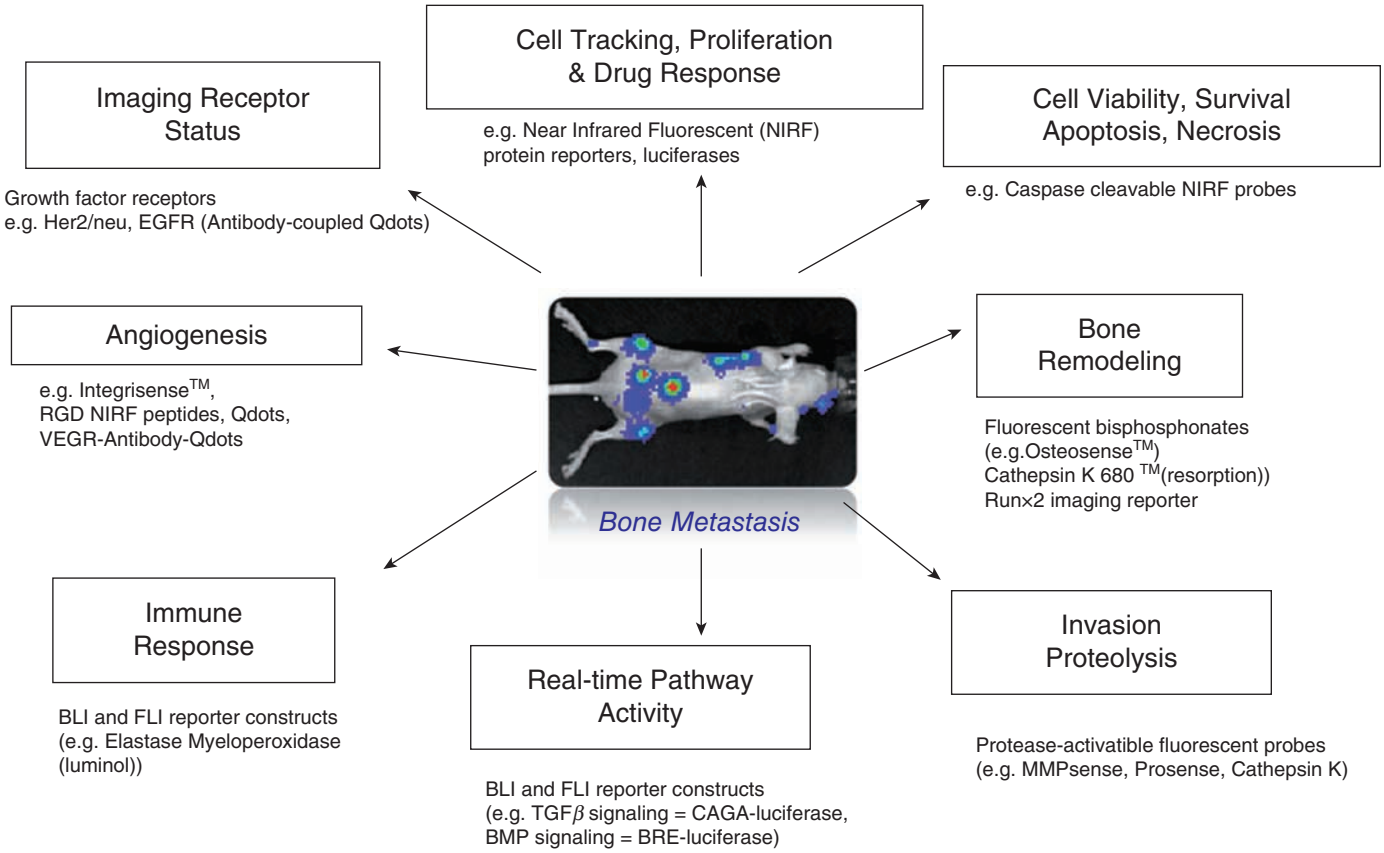

Fig. 82.1. Molecular imaging in preclinical bone metastasis models greatly facilitates real-time assessment of complex processes involved in the pathogenesis of skeletal metastasis. In the center, a representative bioluminescence image of a preclinical bone metastasis model is shown. For this, 100,000 human luciferase-expressing PC-3M-Pro4 prostate cancer cells were inoculated into the left cardiac ventricle of immuno-deficient mice to allow real-time cell tracking of skeletal metastases.

MORPHOLOGICAL/ANATOMICAL IMAGING TECHNIQUES

Plain Film Radiography measures the decline of X-rays passing through tissues. Because of its high resolution, radiography can be used to measure details such as cortical thickness, which is important to assess the risk of a pathologic fracture [4]. However, in the clinic, whole-body plain film radiography is not very often used for detection of bone metastasis. This is due to the fact that an osteolytic bone lesion must display bone resorption of at least 40–50% to be consistently detectable. Only for patients with multiple myeloma is plain film radiography still used, since osteolytic lesions of multiple myeloma have a characteristic appearance and are difficult to detect using a Tc^{99m}MDP bone scan.

Computed tomography (CT) measures the decline of X-rays passing through tissues. The X-rays decline at different rates depending on the density of the tissues. In the clinic, CT is used to obtain three-dimensional (3D) anatomical information, to obtain characterization of bone lesion size and to evaluate soft tissues. Due to the differences in shape, location, and density, CT imaging can detect many tumors. However, many small tumors or micrometastases are not detectable on a CT scan. In preclinical imaging, micro CT (μCT) is now a well-established imaging modality that can be used to image small animals and generate 3D images. Numerous experiments have been performed using μCT mainly because of the high spatial resolution of the images (50–100 μm^3) and the relative rapid data acquisition time (minutes) [5]. This technique is cost-effective and can be used to examine the architecture of bones. In addition, μCT can detect soft tissue and skeletal abnormalities as well as tumors in small animals.

Dynamic CT (DCT) is a technique that can be used to study perfusion, permeability, and blood flow. Instead of a high-resolution image, DCT acquires a series of lower-resolution CT images. A contrast agent is administered to the subject and a series of CT images are acquired imaging the wash-in and wash-out of the contrast. Using a kinetic model, quantitative maps of blood flow, tissue permeability, and perfusion can be derived [6].

However, one of the major drawbacks of both CT and μCT is the low tissue contrast (compared to MRI).

Table. 82.1. Comparison of Different Imaging Modalities Including Source, Possible Applications, and the Benefits and Drawbacks of Each Technique*

Imaging Modality	Source	Possible Applications	Advantages	Drawbacks
MRI: magnetic resonance imaging	Electromagnetic waves	– Structural, anatomical information on tissue architecture – Long-term monitoring of cell viability and metastatic bone tumor burden [Transferrin, Ferritin, Tyrosine (Refs. (11, 21)]. – Monitoring of metabolism, tissue composition and detection of molecular probes (Refs. 11, 12, 21)	– High spatial resolution – Good soft tissue contrast – Quantitative – Small cell number imaging possible	– Low throughput – Highly trained personnel
CT: computed tomography	Radiation (X-rays)	– Structural, anatomical information on the bone architecture (Refs. 8, 9).	– High spatial resolution – High penetration depth	– Low sensitivity – Radiation dose
PET: positron emission tomography	Radiation (high energy γ-rays)	– Early cell localization and bone homing [e.g., 18^{F}-FDG (Refs. 11, 21, 25, 26)]. – Long-term monitoring of cell viability and metastatic bone tumor burden [HSV1-tk (Ref. 63)]. – Visualization of molecular and metabolic processes [e.g., whole-body pharmacokinetics or receptor expression (Refs. 24, 21, 25)]. – *Real-time signaling pathway activity [reporter constructs* (Ref. 64)].	– High sensitivity – High penetration depth	– Limited spatial resolution – Radiation – High costs – Not quantitative
SPECT: single photon emission computed tomography	Radiation (low energy γ-rays)	– Early cell localization and bone homing [e.g., ^{111}In (Ref. 21)]. – Long-term monitoring of cell viability and metastatic bone tumor burden [NIS, somatostatib (Refs. 65, 66)]. – Visualization of molecular and metabolic processes [e.g., apoptosis or receptor expression levels (Refs. 21, 24, 25)].	– High sensitivity (lower than PET) – High penetration depth	– Limited spatial resolution – Radiation – Not quantitative
BLI: bioluminescence imaging	Bioluminescent light	– *Early cell localization and bone homing, small cell numbers* (Refs. 41, 43). – *Long-term monitoring of cell viability and metastatic bone tumor burden [functional and drug response studies* (Refs. 41–43)]. – *Real-time signaling pathway activity [reporter constructs* (Ref. 64)]. – *Visualization of molecular and metabolic processes [e.g., VEGFR activity* (Ref. 67)].	– High sensitivity – High throughput – Low costs – Small cell number imaging possible	– Limited spatial resolution – Limited penetration depth – Not clinically applicable
FLI: fluorescence imaging	Fluorescent light	– *Early cell localization and bone homing* (Ref. 68). – *Long-term monitoring of cell viability and metastatic bone tumor burden [functional and drug response studies NIRFs* (Refs. 69–71)]. – *Real-time signaling pathway activity (reporter constructs).* – *Real-time monitoring of processes involved in bone metastasis [smart probes, e.g.. MMP-sense* (Ref. 55)]. – Image guided surgery (Ref. 56).	– High sensitivity – High throughput – Low costs	– Limited spatial resolution – Limited penetration depth – Auto fluorescence

*Possible applications in *italic* are only available for preclinical imaging.

Moreover, the level of radiation necessary may be high enough to induce changes in the immune response and other biological pathways, thus imitating radiotherapy [7–9]. Especially in longitudinal studies, the cumulative dose can be very high, although in response to the concerns over the mounting radiation exposure, imaging strategies have already been developed that deliver the lowest dose necessary to obtain the desired information with CT [9].

MOLECULAR/FUNCTIONAL IMAGING TECHNIQUES

Several imaging modalities can be used for molecular imaging, which is defined as: "the visualization, characterization, and measurement of biological processes at the molecular and cellular levels in humans and other living systems. Molecular imaging agents are probes used to visualize, characterize and measure biological processes in living systems. Both endogenous molecules and exogenous probes can be molecular imaging agents [10]."

Molecular imaging can be used to identify processes involved in tumor development, progression, and metastasis. Moreover, both pathway activity and pharmacokinetics can be studied using molecular imaging.

Radionuclide bone scintigraphy comprises intravenous administration of a radioactive bone-seeking agent (Tc^{99m} methylene diphosphonate or Tc^{99m} MDP), imaged using a single-photon camera. The bone scans visualize the secondary effect of bone metastases, since they bind to hydroxyapatite mineral in the bone matrix in proportion to the blood flow and are therefore markers of bone turnover and perfusion. Osteoblastic metastases, which display locally increased bone turnover, assemble more Tc^{99m} MDP than normal bone. Bone scintigraphy is a highly sensitive and cost-effective screening modality [4]; even a 5% change in bone turnover can be detected, whereas plain film radiography or CT can only detect 40–50% loss of mineral. Disadvantages of bone scintigraphy include the specificity; false positives can be seen from degenerative change, inflammation, trauma, and Paget's disease. In addition, bone scans display relatively poor spatial resolution and reduced sensitivity for tumor cells that reside in the bone marrow for very aggressive metastasis or for tumor cells that induce little healing reaction, such as multiple myeloma [4]. Therefore, SPECT imaging (see below) is often used as a complementary imaging technique to increase the sensitivity of bone scintigraphy (20–50% increase in lesion detection) and to detect and localize vertebral lesions.

Magnetic resonance imaging (MRI) allows visualization of the properties of various tissues by differences in their absorption and emission of electromagnetic energy. MRI is a very useful technique to show detailed anatomical images. However, not only structural information, but also information regarding tissue composition, perfusion, oxygenation, tissue elasticity, metabolism, detection of molecular probes, and more can be obtained (reviewed in Refs. 11 and 12). In the clinic, MRI is more sensitive than plain radiography, CT, or bone scintigraphy in detecting early lesions in bone before they provoke an osseous response [e.g., confirmed skeletal metastases (91%) versus bone scintigraphy (85%)] [13–16]. For example, in prostate cancer bone metastases, MRI can measure changes prior to the osteoblastic response in the bone marrow [17]. In preclinical imaging, one of the interesting opportunities provided by MRI imaging is its high resolution. MRI can detect early, small-sized tumors or even small amount of cells; for example, 100 embryonic stem cells were labeled by superparamagnetic iron oxide (SPIO) nanoparticles and could be imaged with MRI both *in vitro* and *in vivo*, and even a small cell cluster of 10 cells could be measured in a gel phantom [18]. These data indicate that MRI can potentially be used to image small amounts of cells (e.g., cancer stem cells) [18–20].

The disadvantages of MRI in both the preclinical and clinical setting include poor sensitivity in terms of molecular reactions, the requirement of highly trained personnel, the long acquisition time (minutes to hours), and high costs [21, 22].

Although the previously described conventional imaging methods (e.g., MRI and CT) provide structural information on the bone architecture, which is often altered during the progression of skeletal metastasis, other imaging methods are required for the imaging of other processes important for the progression of the metastases such as tumor cell biology and metabolic processes. For this, highly sensitive methods such as **positron emission tomography (PET)** and **single photon emission computed tomography (SPECT)** imaging modalities are favorable.

PET is an imaging technique that detects pairs of high energy γ-rays emitted indirectly by a positron-emitting radioactive atom (radiotracer), which was introduced into the subject. SPECT combines conventional radionuclide imaging with image reconstruction from projections and is a very promising technique with a variety of available tracers [23]. SPECT can provide true 3D information and uses low-energy γ-rays. PET and SPECT both have excellent temporal resolution and good sensitivity, although SPECT displays a lower sensitivity compared to PET. PET and SPECT imaging cannot only be used to visualize tumors, but also to visualize metabolic processes. Moreover, PET and SPECT allow functional evaluation including whole-body pharmacokinetics (reviewed in Refs. 24 and 25). One of the advantages of SPECT is that multiple molecular functions can be imaged at the same time by using different energy radioisotopes.

In the clinic, the radiotracer [18] F-fluoro-2-deoxyD-glucose (FDG) can be used for detection and staging [25]. In both the clinical and preclinical setting, **FDG-PET** measures metabolism in the tumor cells and the increased glucose transport and glycolysis associated with several tumors [25, 26]. Because FDG-PET detects metabolic activity of the tumor cells, it can detect metastases prior to the osseous response. This technique can

accurately detect bone metastasis in osteolytic bone disease (e.g., multiple myeloma). However, FDG-PET is not very sensitive in detecting osteoblastic lesions (e.g., prostate carcinoma). For prostate carcinoma PET tracers such as ^{11}C-acetate, ^{11}C-choline, and ^{18}F-choline have been investigated as alternatives to FDG [27]. In addition, it has been shown that ^{18}F-NaF PET is superior to ^{99m}Tc-MDP planar scintigraphy or SPECT in detecting prostate cancer bone metastases [28]. PET using ^{18}F-NaF PET detected more lesions and showed higher contrast between tumor and normal bone. Moreover, the detection efficiency of ^{18}F-NaF PET is independent of the localization of the lesion (in contrast to bone scintigraphy) [29]. For mixed phenotypes, FDG-PET is complementary to the bone scintigraphy and allows detection of some of the lesions that are missed by the Tc^{99m} MDP bone scan [30].

Another example of clinical bone imaging using PET is **^{18F}sodium fluoride**. This fluoride, like Tc^{99m} MDP, is incorporated into the bone as part of the bone mineralization process. One of the advantages compared to bone scintigraphy using Tc^{99m} MDP is the ability to provide quantitative information. In addition, ^{18F}sodium fluoride-PET displays higher contrast and superior spatial resolution compared to bone scintigraphy. PET ^{18F}sodium fluoride has also been used successfully in preclinical models [31].

In addition, other biological properties important for tumor growth and survival, including hypoxia, proliferation, apoptosis, and receptor expression are being investigated with PET or SPECT imaging modalities using a wide range or radiotracers [24, 25]. PET is mostly used to visualize molecules with fast kinetics whereas SPECT is used to image molecules with slow kinetics.

One of the main limitations of PET imaging alone is its relatively low spatial resolution and the lack of a clear anatomical reference. Another major drawback of PET and SPECT is the high cost of the technique. Not only a very expensive imaging modality should be purchased, but also expensive cyclotrons are needed to generate the radioisotopes. Another drawback is the possibility that the radiation influences the tumor size, as it imitates radiotherapy.

Noninvasive, whole-body **optical imaging** permits longitudinal real-time gene expression, cellular localization, and drug response studies in small laboratory animals through the use of direct-targeting probes and reporter systems. Optical imaging encompasses *bioluminescence* imaging and *fluorescence* imaging. Of these, only fluorescence imaging has potential clinical applications (e.g.. image-guided surgery).

Bioluminescence imaging (BLI) is most commonly used for tracking cancer cells and studying their distribution and activity *in vivo* because it is easy to use, cost-effective, and very sensitive (reviewed in Ref. 32). BLI is ideally suited to image fundamental biological processes *in vivo* due to the high signal-to-noise ratio, low background, and short acquisition time. Bioluminescence is based on the detection of photons emitted by the enzymatic reaction in which a substrate (either D-luciferin or coelenterazin) is oxidated by a luciferase. Several different luciferases exist including *Photinis pyralis* (firefly) luciferase, red and green *Pyrophorus plagiophthalamus (*click beetle luciferase), *Gaussia* luciferase, and *Renilla* luciferase [33–35]. *Firefly* luciferase (FFLuc), which catalyzes the substrate luciferin, is the most extensively used luciferase in cell-based bioluminescence imaging [36–40]. The use of the new generation of FFLuc (the mammalian codon-optimized FFLuc2), especially, enables extremely sensitive imaging and is very useful for monitoring cell tracking and survival in small animals [41–43].

Although bioluminescence imaging has several advantages, including high sensitivity, a low background signal, a high signal-to-noise ratio, and a short acquisition time, BLI mainly provides planar imaging with limited depth information and signal localization, and the spatial resolution of BLI is relatively poor. For example, changes in depth of the signal can be confused with changes in cell survival. In addition, the technique is restricted to small animals and is very superficial in larger objects. The color of the animals is also important, since dark skin pigmentation or fur color can attenuate the bioluminescent light (the same holds true for fluorescent light).

Other markers for live-cell imaging are fluorescent proteins or fluorochromes targeted to specific cell compartments or molecules. **Fluorescence imaging** is based on the detection of emitted light subsequent to their excitation by light of a specific wavelength. Fluorescence imaging can be divided into fluorescence reflectance imaging (FRI) and fluorescence molecular tomography (FMT), the latter being able to provide 3D information [44]. Fluorescence optical imaging can be used for whole-body imaging and two-photon imaging. Two-photon imaging can be used to visualize molecular processes or cells in a surgically exposed region of the body. It provides a microscopic perspective and can be used to track real time *in vivo* effects [45]. The drawbacks of two-photon imaging are autofluorescence and the need to expose the region of interest. For deeper noninvasive imaging of small animals, the fluorescent proteins optimally need to be in the far-red or near-infrared (NIR), because then autofluorescence of the tissue is less prominent and tissue penetration is improved (reviewed in Ref. 46). The use of fluorescent proteins for imaging cancer dynamics *in vivo* at the tumor and cellular level has been reviewed by Hoffman [47], describing the use of fluorescent proteins to differentially label cancer cells in the nucleus and cytoplasm to visualize the nuclear-cytoplasmic dynamics of cancer cell trafficking in both blood vessels and lymphatic vessels in small animals. The drawbacks of fluorescence imaging include autofluorescence, limited depth information and poor spatial resolution. In addition, the technique is restricted to small animals and is very superficial in larger objects.

Several "smart probes" have been developed to study different biological processes in preclinical models. For example, the skeleton can specifically be studied using bone-specific probes including the fluorescently labeled bisphosphonate Osteosense^{TM} (PerkinElmer) or

the fluorescently labeled tetracycline derivative Bone Tag (LI-COR Biosciences) [48, 49]. These bone probes are incorporated into the bone at sites with high bone turnover, which occurs during cancer-induced bone remodeling [50, 51]. Angiosense (PerkinElmer) is a fluorescent agent that remains localized in the vasculature (Fig. 82.1) and can be used to visualize angiogenesis.

Another interesting probe is the Prosense probe, which can be used to visualize Cathepsin K activity and is highly present at osteolytic lesions and sites of active bone resorption [52–54]. Prosense is one of the smart probes, a cleavable probe that provides information about the activity of an enzyme. The substrate of the enzymes is coupled to a fluorophore, which is quenched due to the structure and location of the fluorophore. Upon cleavage by the enzyme, the fluorophore is released and can be detected.

Other smart probes were designed to visualize the matrix degradation process, which is an important process for cancer cell motility and invasiveness. For example, MMPsense (PerkinElmer) is activated by the matrix metalloproteases MMP2 and MMP9 [55]. These proteases may be produced by the cancer cells as well as the reactive stroma.

IMAGE-GUIDED SURGERY

Clinical application of optical fluorescence imaging is a relatively novel medical imaging technique. Because of the limited depth of light penetration, the imaging can only be performed for surfaces only (e.g., skin or during an endoscopic or surgical procedure). Near-infrared fluorescence imaging during surgery can aid surgeons to search for tissue that needs to be resected (e.g., tumor tissue) and tissue that needs to be spared such as blood vessels or nerves (reviewed in Ref. 56).

In preclinical models, tumor-specific, NIR fluorescent probes (e.g., probes targeting epidermal growth factor receptor) have been used to visualize oral squamous cell carcinoma and cervical lymph node metastasis [57].

MULTIMODALITY IMAGING AND FUNCTIONAL IMAGING

Taking into account that every imaging modality has its advantages and drawbacks, combining two or more imaging modalities may provide a better solution to overcome the limitations of the independent techniques (multimodality imaging).

Combining the imaging modalities will improve and expand the scope of information available. Recently, multimodality instruments have been developed, e.g., combined PET/CT or SPECT/CT scanners [58, 59]. When combining PET and CT imaging, the low resolution and high sensitivity of the PET image is compensated with the high-resolution CT image. Fusion of the functional PET data and the anatomical CT findings has been shown to increase the diagnostic performance of PET alone [60]. Other combinations of imaging modalities are also feasible. For example, the combination of μCT and optical imaging would avoid the use of radioactive tracers. However, this combination can only be used in small animal imaging because of the low light intensity and tissue penetration of fluorescent or bioluminescent light. Integration of PET and MRI imaging allows the acquisition of functional imaging data, which are projected on data sets with anatomical information [61, 62].

In the future, multimodality imaging promises to make significant contribution to both the staging and management of osseous metastatic disease.

SUMMARY

Clinically, planar bone scintigraphy using Tc^{99m} MDP are often sufficient for diagnosis and may be enhanced by SPECT. FDG-PET, CT, and MRI can offer complementary information. Multimodality imaging is, therefore, a powerful tool to acquire spatially and temporally correlated data showing, for example, the distribution of PET radiotracers or MRI contrast agents with registration of the anatomical location. Preclinical imaging has the advantage of adding the sensitive optical imaging modality to this multimodality approach.

Better understanding of the processes involved in skeletal metastasis and the development of new therapies requires noninvasive high-resolution *in vivo* imaging. The development, and clinical application, of new, more sensitive molecular imaging methods will significantly improve the detection of yet undetectable micrometastasis (minimal residual disease) and may eventually lead to better treatment and/or surgical removal of the primary tumor, affected locoregional lymph nodes and bone metastases.

IMPORTANCE OF THE PROBLEM

Cancer metastasis to bone is a common problem in patients with metastatic tumors, such as breast, prostate, and lung cancers. For example, it is estimated that 70% of patients with metastatic breast cancer and 90% of patients with metastatic prostate cancer will develop tumors in bone [1]. Once tumors have established in bone they disrupt normal bone remodeling that can result in an excess of poorly formed bone (osteoblastic-prostate) or the destruction of bone (osteolytic-breast and lung), though many patients display a mixture of both. This disruption in bone results in an increase in fractures, bone pain, and hypercalcemia, resulting in a decrease in quality of life and poor clinical outcome. Importantly, bone metastases are incurable, and while treatments have improved, the patients will eventually die from the disease.

CONCEPT OF THE VICIOUS CYCLE

Dr. Gregory Mundy coined the term "vicious cycle" about 20 years ago to refer to the important interactions between tumor cells and the bone microenvironment. In this model, factors from the tumor stimulate osteoclast mediated bone destruction, which results in growth factors being released from the bone to stimulate further growth of the tumor cells and thus the production of more tumor-derived osteolytic factors (Fig. 83.1) [2].

While the concept is overly simplified in order to illustrate the hypothesis, the "vicious cycle" has held up well over the past 20 years with the mechanistic and clinical data collected. This is especially true in studies using osteoclast inhibitors, such as bisphosphonates. These studies have demonstrated that inhibiting the bone resorption phase also reduces the tumor burden. While there is disagreement in the field as to whether bispohosphonates directly inhibit tumor cell growth, it is likely that inhibiting bone resorption inhibits tumor cell growth [3]. Furthermore, inhibiting tumor-produced factors, such as parathyroid hormone—related protein (PTHrP) inhibits bone destruction and further tumor growth [4, 5].

Our notion of the vicious cycle continues to emerge as we learn more about the interactions between tumor cells and the bone (Fig. 83.1). It has become clear that many factors within the bone microenvironment interact with the tumor cells, and that these interactions are far more complicated than the original vicious cycle model alone can explain. For example, we now know that tumor cells can closely interact with osteoblasts [6–8], bone stroma [9], and immune cells [10, 11].

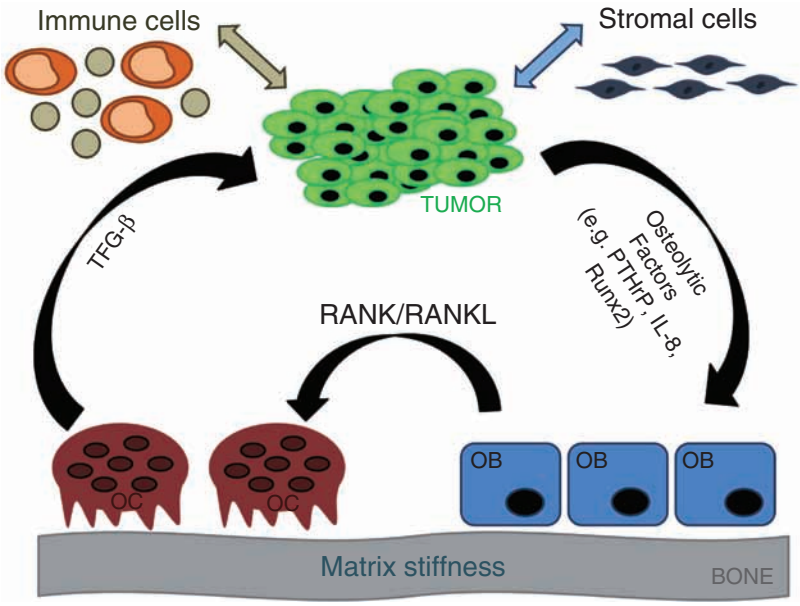

Fig. 83.1. Updated "vicious cycle" diagram. Data collected over many years suggest a complex interaction between tumor cells that metastasize to bone and many cell types that reside in bone marrow. These include immune and stromal cells as well as osteoblasts and osteoclasts. Factors produced by the tumor cells alter the growth of the cells in the microenvironment; in turn, tumor cell behavior is influenced by interactions with these cells. Furthermore, interactions with the physical microenvironment appear to also influence tumor cell behavior and gene expression.

ANIMAL MODELS FOR STUDYING BONE METASTASES

Some of the most common models of tumor-induced bone disease include tail vein [12–14], cardiac [15–17], and intratibial [18–20] inoculation of breast tumor cells. Many breast cancer models rely on cardiac injections, in which tumor cells are inoculated directly into the left cardiac ventricle. This allows for tumor cells to disperse throughout the body, but bypasses the direct blood flow to the lungs. Other tumor–bone models, such as the myeloma models, rely on tail vein injections, which for breast cancer cells result in a large tumor burden and premature death due to lung metastases. In certain cases tumors are inoculated directly into the tibia. While not a model of metastasis, this approach is extremely important for prostate models that do not readily metastasize to bone when injected intravenously. In addition, for certain breast cancer models, intratibial injections can indicate how alterations in gene expression of a tumor cell alter tumor growth in bone separately from metastasis. While these models are the primary models available for the study of human metastasis to bone, the ideal models are those that spontaneously metastasize from the mammary fat pad. Unfortunately, there are currently no human tumors that metastasize from the fat pad in mouse models. There are mouse models, such as the 4T1/BalbC model, which can metastasize to bone from the primary site [21, 22], but this model lacks the clinical significance that can only be achieved through human metastasis models.

Prostate models are particularly challenging. The only metastatic models available utilize PC—3 cells, which unlike most prostate tumors in patients are purely osteolytic. Therefore, these cells are rarely used for tumor–bone models. Instead the field mostly relies on orthotopic models developed by Leland Chung's group from LNCaP C4—2b cells derived from a lymph node metastasis [23, 24] and numerous cell lines isolated by the Vessella group from their rapid autopsy program [25]. These cells can also be directly injected into bone, where they develop into strongly osteoblastic tumors.

The most popular models of cancer metastasis to bone have traditionally focused on breast or prostate, primarily since these cancers tend to be the most prevalent in the population; however, a recent shift in the prevalence of lung cancer metastases to bone has stimulated the use of the RWGT2 model of lung carcinoma, which was generated by the Mundy group [26]. This recent interest can be largely attributed to advancements in the treatment of lung tumors at the primary site, which extends patient survival from the primary tumor but appears to facilitate the opportunity for tumor cells to metastasize to bone. The RWGT2 intracardiac model causes significant bone destruction, similar to the clinical disease.

MOLECULAR MECHANISMS OF BONE METASTASIS (OSTEOLYTIC)

Breast and lung tumors that have metastasized to bone frequently cause significant bone destruction through activation of osteoclasts. This is primarily initiated by tumor cell upregulation and secretion of factors that stimulate receptor activator of nuclear factor-κB ligand (RANKL) expression in osteoblasts and results in osteoclast activation through RANK/RANKL binding. While several factors that will be discussed later in this review

have been implicated, PTHrP has been identified as a major osteolytic factor produced by tumor cells to activate bone destruction [2, 27]. We have identified the developmental transcription factor Gli2 as a key regulator of PTHrP transcription and secretion [15]. Whereas Gli2 is regulated by the Hedgehog (Hh) signaling pathway during development, we have shown that Gli2 expression in osteolytic tumor cells is regulated by a number of factors independent of Hh signaling, such as transforming growth factor-β (TGF-β) [28]. Gli2 was found to be necessary for TFG-β stimulation of PTHrP mRNA expression and is therefore an excellent target in blocking osteolysis. Gli2 blockade has indeed been successful in blocking osteolytic bone destruction in a genetic model [28], and studies are underway to inhibit Gli proteins through small molecules, such as the GANT compounds [29] and *E. agallocha* extracts from Japanese herbals [30].

PTHrP remains the most well studied of the osteolytic factors produced by bone metastatic tumor cells, but there are other molecules that contribute significantly to tumor-induced bone destruction, such as RANKL, IL—8, Runx2, and MMPs. Interleukin—8 (IL—8) has been shown to correlate with increased bone metastases in human breast cancer cells [31] and stimulate osteoclastogenesis independent of osteoprotegerin (OPG) [32] and RANKL [33]. Runx2, which is required for normal bone formation, is elevated in breast and prostate tumors and cells that metastasize to bone; inhibition of Runx2 in breast tumor cells inhibits tumor-induced bone destruction [34]. This inhibition is in part due to alterations in MMP-9 signaling, which is downstream of Runx2, and is important for tumor cell invasive properties [35]. There is also evidence to support significant involvement of MMPs in regulating tumor–bone interactions. For example, MMP-7 has been shown to enhance osteolysis through solubilization of osteoblast-derived RANKL in the PC3 prostate cancer model of bone destruction [36] and was recently found to play a similar role in breast tumor-induced osteolysis [37].

MOLECULAR MECHANISMS OF BONE METASTASIS (OSTEOBLASTIC)

Some cancers such as prostate, and less frequently breast, induce osteoblastic metastases upon establishment in bone. The mechanism driving the formation of osteoblastic lesions is unclear, but bone resorptive markers are often elevated in these patients, suggesting that osteoclast activation may still be necessary. Similar to patients with primarily osteolytic bone metastases, prostate cancer patients frequently present with mixed lesions throughout the skeleton. It is believed that at least in some cases, osteoblastic metastases begin with a heavy resorption component then switch to blastic lesions. This is further supported by the successful use of bisphosphonates, which inhibit osteoclast activity, in the treatment of prostatic bone metastases and associated bone pain [38].

The molecular mechanisms that stimulate bone formation in osteoblastic metastases remain largely undiscovered, but there is evidence to suggest that endothelin-1 (ET-1) and the Wnt signaling pathway make significant contributions. Dikkopf—1 (Dkk-1) is a downstream target and inhibitor of the Wnt signaling pathway, and has been shown to inhibit prostate tumor-induced osteoblastic metastases when overexpressed in prostatic tumor cells by inhibiting transcription factor 4 (TCF-4) activity in osteoblast precursors [39]; conversely, Dkk—1 has been identified as a mediator of tumor-derived ET-1-induced bone formation [40], suggesting an autocrine loop, whereby Dkk-1 and ET-1 upregulate one another. Differences here may be attributable to cell-line specificity, since Thudi et al. utilized ACE-1 prostate tumor cells, and Clines et al. did not test this model in tumor cells. More data are needed to determine the extent of ET-1 regulation of Wnt signaling.

TUMOR MICROENVIRONMENT REGULATION OF BONE DISEASE

Although certain tumor types rely heavily on autocrine signaling, they are not as autonomous as once thought. In recent years, increasing emphasis has been placed on tumor microenvironment influence on tumor cell behavior and the interactions between tumor cells and the stroma in particular. It has become evident that the microenvironment plays a tremendous role in both promoting and hindering tumor progression at different sites of the disease. While the host microenvironment significantly impacts tumor cell evolution, cancer cells may also influence host cells at the site of metastasis in addition to systemic alterations. This is particularly evident in the vicious cycle of bone destruction, which requires extensive interactions and complex signaling between tumor cells, bone, and the bone marrow stroma. While there are numerous interactions occurring within the bone microenvironment, some of the microenvironmental factors that have been identified as significant mediators of tumor–host interactions thus far include matrix stiffness, the reactive stroma surrounding the tumor, TGF-β, Wnt signaling, and Ephrins.

The extracellular matrix (ECM) has long been thought of as a structural scaffold on which tumor cells could rely on for support, but there is now substantial evidence to suggest that breast tumor cells modify their behavior in response to ECM signaling and the changing stiffness of the ECM at the primary site [41]. In the primary site of breast cancer, tumor progression has been connected with increased collagen cross-linking as well as integrin activation [42], and more recently we have shown that the rigidity of bone modulates tumor cell gene expression in a Rho-associated protein kinase (ROCK)-dependent mechanism [43]. The response of tumor cells to the phys-

ical microenvironment is complex and still actively being explored.

Much of the signaling that modulates tumor cell behavior in bone originates from the surrounding stroma. The contribution of the reactive stroma in tumor cell evolution has been well established, particularly in prostate cancer through studies conducted by the Cunha and Hayward groups [44, 45], but the impact of bone stroma on tumor cell behavior is becoming appreciated. Most of the published data support a significant role for bone-derived growth factors and chemokines (e.g., TGF-β, SDF-1/CXCR4) [9, 46, 47], and an emerging role for immune cells such as myeloid derived suppressor cells (MDSCs). It is well established that stromal-derived factor-1 (SDF-1/CXCL12) is involved in tumor cell homing to bone [48], where it has been shown that bone metastatic breast cancer cells express elevated levels of the SDF-1 receptor CXCR4 [49, 50], and conditioned media from primary human bone marrow contains CXCL12 [50], which presumably promotes metastasis to bone. Indeed, tumor cell migration can be blocked when the CXCR4/CXCL12 interactions are blocked by a neutralizing antibody against CXCR4 [50].

TGF-β signaling is known to regulate such cell autonomous events as proliferation, migration, apoptosis, and tumor invasion [51], and has been shown to directly promote tumor cell growth in bone following release from the mineralized bone matrix [2]. Interestingly, these same processes are controlled during development in part by the Wnt signaling pathway [52], which has been identified as an important stromal component in metastatic prostate cancer [53]. Convergence of TGF-β and Wnt signaling has been repeatedly demonstrated at the transcriptional level on the Gli proteins, which are downstream of the Hh signaling pathway. Previous reports have indicated that Wnt signaling can both regulate and be regulated by Gli proteins [54], although most publications place Hh signaling upstream of Wnt during development [55, 56]. Likewise, Hh and TGF-β signaling have been reported to crosstalk [51], and our group, as well as others, has reported that Gli2 transcription is regulated at least in part by TGF-β signaling through Smads [28, 57], suggesting the importance of this crosstalk for regulating bone destruction.

More recently, Ephrin/Eph signaling has been identified as an important mediator in tumor promotion and angiogenesis, and preclinical studies have shown the soluble EphB4 and EphB4 neutralizing antibody to be efficacious treatment in breast and prostate solid tumors [58, 59]; however, disruption of the Ephrin/Eph family signaling results in skeletal abnormalities and increased bone resorption [60–62]. Further studies are needed to determine whether blockade of Ephrin/Eph signaling is detrimental in patients with potential bone metastatic disease, but it remains possible that Ephrin/Eph signaling, similar to TGF-β, may play a biphasic role in tumor metastasis.

Immune cells such as MDSCs have been implicated in tumor promotion and metastasis to distant organs [10], and more recently these cells have been suspected to play a key role in tumor metastasis to bone [63]. For example, it has been previously demonstrated that Gr-1$^+$ CD11b$^+$ MDSCs are capable of differentiating into osteoclasts in the 5T model of multiple myeloma [63], but further studies are needed to determine if this same potential exists in solid tumor metastasis to bone. More recent data examining CD8+ T cells in breast tumor metastasis to bone suggest that immune cells influence tumor cell metastasis independent of tumor effects on bone, specifically showing that osteoclast activation of T cells reduces tumor burden but increases osteolysis [64]. As indicated by Fowler et al., the B-cell population may be an important factor in the development of myeloma, since RAG—2 mice that lack B cells develop 5T myeloma while nude mice do not [65]; however, it was also suggested that the elevated natural killer cell population in nude mice may contribute to this phenomenon. More studies are required to determine if these cell populations are significant in solid tumor metastases to bone, but the evidence on MDSCs and T cells is compelling.

CURRENT PROMISING CLINICAL TARGETS

Despite decades of research focusing on the treatment of bone metastases, they remain incurable. Bisphosphonates are currently the clinical standard of care for treating patients with bone metastases and have been highly effective in patients to reduce fractures and improve quality of life [66]. However, they are not a permanent cure and are not without risk. Severe side effects are rare but include severe muscle pain and osteonecrosis of the jaw and atypical subtrochanteric fractures in patients with long-term high-dose treatments [67–69]. Because of these risks, newer drugs are currently of great interest. The emerging drug for clinical use, denosumab or XGEVA™ (Amgen), which targets RANKL, has been demonstrated to reduce bone turnover and increase bone density in clinical studies [70]. Interestingly, this drug seems to have the capability of inhibiting tumor growth, which may be an indirect effect [71]. However, XGEVA™ also presents safety risks, including hypocalcemia and osteonecrosis of the jaw, though the prevalence is unclear due to limited clinical data [67]. Despite the clinical success of these drugs, they may not target the tumor, and therefore do not address the root of the disease and are not a cure for tumors growing in the bone. Other groups are investigating drugs that can target the tumor cells directly.

One such approach is by inhibiting TGF-β. TGF-β is thought to affect both the tumor cells and the microenvironment, suggesting that an inhibitor of this pathway may be able to block bone destruction through multiple targets. Thus far, TGF-β inhibitors have been very successful with several groups, demonstrating that they can inhibit metastasis to soft tissues [72, 73] and bone [74]. In addition to direct effects on the tumor, they appear to

have positive effects on bone in non-tumor-bearing mice. It has been reported by two independent groups that TGF-β inhibitors 1D11 (Genzyme, Cambridge, MA) and SD-208 (Scios, Inc., Sunnyvale, CA) increase bone density and biomechanical properties as well as numerous measures of bone quality (e.g., trabecular bone architecture and the mineral:collagen ratio) [75, 76]. These studies also demonstrate an increase in osteoblast number and a decrease in osteoclast number in the bone marrow of healthy mice. Taken together, these data suggest that TGF-β inhibitors may be ideal drugs for bone metastases, since they can both inhibit tumor growth and improve bone quality. Despite their promise in preclinical models, their use may be complicated in patients due to the biphasic effects of TGF-β in tumor growth and its effects throughout the body on normal cells [77], with particular concerns in patients with residual primary tumor or multiple metastases.

It is clear that more specific drugs are needed to target tumors growing in bone. Some potential pathways are being studied by multiple groups to block metastasis and establishment in bone through inhibition of integrins [78], SDF-1/CXCR4 [79], and ROCK [43, 80]. Other groups have specifically targeted certain cell types, such as inhibiting osteoclasts using Src inhibitors [81, 82] and stimulating osteoblasts using DKK-1 inhibitors, while still others are investigating inhibitors of the tumors themselves. Some current promising approaches include the histone deacetylase inhibitor vorinostat, which inhibits tumor growth in bone but can stimulate bone loss [83], suggesting possible combination treatments to protect bone. Erlotinib, an inhibitor against epidermal growth factor receptor (EGF-R) tyrosine kinase, has been successfully tested in a preclinical model of non-small-cell lung cancer metastasis to bone and effectively inhibited release of osteolytic factors such as PTHrP and IL—8 [84]. In our studies and others', inhibiting the transcription factor GLI2 appears promising in melanoma [85] and breast cancer metastasis [15, 28]. Inhibitors to this pathway are currently under investigation in preclinical models of prostate cancer; they are promising for treatment of primary tumor burden [29]. For bone they are an attractive target since GLI2 has limited expression in adult tissues, suggesting minimal side effects.

Hematologic Malignancies and Bone

Rebecca Silbermann and G. David Roodman

Introduction 694
Hematologic Malignancies Involving Bone 694
Summary 698
References 698

INTRODUCTION

Hematologic malignancies can have multiple direct and indirect effects on bone including pathologic fractures, bone pain, and hypercalcemia. The frequency of bone involvement in association with these malignancies varies widely depending on the underlying diagnosis. Bone involvement in multiple myeloma occurs in nearly 80% of patients over their disease course [1], and significantly impacts quality of life, morbidity, performance status, and survival [2]. Skeletal complications in the much rarer human T-lymphotropic virus type 1(HTLV-1) associated adult T-cell leukemia and lymphoma, the second most common hematologic malignancy to affect the bone, most frequently manifest as hypercalcemia, which affects approximately 70% of patients over the course of their disease [3]. In contrast, bone involvement from Hodgkin's disease and non-Hodgkin's lymphoma is rare. Under normal conditions, interactions between bone resorbing cells [osteoclasts (OCL)] and bone forming cells [osteoblasts (OBL)] are balanced, allowing for coupled bone remodeling and normal hematopoiesis. Dysregulation of the normal bone remodeling process can occur in the setting of malignancy, resulting in either osteolytic, osteoblastic, or mixed osteolytic/osteoblastic lesions. In addition, increased production of parathyroid hormone-related protein (PTHrP) by tumor cells can increase osteoclastic bone resorption, resulting in increased renal tubular calcium resorption. This impairs glomerular filtration and can result in hypercalcemia.

This review will discuss the pathophysiology of skeletal lesions in hematologic malignancies, with a focus on the current understanding of their associated bone disease, and includes brief discussions of radiologic imaging of skeletal lesions, pharmacologic treatments, and other hematologic malignancies that affect the bone.

HEMATOLOGIC MALIGNANCIES INVOLVING BONE

Multiple myeloma

Multiple myeloma (MM) is a plasma cell malignancy characterized by monoclonal paraprotein production from terminally differentiated plasma cells and lytic bone disease [4]. Laboratory findings include an elevated monoclonal paraprotein in the serum and/or urine and decreased normal immunoglobulin (Ig) levels. Expansion of the plasma cell population in the bone marrow leads to leukopenia, anemia, and thrombocytopenia.

MM has the highest incidence of bone involvement among malignant diseases and is the second most common hematologic malignancy, accounting for approximately 15% of all hematologic malignancies. The age-adjusted incidence of myeloma in Western countries is 5.6 cases per 100,000 persons [5]. Approximately 60% of patients present with bone pain at diagnosis, 80% of patients develop bone lesions during their disease course, and up to 60% of patients develop pathologic fractures [6].

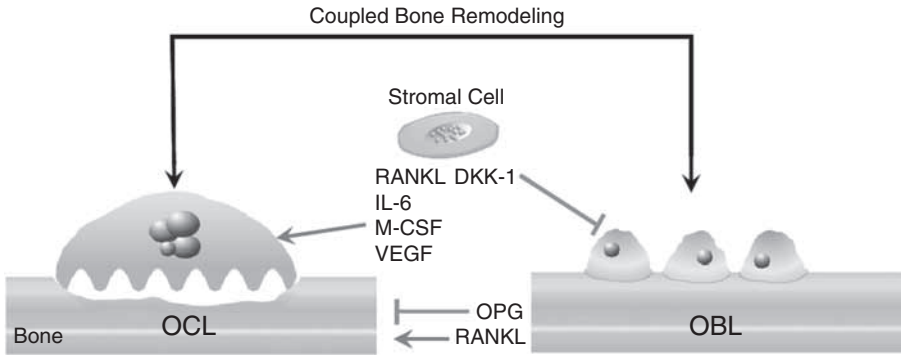

Fig. 84.1. Balanced physiologic bone remodeling. Physiologic bone remodeling is marked by balanced interactions between osteoclasts (OCL) and osteoblasts (OBL) within the bone marrow microenvironment. Locally produced cytokines and systemic hormones regulate the formation and activation of OCL. Systemic hormones (not pictured) stimulate OCL formation by inducing the expression of receptor activator of nuclear factor-κB ligand (RANKL) on marrow stromal cells and OBL. Stromal cells also produce OCL-stimulating factors including interleukin-6, macrophage colony-stimulating factor (M-CSF) and vascular endothelial growth factor (VEGF) that induce OCL formation. In addition, stromal cells produce dickkopf (DKK)-1, an OBL inhibitory factor. Coupling factors produced by OCL such as ephrins (not shown), also drive OBL differentiation while suppressing further OCL formation and activity. OBLs produce osteoprotegerin (OPG), a soluble RANKL inhibitor. Under physiologic conditions, OBL and OCL activity is balanced, in part due to the OPG/RANKL ratio. In myeloma bone disease, osteoclastogenesis is favored and osteoblastogenesis is inhibited.

While the clinical presentation of myeloma is quite variable, with approximately 20% of patients asymptomatic at presentation (disease in these patients is generally identified through routine lab studies), bone pain is the most common symptom at presentation. Bone pain, frequently centered on the chest or back and exacerbated by movement, is present in more than two-thirds of patients at diagnosis [7].

It is estimated that up to 90% of patients with myeloma have evidence of osteolysis in the form of generalized osteopenia or discrete lytic lesions [8]. In contrast to other tumors that involve bone, myeloma is rarely associated with osteosclerotic lesions except in POEMS syndrome (**P**olyneuropathy, **O**rganomegaly, **E**ndocrinopathy, **M**onoclonal Gammopathy and **S**kin changes), a multisystemic disease occurring rarely in the setting of plasma cell dyscrasias [9]. Skeletal manifestations, particularly osteolytic bone lesions, represent the most prominent source of pain and disability in MM. Bone pain occurs in 60–70% of patients and pathologic fractures in 60% of myeloma patients [10, 11]. Osteolytic lesions most often involve the axial skeleton, skull and femur. In addition, lytic lesions rarely heal, even when complete remission is attained.

Fifteen to 20% of newly diagnosed myeloma patients have hypercalcemia (defined as a corrected serum calcium level greater than 11.5 mg/dL) due to increased bone resorption, decreased bone formation, and impaired renal function, all of which are often exacerbated by immobility. Unlike other malignancies resulting in metastatic disease to the bone, PTHrP is rarely overproduced by myeloma cells. The severity of hypercalcemia in patients with myeloma is not correlated with serum PTHrP levels and instead reflects tumor burden [7]. Symptomatic hypercalcemia can result in anorexia, nausea, vomiting, confusion, fatigue, constipation, renal stones, depression, and polyuria, and is suggestive of a high tumor burden.

The bone marrow (BM) microenvironment in MM also contributes to tumor growth and the bone destructive process. It comprises cellular and extracellular elements including OBLs, OCLs, endothelial cells, immune cells, and MM cells. Interactions between MM cells and their BM microenvironment are tightly regulated. Under normal physiologic conditions, balanced interactions within the BM microenvironment result in coupled bone remodeling (Fig. 84.1). In MM, bone remodeling is uncoupled in the BM microenvironment and is characterized by generalized OCL activation and suppressed OBL function with decreased bone formation. Bone marrow biopsies from MM patients demonstrate a correlation between tumor burden, OCL number, and resorptive surface [1, 12].

MM cells produce or induce multiple osteoclastogenic factors in the bone marrow microenvironment that directly increase OCL formation and activity, and decrease production of osteoprotegerin (OPG), a soluble decoy receptor for receptor activator of nuclear factor-κB ligand (RANKL), a critical differentiation factor for OCLs produced by marrow stromal cells and OBL [13]. Myeloma cells adhere to bone marrow stromal cells via binding of surface VLA-4 ($\alpha_4\beta_1$ integrin) to VCAM-1 expressed on stromal cells, resulting in production of osteoclastogenic cytokines such as RANKL, macrophage colony-stimulating factor (M-CSF), interleukin-11, and interleukin-6 by marrow stromal cells and osteoclastogenic cytokines including macrophage inflammatory protein-1α (MIP-1α) and interleukin-3 by MM cells [14–17]. RANKL increases OCL formation and survival by

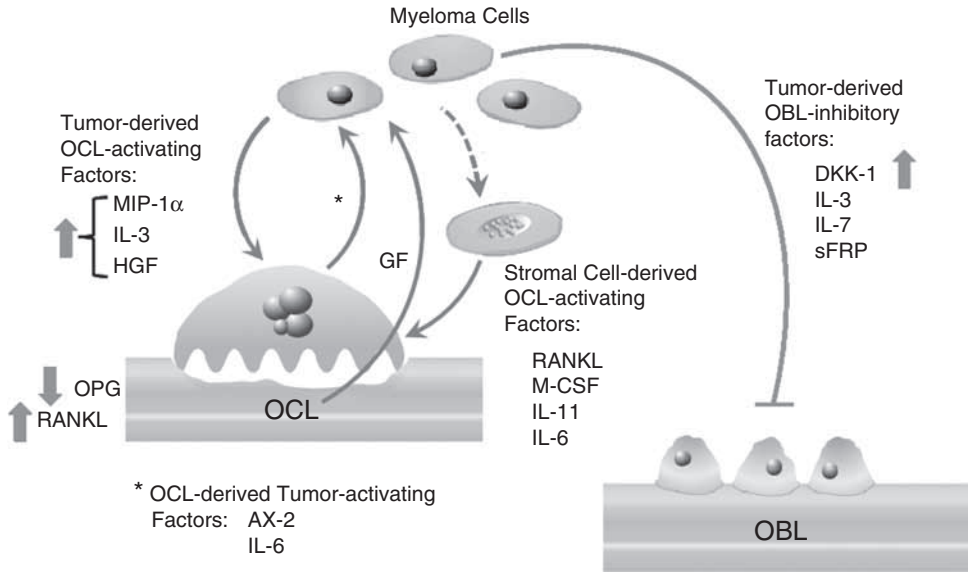

Fig. 84.2. The vicious cycle of myeloma bone disease. Myeloma cells produce factors that directly or indirectly activate osteoclasts, such as MIP-1α, IL-3, and hepatocyte growth factor (HGF). Myeloma cells also induce RANKL and IL-6 production by marrow stromal cells to enhance OCL formation. OCLs in turn produce soluble factors such as annexin II (AXII) and IL-6 that stimulate tumor growth. The bone destructive process also releases growth factors that increase the growth of myeloma cells, further exacerbating the osteolytic process, resulting in a "vicious cycle" of bone destruction. OBL differentiation is suppressed by tumor-derived OBL-inhibitory factors such as DKK-1, IL-3, IL-7, and the secreted frizzled-related proteins (sFRPs). In addition, the RANKL/OPG ratio is increased, promoting OCL development. DKK-1, MIP-1α, and RANKL levels are all increased in myeloma bone disease as compared with the physiologic state.

binding to its receptor RANK on OCL precursor cells and OCL [18], while MIP-1α acts as a chemotactic factor for OCL precursors and can induce differentiation of OCL progenitors contributing to OCL formation [19–21]. MIP-1α also directly promotes the growth, survival and migration of MM cells by inducing the activation of multiple signaling pathways crucial for MM cell growth and survival [22]. Further, the bone destructive process releases growth factors from the bone matrix that increase the proliferation of MM cells. This results in a "vicious cycle," of bone destruction, leading to increased tumor mass and further bone destruction (Fig. 84.2).

While OCLs are activated in MM, OBL activity is suppressed, with decreased bone formation and calcification despite increased bone resorption [1, 23]. As a result, serum alkaline phosphatase and osteocalcin are normal or decreased in patients with myeloma bone involvement. Co-culture experiments have demonstrated reduced myeloma cell proliferation in the presence of OBLs as compared with OCL or marrow stromal cells [24], a finding that has been confirmed in murine models of myeloma bone disease [25].

OBLs also affect myeloma cell growth indirectly via their regulation of OCLs. OBLs secrete RANKL, an OCL differentiation factor, as well as the soluble RANKL inhibitor, OPG. The balance between RANKL and OPG regulates osteoclastogenesis. In myeloma the RANKL/OPG ratio is typically increased, promoting OCL development [26, 27].

Other mechanisms of OBL suppression under investigation include downregulation of the osteogenic transcription factor runt-related transcription factor 2 (RUNX2) via direct cell-to-cell contact between MM and OB progenitor cells [28]; Wnt signaling inhibitors such as dickkopf-1 (DKK-1), soluble frizzled receptor-like protein 3 (sFRP3), and sclerostin that inhibit osteogenesis [29–31]; and modulation of OB differentiation by transforming growth factor-β (TGF-β) superfamily members including bone morphogenic protein 2 (BMP2) [32], activin A[33], and TGF-β itself [34]. DKK-1 is of particular interest as it is highly expressed in the BM of MM patients with bone lesions, appears to be involved in early bone disease, and has roles in the regulation of both OCL and OBL function [35, 36].

At this time, conventional radiography is the gold standard for evaluation of bone disease in myeloma patients. Magnetic resonance imaging (MRI) is also effective in identification of lytic lesions and is indicated for staging in patients with solitary plasmacytoma of the bone [37]. Traditional technetium bone scintigraphy scans underestimate the extent of bone disease and are thus not recommended in patients with MM [38]. The utility of F18-fluorodeoxyglucose positron emission tomography/computed tomography (FDG-PET/CT) has been evalu-

ated in MM and has a sensitivity of approximately 85% and a specificity of approximately 90% [39]. Several studies have recently combined FDG-PET/CT and MRI of the spine and pelvis for detection of active MM. In cases where the findings from the two studies are concordant, the ability to detect sites of active disease was greater than 90% [37].

Management of MM bone disease

Bisphosphonates remain the standard of care for MM-related bone disease at this time. Bisphosphonates are potent inhibitors of osteoclast activity, and intravenous bisphosphonates given every 3 to 4 weeks are the current treatment of choice for management of pain related to bone disease and the prevention of skeletal-related events. Oral clodronate treatment has been shown to reduce the development of osteolytic lesions, fractures, hypercalcemia, and bone pain in MM [40]. The recently published Medical Research Council (MRC) IX trial demonstrated that intravenous zoledronic acid reduced the incidence of skeletal-related events (SREs) (hypercalcemia, new bone lesions, and fractures) as compared with oral clodronate in patients with newly diagnosed MM [41]. In addition, patients treated with zoledronic acid had improved disease response rates and overall survival after a median follow-up of 3.7 years, compared with patients treated with clodronate. This suggests that bisphosphonates have a direct anti-myeloma effect, a hypothesis supported by *in vitro* data [42].

Denosumab, a human monoclonal antibody that binds to RANKL with high affinity and specificity, was approved by the FDA for prevention of SREs in patients with bone metastases from solid tumors in 2010 and is currently under investigation for use in MM bone disease. A recent clinical trial has demonstrated that denosumab inhibits bone resorption and prevents SREs in patients refractory to bisphosphonate therapy [43, 44].

Bortezomib, a proteasome inhibitor active against MM, directly alters osteoblast and osteoclast activity by decreasing RANKL and DKK-1 levels in the sera of myeloma patients [45, 46]. In clinical studies of both newly diagnosed and relapsed myeloma patients, bortezomib therapy, either alone or in combination with other agents, demonstrated improvement in markers of osteoblastic activity and osteoclast inhibition [46–49]. Bortezomib's effects on osteoblast differentiation have been extensively studied. Several clinical trials showed increased bone specific alkaline phosphatase, a marker for osteoblast activation, in myeloma patients whose tumor responded to the drug [49, 50]. Some authors have interpreted these findings as evidence that bortezomib directly stimulates osteoblasts and inhibits osteoclasts. Others have suggested that biochemical markers of bone formation peak after 6 weeks of bortezomib treatment due to a direct inhibitory effect on bone resorption by osteoclasts that counteract bortezomib's initial direct osteoblast stimulatory effect [51]. Alternatively, bortezomib's direct inhibition of myeloma cells in the bone marrow microenvironment allows for normalization of osteoblast and osteoclast function, as these effects are only seen in patients whose myeloma responds to bortezomib treatment.

Other hematologic malignancies

Adult T-Cell leukemia/lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a malignancy of CD4+ T cells caused by infection with human T-lymphotropic virus type 1(HTLV-1). ATLL was initially reported in southern Japan and has been reported sporadically in areas where HTLV-1 infection is rare, including the United States. The additive lifetime risk of developing ATLL among HTLV-1 carriers varies depending on the population surveyed, but it has been reported to range between 1% and 5% in Japan and Jamaica [52]. Approximately 70% of ATLL patients develop hypercalcemia, and many of these patients also develop lytic bone lesions [3]. In contrast to the hypercalcemia that typically develops in myeloma patients, PTHrP mediates the hypercalcemia associated with ATLL. It is hypothesized that the HTLV-1 and HTLV-II tax proteins transactivate PTHrP via the cellular transcription factors activator protein (AP)-2 and AP-1, a novel mechanism of transactivation [53, 54]. However, increased transcription of PTHrP can also occur in a tax-independent manner [55]. In addition, MIP-1α has been proposed as a mediator for the hypercalcemia in ATLL, by enhancing OCL formation and inducing RANKL expression on ATLL cells in an autocrine fashion [56]. Increased RANKL expression has been noted in ATLL cells in patients with hypercalcemia [57].

ATLL cells produce chemokines that affect bone remodeling, including IL-1, IL-6, tumor necrosis factor-α (TNF-α), and MIP-1α/MIP-1β. Circulating ATLL cells infiltrate a variety of tissues, mediated by MIP-1α induction of integrin-mediated adhesion to the endothelium and subsequent transmigration [53]. As in myeloma, MIP-1α in ATLL is important for the chemotaxis of monocytes, including OCL progenitor cells, and the production of the osteoclastogenic factors IL-6, PTHrP, and RANKL by osteoblasts or stromal cells [58, 59]. In addition, IL-1 and PTHrP have also been reported to mediate bone destruction in ATLL, with elevated PTHrP levels in patients and increased concentrations of IL-1 and PTHrP in media conditioned by ATLL cells *in vitro* [60].

Bone involvement has also been infrequently reported in more classical forms of acute lymphoid leukemia and is thought to be similarly mediated by PTHrP production by malignant cells [61].

Non-Hodgkin's lymphoma

Bone involvement with non-Hodgkin's lymphoma (NHL) is rare. Less than 10% of NHL patients present with bone involvement; however, 7–25% of all patients with NHL eventually develop bone findings during the

course of their disease. The most common histologic subtypes of NHL that present with bone manifestations include histiocytic, undifferentiated, and poorly differentiated NHL. In addition, lytic bone lesions are more often seen in patients with diffuse rather than nodular patterns of lymph node involvement, and frequently involve the axial skeleton [62]. As in ATLL, serum levels of PTHrP are elevated in NHL patients with hypercalcemia [63].

Hodgkin's disease

Bone involvement in Hodgkin's disease (HD) is uncommon and seldom encountered at diagnosis. Sites of involvement include the spine, pelvis, femur, humerus, ribs, sternum, scapula, and base of the skull [64, 65]; however, as with NHL, vertebral and femoral involvement is most common [66]. The most frequent presentation is that of a localized, solitary osteoblastic mass in a patient with mixed cellularity, nodular sclerosing disease [64, 65]. Bone biopsies often show fibrosis and a mixed inflammatory infiltrate with rare atypical cells. Radiologic findings include a vertebral sclerotic pattern along with a periosteal reaction and hypertrophic pulmonary osteoarthropathy [66]. As in NHL, radiographic patterns cannot predict the histologic type or the prognosis of HD and must be used with clinical staging to predict prognosis.

Bone disease in patients with HD can be lytic, blastic, or mixed. Increased new bone formation by tumor cell stimulation of osteoblast activity occurs at sites of previous osteoclastic activity. Hypercalcemia does occur in HD and is associated with excess production of $1,25(OH)_2$ vitamin D_3 or PTHrP by the lymphoma cells [66, 67].

SUMMARY

Dysregulation of physiologic bone remodeling in the setting of malignancy results in osteolytic, osteoblastic, or mixed lesions. PTHrP frequently mediates non-myelomatous bone disease. With the exception of multiple myeloma, bone involvement in hematologic malignancies is rare; however, bone lesions can significantly contribute to patient morbidity and pain. Thus, consideration of the potential consequences of skeletal manifestations of hematologic malignancies is an important component of the care of these patients.

INTRODUCTION

Osteogenic sarcoma (also known as osteosarcoma or OS), a well-defined clinical entity, is the most common primary malignant tumor of bone [1, 2]. Nevertheless, it is a rare disease, and only about 900 new cases are diagnosed annually in the United States, accounting for less than 1% of all cancers [3]. Incidence and survival rates have been recently reported based on a study of 3,482 patients with osteosarcoma from the National Cancer Institute's population-based Surveillance, Epidemiology, and End Results (SEER) Program between 1973 and 2004 [1]. Osteosarcoma affects all ages, but its incidence is bimodal, with the first peak in adolescents (8 per million at age group of 15–19 years) and the second peak in the elderly (6 per million at age group of 75–79 years) and a middle lower plateau (approximately 1–2 per million) among individuals ages 25–59 years [1, 4]. Accordingly, osteosarcoma accounts for 5% of pediatric cancers overall (about 400 new cases each year) [5]. There is a high percentage of osteosarcoma with Paget disease and osteosarcoma as a second or later cancer among the elderly [1, 4]. Males are slightly more affected than females (1.2~1.5 to 1) in all age groups. Although osteosarcoma can arise in any bone, it preferentially affects anatomic sites where rapid bone remodeling occurs such as the metaphyses of long bones (distal femur > proximal tibia > proximal humerus) [6]. In children and adolescents, these anatomical regions account for the majority of primary tumors. However, in the elderly, the distribution of anatomic sites is more variable and can include the axial skeleton and skull [1].

Biopsy is required for the diagnosis of osteosarcoma. There are several different histologic subtypes of osteosarcoma including conventional, telangiectatic, small-cell, high-grade surface, secondary, low-grade central, and periosteal and parosteal [7], but the conventional subtype, the most common in childhood and adolescence (the first peak), comprises about 85% of all cases and also has been subdivided on the basis of the predominant features of the cells (i.e., osteoblastic, chondroblastic, fibroblastic types) [8, 9]. Other subtypes comprise the remaining 15% of cases. The grades and stages of osteosarcoma [4, 9] are summarized in Table 85.1. Approximately 20% of patients will have detectable metastatic disease at the time of initial presentation, with the lungs and bones being the most common sites of metastasis. Treatment consists of surgery to remove the primary tumor and intensive chemotherapy to treat micrometastatic disease. In general, the 5-year survival rate for nonmetastatic disease is about 70% in younger patients aged younger than 25 years and approximately 45% in patients aged 60 and above. Patients with distant metastases have much poorer 5-year survival rates, on the order of 30% or less [1, 4]. Strikingly, there have been no substantial improvements in survival rates for either group of patients over the past several decades. Clearly, new treatment strategies and drugs are needed.

Table 85.1. Summary of Grades and Stages of Osteosarcoma

Stage		Tumor	Metastases	Grade
I	IA	≤8 cm	No	Low
	IB	>8 cm	No	Low
II	IIA	≤8 cm	No	High
	IIB	>8 cm	No	High
III		"Skipped" bone	to other sites in the same	High
IV	IVA	Any size	Only to lung	Any
	IVB	Any size	To other distant sites	Any

Notes: Grades and stages in this table are simplified according to American Joint Committee on Cancer (AJCC) Staging System. Low grade OS includes well and moderately differentiated, whereas high grade includes poorly and undifferentiated and anaplastic lesions. This system is different from a three-stage system (Stage I: low grade; II: high grade; III: metastatic disease), which is applied by the Musculoskeletal Tumor Society Staging (MSTS) System and Enneking System.

The etiology of osteosarcoma remains largely unknown. However, there has been renewed effort in understanding the molecular biology and pathogenesis of osteosarcoma over the past 2 decades [10]. Recent reviews on studies of familial syndromes, specimens, and cell lines derived from human osteosarcoma patients describe the genetic factors and signaling pathways that may be involved in several key processes in the pathogenesis, including initiation, progression, invasion, and metastasis [2, 5, 11–13]. Several genetic factors have been tested as potential diagnostic and prognostic biomarkers of disease as well as potential therapeutic targets. Based on these findings, novel agents have been tested in several molecularly targeted phase 1 clinical trials, which may lead to second-line treatment options for patients with resistant disease and/or with distant metastases [14]. Most recently, genetically engineered osteosarcoma mouse models have been generated in an attempt to recapitulate the human disease [15]. Understanding these models will broaden our knowledge of the molecular basis of osteosarcoma and will also advance preclinical studies for new therapeutic strategies [16]. This chapter updates the current understanding of osteosarcoma biology and reviews these recent findings from animal models.

CHALLENGES IN THE TREATMENTS OF OSTEOSARCOMA

Current standard treatments of osteosarcoma

Surgery and chemotherapy are two essential components of therapy for osteosarcoma. Unlike other sarcomas such as Ewing sarcoma or rhabdomyosarcoma, osteosarcoma is relatively resistant to radiation therapy. The importance of surgery was described as early as 1879 in a study of 165 cases of sarcoma of the long bones [17]. Surgery mainly consisted of amputation of the affected limb. Prior to the 1970s, before the introduction of chemotherapy for the treatment of osteosarcoma, when amputation was the sole effective treatment, the 5-year survival rates were only 10–20% [8]. Most patients developed distant metastatic disease postoperatively, most often to the lungs, despite complete removal of the tumor [9]. Thus, although only 20% of patients initially present with clinically detectable metastatic disease, as seen by modern imaging technologies, including computerized tomography, bone scintigraphy, and magnetic resonance imaging, virtually all patients already have undetectable micrometastases at the time of diagnosis [8]. After the introduction of adjuvant (postoperative) chemotherapy in the 1970s in addition to surgery, the survival rates increased dramatically, thus establishing the critical role of chemotherapy in the treatment of osteosarcoma [18, 19].

The most effective chemotherapeutic agents currently used to treat osteosarcoma include doxorubicin (or adriamycin), methotrexate, cisplatin, and ifosfamide. In the late 1970s, the concept of neoadjuvant (preoperative) chemotherapy was introduced, which offered several advantages such as early eradication of micrometastases, shrinkage of the bulk of the tumor (making surgery more feasible), and, importantly, the ability to determine the degree of tumor necrosis at the time of definitive resection [20]. The percentage of tumor necrosis (or histologic response) has been found to be a prognostic factor, with greater than 90% tumor necrosis being considered a good response and favorable prognostic factor [9]. In addition to assessment of histologic response, administration of neoadjuvant chemotherapy allows time for the orthopedic surgeon to plan for limb salvage surgery [8]. Other agents that have shown to have some response in osteosarcoma include cyclophosphamide, vincristine, melphalan, decarbazine, bleomycin, dactinomycin, and actinomycin, but their effects are more controversial since the 5-year survival rates in the past 2 decades have not significantly improved by adding them into the standard regimens [8, 21].

While chemotherapy has been important for survival in osteosarcoma, surgery is still a mainstay of therapy and is essential for survival [22]. Complete resection of tumors is difficult in some cases depending on the tumor location, for example, in the spine and pelvic bones, where complete resection is often difficult and the risk of local recurrence is high. A dismal outcome was reported for those patients with pelvic osteosarcoma where the 5-year survival rate was only about 19% [23, 24]. A major challenge is curing patients who are not eligible for metastasectomy; in those cases, less effective radiotherapy and palliative chemotherapy can be applied in the treatments [8]. Thus, despite improvements in survival from use of intensive chemotherapy and surgical regimens, there is a continued need for new therapeutic approaches.

Limitations of current standard treatments

Despite the success of current treatments, about 40% of all patients still relapse, mostly within 2 years, and half

of them die in less than 5 years [2, 8]. This is attributable in large part to chemoresistance of tumor cells, which is a major challenge to current therapies. Another limitation to current treatment regimens is the toxicity associated with chemotherapy. Chemotherapeutic drugs kill not only tumor cells but normal tissues as well, causing major renal, hematologic, and cardiac toxicities [2]. Some of these toxicities occur during administration of the drugs, while others, such as cardiotoxicity from doxorubicin, can occur many years later. The recent Childhood Cancer Survivor Study (CCSS) performed on 733 long-term survivors (more than 5 years) of childhood cancer with a mean follow-up of 21.6 years, showed that 86.9% of osteosarcoma survivors experienced at least one chronic medical condition such as tinnitus and deafness. More than 50% of them experienced adverse health effects such as physical limitation, pain, and anxiety. Prospective evaluation of survivors will be important to assess both acute and long-term effects of current treatments and their impact on survivorship [25]. Another potential late effect of chemotherapy is secondary malignancy, particularly with alkylating agents such as ifosfamide. The majority of secondary malignant neoplasms such as breast, thyroid, and gastrointestinal cancers occurred around 10 years from diagnosis, and their incidence is 3–5% [25, 26].

Given the problems of chemoresistance, organ toxicity, and secondary malignancies associated with medical treatment for osteosarcoma, researchers have investigated other therapeutic avenues. Two recent pilot clinical trials have reported a modest increase of 6-year overall survival rate from 70% to 78% by the addition of the immune-enhancing drug muramyl tripeptide and an increase of 5-year overall survival rate up to 93% in treatments of localized disease with addition of the anti-osteoclast drug pamidronate to the standard 3-drug regimen [21, 27]. Another approach for the treatment of osteosarcoma in addition to novel drugs is the use of immunotherapy to eradicate tumor cells that express specific antigens recognized by the host immune system. A recent preclinical immunotherapy study showed that genetically modified T cells can recognize low levels of tumor antigen expression of Her2 and kill osteosarcoma cells [28]. However, further investigation is warranted before these new therapies can become incorporated into standard treatments.

UNDERSTANDING OF GENETIC FACTORS AND PATHWAYS THAT CAUSE HUMAN OSTEOSARCOMA

Mutations in familial syndromes

Germline mutations in *p53*, *Rb*, *RECQL4*, and *REQCL2* genes cause Li-Fraumeni, hereditary retinoblastoma, Rothmund-Thomson, and Werner syndromes, respectively, and all of these syndromes are predisposed to osteosarcoma [5]. Li-Fraumeni syndrome displays a wide spectrum of cancers, including breast, adrenocortical, brain tumors, leukemias, and osteosarcomas. P53 protein regulates cell cycle, DNA repair, and apoptosis. More than 50% of sporadic OS cases contain p53 gene mutations (point, missense, rearrangement, allelic loss) [10]. Inactivation of p53 in mice leads to osteosarcoma [29]. Along with p53, Rb protein is also a well-defined tumor suppressor in the pathogenesis of osteosarcoma [10]. Rb protein regulates the G1/S transition. About 70% of sporadic OS cases contain a genetic alteration of Rb, but few point mutations have been found. The inactivation of Rb alone in mice does not cause osteosarcoma, so it is likely that Rb is an enhancer during osteosarcomagenesis [15]. RECQL proteins have a role in maintaining genomic integrity. While less is known about the direct role of these proteins in osteosarcomagenesis, Rothmund-Thomson syndrome patients with *RECQL4* mutations have an extremely high rate of osteosarcoma as well as skeletal dysplasias [5].

Alterations of tumor suppressors in osteosarcoma

In the p53 pathway, p53 directly activates p21, a cyclin-dependent kinase (CDK) inhibitor that inhibits the activity of cyclin D-CDK4/6 or cyclin E-CDK2, thereby decreasing Rb phosphorylation, which leads to cell cycle arrest in the G1 phase [5]. P53 protein is degraded by the proteasome after binding with MDM2, an E3 ubiquitin ligase, which is negatively regulated by $p14^{ARF}$; therefore, $p14^{ARF}$ acts as a tumor suppressor. In the Rb pathway, a complex of cyclin D1 and CDK4/6, which is inhibited by $p16^{INK4a}$, phosphorylates Rb followed by inhibition of E2F, a transcription factor that promotes DNA synthesis and cell cycle transition from G1 to S. The $p16^{INK4a}$ protein also serves as a tumor suppressor. The $p16^{INK4a}$ and $p14^{ARF}$ proteins are encoded by the INK4a/ARF locus (also called CDKN2a) located on chromosome 9p21. All genes in the p53 and Rb pathways have been frequently found to be either deleted, amplified, or mutated in sporadic osteosarcoma tumors [11]. Therefore, alterations in any of the genes in these tumor suppressor pathways may contribute to osteosarcoma tumorigenesis.

Activation of oncogenes in osteosarcoma

Several oncogenes have been associated with developing osteosarcoma [5, 11]. They include *c-MYC*, *c-FOS*, *SAS*, *GLI*, *MET*, and *ERBB2*. Since MDM2, cyclin D1 and CDK4 can inhibit p53 and Rb tumor suppressor pathways, they possibly play oncogenic roles during development and progression of osteosarcoma. The nuclear transcription factor c-MYC regulates DNA replication and cell growth. JUN and c-FOS form a heterodimeric transcription complex constituting AP1 that regulates genes involved in cell growth, differentiation, transfor-

mation, and bone metabolism [30]. The c-MYC locus has been reported to be amplified up to 12% of osteosarcoma tumors. Hitherto, overexpression of either c-MYC or c-FOS in transgenic mouse models resulted in osteosarcoma development, suggesting their potential role in tumor initiation [31, 32]. However, whether any of these proteins alone can cause osteosarcoma is not yet certain.

Cytogenetic alterations

Cytogenetic abnormalities highlight the inherent complexity and instability of osteosarcomas. About 70% of OS tumors display a multitude of cytogenetic abnormalities, which vary between individuals [5]. Haploidy and up to near-hexaploidy have been found in osteosarcomas. Rearrangements can involve 1p11–p13, 1q11–q12, 1q21–q22, 11p14–p15, 14p11–p13, 15p11–p13, 17p, and 19q13. The gain of chromosome 1 and the loss of chromosomes 9, 10, 13, and 17 are most common overall. Less frequently involved chromosomal regions are 13q14 (locus of RB1), 12p12–pter (locus of KRAS), 6q11–q4, and 8p23 [30]. The most frequently detected amplifications include chromosomal regions 6p12–p21 (28%), 17p11.2 (32%), and 12q13–q14 (8%). Several other recurrent chromosomal losses (2q, 3p, 9, 10p, 12q, 13q, 14q, 15q, 16, 17p, and 18q) and chromosomal gains (Xp, Xq, 5q, 6p, 8q, 17p, and 20q) have also been identified as well as several recurrent breakpoint clusters and nonrecurrent reciprocal translocations. Identification of specific chromosomal regions perturbed in osteosarcoma will allow future detailed investigations of the affected regions for potential candidate genes that may play a role in the pathogenesis of osteosarcoma.

Altered signaling pathways contributing to the osteosarcomagenesis

Recently, several evolutionally conserved signaling pathways have been linked with the pathogenesis of osteosarcoma. They include Wnt (wingless-type MMTV integration site), Notch, TGF/BMPs (transforming growth factor/bone morphogenetic proteins), Shh (Sonic hedgehog) and GFs (growth factors) pathways. Thus far, the Wnt and Notch pathways have been the most extensively studied. Aberrant activation of Wnt signaling is associated with many common cancers in human patients [30]. Elevated levels of cytoplasmic and/or nuclear localized β-catenin, a critical mediator of the canonical Wnt pathway, have been detected in the majority of osteosarcoma tumors, and sporadic mutations of β-catenin have also been identified among the tumors [11]. Ectopic expression of the Wnt antagonist Dkk3 suppresses invasion and motility of osteosarcoma cell lines [33]. Inactivation of Wif1, a secreted Wnt antagonist, increases β-catenin levels and accelerates development of osteosarcomas in mice [34]. Altered Notch signaling has been associated with several human cancers suggesting that Notch can act both as an oncogene and tumor suppressor gene depending on its level and temporal expression [35]. In osteosarcomas, activation of Notch signaling contributes to invasiveness and metastatic potential, and inhibition of this pathway may provide a therapeutic approach for the treatment of osteosarcomas [36–38]. In other signaling pathways such as TGFb1, TGFb2, TGFb3, BMPs, BMPRs, HGF, GLI1, FGFR2, IGF1R, and VEGF, abnormal levels of expression of the various pathway members have been demonstrated in osteosarcoma. Thus far, studies of these pathways in the pathogenesis of osteosarcoma have been limited, and further investigations are warranted.

MicroRNAs and osteosarcoma

Recent studies have shown that microRNAs (miRs) play important roles in tumorigenesis, and several miRs such as miR-34s, miR-140, miR-143, and miR-199 have been found to be dysregulated in osteosarcoma [39–42]. MiRs are non-coding RNAs of 19–25 nucleotides that mediate post-transcriptional silencing of specific target mRNAs. The miR-34 family has been identified as a direct target of p53 by p53-ChiP analysis. MiR-34 shares a similar function as p53 by inducing apoptosis, cell cycle arrest, and senescence. Ectopic expression of miR-34 partially induced cell cycle arrest and apoptosis in OS cell lines [40]. Further analysis of miR-34 genes showed the epigenetic silencing of their promoter in primary OS samples, and the miR-34 genes underwent minimal deletions in primary OS samples. These genetic alterations of miR-34 genes are associated with decreased expression of miR-34s in OS samples [40]. In the miR-140 study, expression of miR-140 was associated with chemosensitivity in osteosarcoma xenografts. Tumor cells ectopically transfected with miR-140 were more resistant to methotrexate and 5-fluorouracil (5-FU). Overexpression of miR-140 inhibited cell proliferation in osteosarcoma cell line U-2 OS (wild type p53), so miR-140 may be a candidate for developing a therapeutic strategy to overcome chemoresistance [41]. MiR-143 was found to be downregulated in osteosarcoma cell lines and primary tumor samples, and restoration of miR-143 promoted cell apoptosis and suppressed tumorigenesis by targeting Bcl-2, an antiapoptotic factor [43]. Interestingly, it was demonstrated that downregulation of miR-143 correlated with pulmonary metastasis of human osteosarcoma cells by cellular invasion, probably through elevated expression of MMP13 [42]. Also, miR-199 expression was altered in osteosarcoma cell lines and tumor tissues [39]. Ectopic expression of miR-199 precursors in osteosarcoma cell lines significantly decreased cell growth and migration by inhibition of G1/S cell cycle arrest. It has been suggested in various studies that miRNAs can be potential therapeutic targets for osteosarcoma. However, further studies are needed to dissect the molecular mechanism of miRNAs in osteosarcoma, their efficacy for treatment, and delivery of miRNAs to tumor cells.

CELL OF ORIGIN AND CANCER STEM CELLS IN OSTEOSARCOMA

Cell of origin

Mesenchymal stem cells (MSCs) reside in bone marrow and can differentiate into osteogenic, chondrogenic, adipogenic, neurogenic, or myogenic lineages [11]. During osteogenic differentiation of MSCs, the balance between proliferation and differentiation is tightly regulated in each sequential stage from preosteoblast to immature and mature osteoblasts and to terminally differentiated osteocytes [35] (Fig. 85.1). Dysregulation of this balance such as an increase in proliferation or the blocking of differentiation at early stages can lead to propensity to bone cancer [10, 11]. It remains unknown which cells along this differentiation pathway can undergo malignant transformation to osteosarcoma, and it is also unknown where this occurs at the tissue level. In a rat model, it has been shown that the transition from premalignancy to malignancy might occur in the peritrabecular regions of the metaphysis [44].

Recent studies using mouse models have suggested that the cells of origin in osteosarcoma are MSC-derived bone-forming cells. Osteosarcoma premalignant cells may arise from a MSC that acquires patterns of pathological osteoblastic differentiation during tumor progression [45]. Similarly, they may arise from either the preosteoblast or immature osteoblast that has proliferative capacity [15, 45]. In each case, these premalignant cells that initially acquire a mutation in different stages of osteoblast differentiation may transform or evolve into cancer stem cells (CSCs) or tumor initiating cells (TICs) through accumulation of additional genetic mutations during the tumor progression (Fig. 85.1). Simultaneously, the acquisition and loss of differentiation properties can be seen in the CSCs.

Cancer stem cells in osteosarcoma

The putative CSCs of osteosarcoma are able to undergo not only osteogenic but also chondrogenic and adipogenic lineage differentiation in response to appropriate environmental cues [15]. Osteosarcomas with various

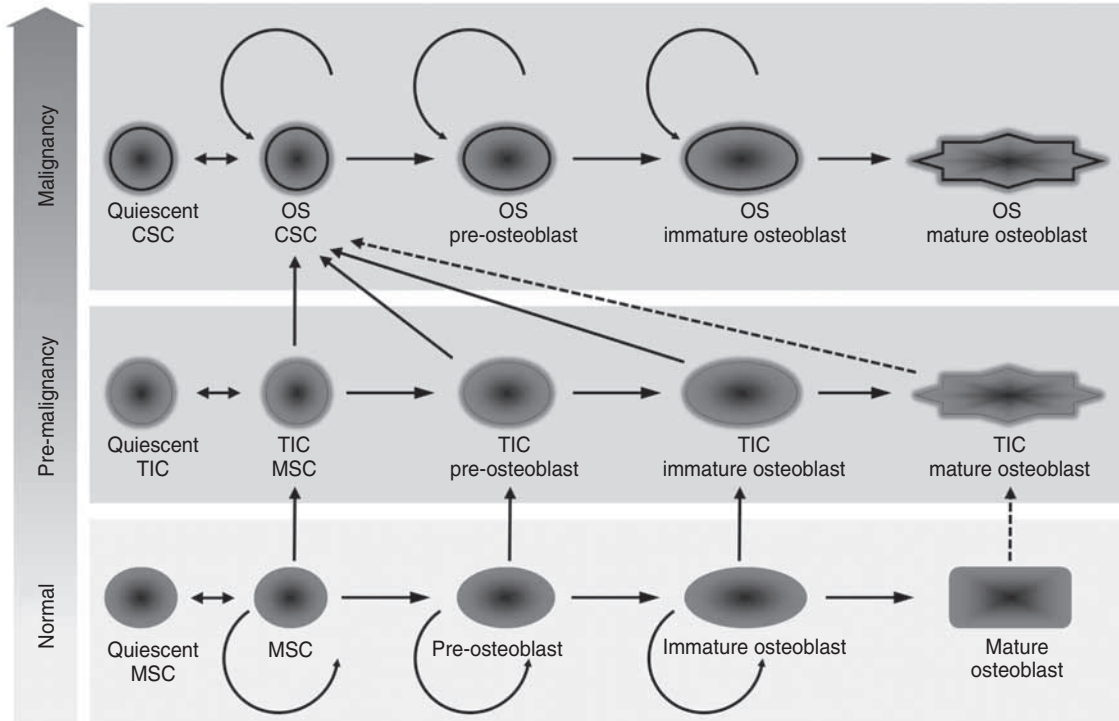

Fig. 85.1. Schematic working model for cell of origin in osteosarcoma formation. Osteogenic differentiation of the mesenchymal stem cell (MSC) occurs through multiple still poorly defined stages (preosteoblast, immature, and mature osteoblast) and culminates in the terminally differentiated osteocyte (not shown in the figure). Osteosarcoma (OS) premalignant cells, sometimes called tumor initiating cells (TICs), can arise not only from a mesenchymal stem cell, but potentially from either preosteoblast or immature osteoblast that have proliferative capacity. The potential dedifferentiation of fibroblasts into pluripotent progenitors opens the possibility that dedifferentiation of mature osteoblasts may lead to a cancer stem cell (CSC) or OS (dashed line), but this currently remains unknown. Next, the premalignant cells can transform into cancer stem cells, which may be able to undergo not only osteogenic, but also chondrogenic and adipogenic lineage differentiation in response to environmental cues.

differentiation patterns are traditionally referred as histologic subtypes. It is well recognized that many of them have mixed patterns. It is also known that the histologic subtype does not impact on chemotherapy response or outcome; therefore, patients are treated identically irrespective of subtype. This suggests that these various differentiation patterns are reflective of a single clinical disease [10].

In our model (Fig. 85.1), we propose that human osteosarcoma can originate from the various stages of osteogenic lineage differentiation from MSCs. Those premalignant cells exist at different stages of differentiation and can transform into CSCs, which can either become quiescent stem cells or differentiate pathologically into various subpopulations cells at each differentiation stage. It is thus far unclear which pools serve as the CSCs or TICs through their signature-genes clusters or surface markers. A recent study has shown that TICs may be a type of subpopulation cells that can retain dye PKH26 [46]. Thus, identifying the cell of origin and the CSCs of osteosarcoma is likely to be of critical clinical importance, especially with respect to development of molecularly targeted therapies and definition of biomarkers for diagnosis and prognosis.

TARGETED THERAPIES AND APPLICATION OF ANIMAL MODELS AND BIOMARKERS

Promise of molecularly targeted therapies in osteosarcoma patients and application of animal models

Several phase 1/2 studies have recently been conducted testing new agents in pediatric patients and have demonstrated objective responses in osteosarcoma [14]. For example, Cediranib, an orally bioavailable small molecule that potently inhibits the tyrosine kinase activity of vascular endothelial growth factor receptor 1 (VEGFR-1; Flt-1), VEGFR-2 (KDR), and VEGFR-3 (Flt-4) showed response in osteosarcoma patients with pulmonary metastases in a pediatric phase 1 trial. Another new agent is Rexin-G, a pathotropic nanoparticle incorporating a collagen matrix binding motif on its surface and bearing a dominant negative cyclin G1 construct that inhibits the cell cycle in the G1 phase. In a phase 2 study of 20 chemotherapy-resistant osteosarcoma patients, Rexin-G resulted in stable disease in 10 out of 17 patients treated [47]. There are several other currently available novel targeted agents that might potentially confer benefit for osteosarcoma patients enrolled in in targeted phase 1 or 2 trials. They include p53/MDM2 antagonists, pro-apoptotic receptor agonists, Notch inhibitors, HER2/neu antagonists, c-MET inhibitors, and IGF1R receptor antagonists [48]. Other promising novel agents include RANKL inhibitors, KIT inhibitors, mTOR inhibitors, vascular-disrupting agents, and Hsp90 inhibitors (IPI-504) [14]. Generally, all of the future targeted therapies should be able to inhibit key pathways that contribute to tumorigenesis and cell survival, and clinical trials using this approach will ultimately yield the necessary answers about efficacy. On the other hand, application of animal models [13, 15, 44, 45, 49–52] may serve as an efficient approach to identifying novel agents for phase 1 or 2 trials (Table 85.2).

Biomarkers for diagnosis and prognosis

The current challenge in application of targeted agents lies in the identification of biomarkers predictive of

Table 85.2. Summary of Osteosarcoma Animal Models

	Mouse	Rat	Dog
Approaches to generate models	Genetically engineered mice. Xenograft or allograft into immunocompromised mice	Administration of PTH 1–34 or radioactive agents	Spontaneous development
Etiology	Known	Unknown	Unknown
Penetrance	High,60–100% depending on the Cre line used	High	Low,~8,000 dogs per year (U.S.)
Similarity to human OS	High. OSs share common features of human OS, such as karyotypic complexity, gene signatures, histology, and metastatic potential	Only a small proportion of human OS are radiation induced	Very high. OSs share common features of human OS, high grade, metastasis to the lungs
Advantages	Amenable to genetic modeling and testing novel therapeutic approaches in xenograft models	Well-established model for studying physiology	Large size, intact immune system, amenable to modeling human treatments
Limitations	Small body size, difficult to develop devices or treatments applicable to humans	Relevance of these tumors to the human is low	Small number of cases. Mean age is about 7 years old

response/resistance and matching them with the particular histologic response of individual patients, hopefully resulting in successful translation of biology into clinical benefit [14]. Other than the presence of metastatic disease, definitive prognostic and diagnostic markers for osteosarcoma are limited. There are only a few available common laboratory tests biomarkers. For example, elevations in lactate dehydrogenase (LDH) and alkaline phosphatase (ALK) occur in 30–40% of cases and in some studies have been found to be prognostic; however, they are not used clinically for either stratification of patients or treatment decisions [9]. Recent studies have reported many potential biomarkers for diagnosis and prognosis, which include CTGF, osteocalcin, OPN, P27KIP1, LRP5, CDKN2A/p16, cyclin E1, RB1, FOS, MDM2, cyclin D1, telomerase, platelet-derived growth factor receptor, c-MYC, Her-2, S100A6, RUNX2, membrane-type matrix metalloproteinase type 1, Fas, CXCR4, CXCL6, Twist, P-glycoprotein expression, Snail2, TIMP1, CXCR4, FAS, Annexin2, and Ezrin [5, 11, 30]. However, each of these potential biomarkers was reported in small series, few have been tested prospectively, and none has yet become standard of care. Recently, a multigene classifier has been developed based on microarray technology to predict the response of osteosarcoma to preoperative chemotherapy at the time of diagnosis. Forty-five genes that could distinguish good and poor responders to primary chemotherapy were identified [8]. It is expected that, over the coming years, the new molecular markers identified through high-throughput approaches such as microarray and proteomics may be able not only to prognosticate osteosarcoma patients but also to serve as therapeutic targets and thereby further improve survival rates.

DISCUSSION

The challenges that lie ahead in osteosarcoma biology are to understand the functional interactions of the different genetic factors and pathways and how they intersect with each other during tumor initiation, progression, and metastasis. For example, mutations in tumor suppressor genes p53 and Rb are considered an initiation event in tumorigenesis. Further mutations in other tumor suppressors (e.g., the RECQ helicases) may lead to multiple genetic alterations due to loss of genomic integrity. However, p53 and Rb can also function in the maintenance of genomic stability and as such play multiple roles in limiting the process of tumorigenesis. Perhaps after those critical initiating events, other subsequent events will follow, such as alterations in oncogenes and/or signaling pathways, which may aid in tumor formation. Once established, other factors including additional oncogene overexpression and increased signaling through classical developmental pathways (such as Notch or Wnt), can then play a role in progression and metastasis [2, 5]. Dissecting the various interactions between pathways involved in cell cycle regulation, DNA metabolism, and maintenance of genomic integrity, and understanding the role of oncogenes, signaling and drug resistance pathways, will eventually provide a rational strategy for devising specific therapies that target the pathways leading to osteosarcoma.

INTRODUCTION

The term "cancer survivorship" represents those living following the diagnosis of cancer. It denotes a continual process beginning at the moment of diagnosis and continues lifelong, however long that may be. Anticancer therapies may be administered in an attempt to decrease the risk of distant metastases by affecting occult tumor cells or to control known tumor burden. Those with a diagnosis of cancer may be at risk for skeletal complications from the cancer and/or cancer therapy. This chapter reviews skeletal complications of cancer therapies with a focus on breast cancer and prostate cancer survivors.

BREAST CANCER

The median age at breast cancer diagnosis is 61, with 95% of cases occurring in women over the age of 40 [1]. Approximately 75% of all invasive breast cancers express the estrogen receptor (ER) and/or the progesterone receptor (PR). Blocking estrogen signaling is an important means of controlling endocrine responsive breast cancers. Adjuvant antiestrogen therapy may reduce the risk of breast cancer recurrence by approximately 30–50% in a woman with ER/PR expressing breast cancer [2]. In the metastatic setting, a first line clinical benefit rate of approximately 50% may be seen with antiestrogen therapy [3]. Hence, endocrine therapy is a standard intervention in the management of ER/PR expressing tumors. In tumors that express neither ER nor PR, chemotherapy is often used.

Endocrine therapy, breast cancer, and bone

In premenopausal and postmenopausal women with ER/PR expressing breast cancer, systemic endocrine therapies are considered as part of the cancer treatment plan. In the adjuvant setting, 5 years of endocrine therapy is a standard duration of treatment in the United States [4]. In the metastatic setting, a particular intervention is often used until there is evidence of disease progression or intolerable toxicity. The impact of endocrine therapy on bone is influenced by the menopausal status of the patient and the drugs used. Table 86.1 highlights representative studies examining adjuvant breast cancer endocrine therapy and the effect on bone-related parameters.

Tamoxifen, a selective estrogen receptor modulator (SERM), is an established adjuvant endocrine intervention in both premenopausal and postmenopausal women with ER/PR expressing breast cancer. Whether tamoxifen serves as an estrogen agonist or antagonist depends on the exposed tissue, as well as the milieu of ER coactivators and corepressors in those tissues [5]. Within the breast, tamoxifen is an estrogen antagonist regardless of menopausal status. Within bone, tamoxifen is associated with loss of bone mineral density (BMD) in premenopausal women and with gain of BMD in postmenopausal women [6].

Table 86.1. Representative Reports of the Effects of Breast Cancer Therapy on Bone

Adjuvant Endocrine Intervention	Premenopausal BMD	Premenopausal Fracture Risk	Postmenopausal BMD	Postmenopausal Fracture Risk
Chemical ovarian ablation (LHRH)	5% loss of total body bone density at 2 years (Ref. 54)	Not defined	Not applicable	
Chemical ovarian ablation (LHRH) and oral endocrine therapy (without osteoclast inhibition)	Loss of BMD at lumbar spine at 3 years Tamoxifen: 9.0% Anastrozole: 13.6% (Ref. 7)	Not defined. One study demonstrated fracture (0.2%) noted in both arms at 48 months of follow-up (Ref. 7).	Not applicable	
Oophorectomy	In a non-cancer population oophorectomy resulted in significant loss of vertebral bone mass at 12 months (Ref. 55)	A non-cancer population cohort study suggests a slight increase in risk of forearm and vertebral fractures (Ref. 56)	Non-cancer population results are mixed (Refs. 57, 58)	
Chemotherapy	Reports of chemotherapy-induced ovarian use variable definitions of amenorrhea, menopausal status, and ovarian function. Loss of lumbar spine BMD at 1 year has been reported to be 3.2–7.7% in those with ovarian dysfunction. In those who retain their menses, BMD was essentially stable (change of increase of 0.6) at 3 years (Refs. 59, 60).	Not defined	Chemotherapy and its associated supportive interventions may decrease BMD and fractures as noted in observational and epidemiologic studies (Refs. 13, 59).	
Tamoxifen	Non-cancer population results demonstrate a loss of 1.44% of lumbar spine BMD in 3 years (Ref. 6). In women who remained premenopausal after chemotherapy, tamoxifen was associated with a 4.6% loss of lumbar spine BMD at 3 years (Ref. 60).	Not defined	Non-cancer population results demonstrate an average annual increase in BMD of 1.17% in the lumbar spine (Ref. 6). In a second, non-cancer population, there was no difference in rates of fracture between tamoxifen and raloxifene (Ref. 61). Adjuvant tamoxifen is associated with an approximate 0.5–1.0% gain in bone mass per year (Ref. 62).	Current use of tamoxifen has been associated with an approximate 30% reduction in risk of osteoporotic fracture (Ref. 63).
Aromatase inhibitor	Adjuvant aromatase inhibitors are not indicated for women with preserved ovarian function		In women who have completed 5 years of adjuvant tamoxifen, continued adjuvant therapy with anastrozole decreased BMD by 5.35% at 24 months (Ref. 64). In those without prior exposure to tamoxifen, loss of lumbar spine BMD is approximately 1–2% per year of therapy. In one study, at the end of 5 years of therapy the lumbar spine BMD had decreased 6.1% (Refs. 59, 65).	During treatment with anastrozole, the annual rate of fracture was approximately 3% (Ref. 66). At 5 years of adjuvant AI therapy or more, the risk of fracture ranges from approximately 3 to 12% (Refs. 4, 67).

Decreasing ovarian estrogen production may be a component of breast cancer care in premenopausal women with ER/PR expressing tumors. Options for ovarian ablation include use of gonadotropin releasing hormone (GnRH) agonists, surgery, or radiation (not commonly used). In addition, chemotherapy may induce ovarian dysfunction. The lower circulating estrogen levels observed with ovarian ablation correlate with loss of BMD. This loss of BMD may be partially recovered upon cessation of therapy [7]. Of note, when a GnRH agonist is used with an oral endocrine therapy there does not appear to be an anticancer advantage with an aromatase inhibitor (AI) over tamoxifen, but there may be a greater loss of BMD with the AI–GnRH combination [7].

Postmenpausal women with ER/PR expressing breast cancers have the option of adjuvant treatment with tamoxifen, an aromatase inhibitor or the sequential use of tamoxifen and AI [4]. The third generation AIs (anastrozole, exemestane, letrozole) effectively block peripheral conversion of androgens to estrogens primarily in adipose tissue, as well as androstenedione to estrone in the adrenal gland by inhibiting the aromatase enzyme (cytochrome P-450, CYP 19). The AI-induced decrease in serum estradiol is associated with a decrease in risk of breast cancer recurrence and new breast cancer and is also associated with accelerated loss of BMD and fracture, regardless of the particular AI studied [4]. In spite of adjuvant studies demonstrating an increased risk of fracture with adjuvant AI use, the Phase III Mammary Prevention 3 trial (MAP.3) of exemestane versus placebo demonstrated no statistical difference between the two groups in terms of fracture [8]. The interpretation of the BMD changes associated with the AIs may be confounded in studies where tamoxifen is the comparator, given tamoxifen is a partial estrogen agonist and may have a positive impact on BMD.

Fulvestrant is a selective estrogen receptor antagonist that is FDA approved for treatment of hormone receptor positive metastatic breast cancer in postmenopausal women. In women who are gaining clinical benefit from fulvestrant, pilot data suggest that markers of bone turnover are not significantly altered over an 18-month course [9]. Concerns for loss of BMD in metastatic disease are often supplanted by the frequent presence of bone metastases and the routine use of high potency osteoclast inhibitors to decrease the risk of skeletal-related events. The impact of anticancer therapies on BMD in women with advanced breast cancer, but without osseous metastases, is not well established, although there is an increased risk of fracture in women with recurrent breast cancer who are without evidence of skeletal metastases (hazard ratio 22.7; 95% CI 9.1, 57.1; $P < 0.0001$) [10].

Chemotherapy, breast cancer, and bone

Chemotherapy regimens may also be associated with loss of BMD and fracture. Apart from chemotherapy-induced ovarian dysfunction, chemotherapy-induced bone changes are less well defined than those of endocrine therapy. Retrospective studies have suggested that adjuvant therapies have a negative impact on BMD [11] and epidemiologic data from the Women's Health Initiative Observational Study demonstrate an increased rate of fractures in women breast cancer survivors compared to women without a history of breast cancer [12]. Prospective data from a small study of postmenopausal women with breast cancer treated only with chemotherapy or observation (no endocrine therapy in either cohort) demonstrated that the majority of women treated with adjuvant chemotherapy lost 1–10% of lumbar spine BMD at 1 year [13]. The etiology of the observed loss of BMD may be due to chemotherapy itself, or the supportive therapies that may have negative impact on BMD, such as glucocorticoids.

Pharmacologic interventions to preserve BMD and prevent fractures secondary to breast cancer therapy

Randomized clinical trials investigating means to mitigate the bone loss associated with adjuvant breast cancer therapies have been reported, and additional studies are ongoing [4]. The study designs have either included established drugs, doses, and intervals used to manage postmenopausal osteopenia and osteoporosis or the studies have included investigational and more intensive regimens of osteoclast inhibition. The vast majority of these clinical trials have demonstrated that osteoclast inhibition, with oral or intravenous bisphosphonates or denosumab, can preserve or increase BMD in the setting of cancer treatment-induced bone loss (CTIBL) [14, 15]. Sufficient fracture data does not presently exist to address the impact of osteoclast inhibition prescribed to treat CTIBL in either premenopausal or postmenopausal women with breast cancer; additional studies are needed. Given the efficacy of the FDA-approved therapies in postmenopausal women, these standard regimens are often selected in the clinic when an established indication for osteoporosis prevention or treatment is present.

PROSTATE CANCER

The median age at prostate cancer diagnosis is 67 years, and over 8% of men will develop cancer of the prostate between the ages of 50 and 70 years [16]. It is estimated that 70% of prostate cancers are androgen dependent [17] and respond to endocrine (hormonal ablation) therapy. Diminishing circulating testosterone, a growth factor for prostate cancer, is an effective anticancer therapy. Thus, androgen deprivation therapy (ADT) is a mainstay of treatment for prostate cancer and is commonly used at initial diagnosis in the management of intermediate to high risk prostate cancer.

Endocrine therapy, prostate cancer, and bone

ADT can be achieved medically with the use of GnRH agonists and/or antiandrogen medications, as well as surgically with bilateral orchidectomy (less commonly used). GnRH agonist therapy lowers testosterone and estrogen levels, both of which negatively effects skeletal health [18]. Antiandrogens such as biclutamide and flutamide are competitive inhibitors of the androgen receptor, blocking testosterone action and are typically used in conjunction with GnRH agonists. Estrogen preparations were used historically but are not commonly used now.

Approximately 33–70% of men with prostate cancer receive a GnRH agonist as primary therapy with or without antiandrogens for localized disease before (neoadjuvant) or after other (adjuvant) treatment modalities, or in men with a rising prostate-specific antigen (PSA) after primary therapy with surgery or radiotherapy [17, 19]. In patients with locally advanced disease, as well as those with high-risk localized disease (based on tumor stage, Gleason score, and PSA), neoadjuvant therapy has shown benefit in disease-specific survival, time to progression, and all-cause mortality [20]. In the adjuvant setting, ADT for more than 2 years given in conjunction with external-beam radiotherapy in men with locally advanced, high-risk prostate cancer has been demonstrated in randomized trials to improve survival in this population [20]. In metastatic disease, ADT is the first line of therapy and the duration of therapy may be measured in years. Abiraterone is a selective and irreversible inhibitor of CYP-17, reducing adrenal androgen production. Abiraterone used in combination with prednisone was FDA approved in 2011 for metastatic, castrate-resistant prostate cancer after exposure to docetaxel. The impact of abiraterone on BMD has not been reported.

Dual energy X-ray absorptiometry (DXA) hip and spine measurements of men on GnRH agonists demonstrate a loss of 2–3% per year within the first several years after the initiation of ADT therapy [19]. This loss continues, albeit more slowly, throughout therapy duration. In men who have had surgical castration with bilateral orchiectomies, hip BMD decreases by approximately 10% over 1 year, as compared with only a 1% decline in men given estrogen for medical castration [21]. In contrast, annual rates of bone loss in healthy community-dwelling men are approximately 0.5–1.0% per year [22].

Men receiving ADT have a rate of fracture as high as 20% after 5 years of treatment. In a study that utilized the Surveillance, Epidemiology and End Results (SEER) database, investigators found that 19.4% of men receiving GnRH-agonist therapy or orchiectomy had fractures compared with 12.6% of those with prostate cancer not receiving these treatments ($p < .001$). Longer duration of treatment was also predictive of fracture [23]. In a study of Medicare claims data, men treated with ADT for prostate cancer had an increased risk of fracture compared with a control group (hazard ratio 1.4, $p < .001$), and GnRH agonist treatment independently predicted fracture after controlling for age, race, comorbidity, and location [24].

Due to the typical long-standing nature and general indolence of prostate cancer in older men, many will live with the consequences of CTIBL in addition to preexisting comorbid conditions. Hyogonadism leads to decreased BMD, decreased muscle mass, increased fall risk, and impaired balance. Thus, it would stand to reason that ADT is associated with some of these adverse events and a potential for the development of the geriatric syndrome of frailty [25].

Pharmacologic interventions to preserve BMD and prevent fractures secondary to prostate cancer therapy

Bisphosphonates: Alendronate, risedronate, and zoledronic acid are FDA approved for men with osteoporosis, and only zoledronic acid is FDA approved in metastatic prostate cancer. A series of clinical trials have demonstrated efficacy of intravenous and oral bisphosphonates in preserving BMD in men on ADT [26]. In a 48-week trial, pamidronate, 60 mg intravenously every 12 weeks, maintained BMD at the spine and hip in the group receiving pamidronate as compared with controls receiving placebo; they had significant loss at these sites [19]. In a 1-year trial of a single 4-mg dose of zoledronic acid versus placebo in a similar population of men, those who received zoledronic acid had increased BMD in the spine and hip compared with loss of BMD in the placebo control group [27].

Within a double-blind, randomized, placebo-controlled trial, Greenspan et al. demonstrated that alendronate dosed at 70 mg weekly could prevent bone loss and reduce biochemical markers of bone turnover in men with prostate cancer who receive ADT [28]. After 1 year, men treated with alendronate had significant gains in BMD of 3.7% at the spine and 1.6% at the hip whereas men in the placebo group had losses of 1.4% at the spine and 0.7% at the hip.

In a smaller, double-blind, placebo-controlled, randomized trial of older men with locally advanced prostate cancer during the first 6 months of GnRH agonist therapy, 40 men completed a trial of risedronate 35 mg/week versus placebo. After 6 months, the risedronate group showed no change in femoral neck and total hip BMD while the placebo group decreased significantly by 2.0% and 2.2%, respectively. Spine BMD of the risedronate group increased significantly by 1.7% over baseline while the placebo group did not change [29]. Thus, oral and intravenous bisphosphonates can prevent loss or increase bone mass; however, long-term and larger studies are required to determine if fractures can be decreased.

Estrogens and SERMS: Historically, medical castration with estrogen, specifically diethylstilbestrol (DES) was the mainstay of treatment for metastatic prostate cancer. In a small study using transdermal estradiol patches to

achieve castration, 20 men with advanced or metastatic prostate cancer showed increases in BMD at the spine and hip after 1 year of treatment [30]. Other investigators have also shown decreases in bone turnover in response to intramuscular estrogen preparation in men treated with orchiectomy [31] or DES [32] as well as in men on GnRH agonist therapy receiving 1 mg/day of oral micronized estradiol [33]. To date, long-term trials of estrogen to determine if it can improve BMD and decrease fractures have not been performed.

SERMs are not FDA approved for preserving BMD or reducing fracture risk in men with prostate cancer on ADT, but they have been evaluated. Raloxifene, a SERM, has been shown in a 12-month open label trial to have a modest effect on BMD of the spine and hip compared with men not on the medication [34]. In a study of 847 men on ADT, subjects under 80 years of age were randomized to receive either 80 mg/day of toremifene, another SERM, versus placebo for 24 months. The average time on ADT was 4 years for both groups, and the mean age of the subjects was 72 years. Vertebral fracture, a primary end point, was assessed morphometrically. One percent of the toremifene group sustained new vertebral fractures compared with 4.8% of the placebo group, a relative risk reduction of 79.5% ($p < .005$) and an absolute risk reduction of 3.8%. BMD increased at all sites in the toremifene group ($p < .001$) [35].

Denosumab: Denosumab, a human monoclonal antibody for receptor activator of nuclear factor-κB ligand (RANKL) has recently been approved for men receiving ADT at risk of fracture. In a 24-month, randomized, placebo-controlled multicenter trial, more than 770 men per group were randomized to receive denosumab, 60 mg subcutaneously or placebo every 6 months [36]. Subjects had a median duration of ADT of 20 months, with 75% over 6-months duration. BMD increased significantly compared with the placebo (6.7% difference at L-spine, 3.9% at femoral neck, 4.8% at total hip, and 5.5% at 1/3 radius, $p < .001$ for all comparisons). The denosumab group experienced lower rates of new vertebral fractures (morphometric) at 12, 24, and 36 months, with a decrease of 62% at 36 months (1.5% vs 3.6% in the denosumab vs placebo group, $p = .006$). A similar proportion of subjects in each group had adverse events. One case of hypocalcemia was reported, and there was a higher infection rate in the denosumab group; no cases of osteonecrosis of the jaws (ONJ) were documented. Denosumab is also FDA approved for the prevention of skeletal-related events in men with bone metastases from prostate cancer.

RADIATION AND FRACTURE

The mechanism of radiation therapy induced bone injury has not been fully defined and may occur secondary to alterations in the marrow microenvironment including changes to the vasculature, osteoblasts, osteoclasts, and osteocytes [37, 38]. Insufficiency fractures may occur in an irradiated field. It is essential to rule out metastasic disease and pathologic fracture to direct clinical management of fractures in patients with a history of cancer [39].

Radiation therapy and breast cancer

The clinical indications for adjuvant radiation therapy to the breast or chest wall and axillary region is directed by the surgery performed (breast conservation), surgical margin status, size of the primary tumor and number of lymph nodes involved. Adjuvant radiation therapy is associated with a small increase (less than 2%) in rib fractures, whether it be post-mastectomy, post-lumpectomy with external beam, or partial breast radiation [40, 41, 42].

Radiation therapy and prostate cancer

Men with prostate cancer may receive external beam radiation therapy (EBRT) or brachytherapy (radioactive seed implants) to the prostate as therapy for the primary tumor. In women who undergo pelvic radiation therapy for treatment of cervical, rectal, or anal cancer there is an increased risk for pelvic fractures compared to women with these types of cancers who do not receive pelvic radiation [43]. The effect of radiation therapy on pelvic fracture rates in men with prostate cancer has not been well characterized; however, there appears to be an increased risk of hip fractures associated with EBRT [44].

OSTEOCLAST INHIBITION AND METASTATIC BONE DISEASE

The incidence of bone metastases in patients with metastatic breast or prostate cancer is approximately 70%. Bone metastases are generally considered an incurable diagnosis and the goals of care are palliative. The selection of a particular osteoclast inhibitor for a patient is influenced by efficacy data, drug availability, toxicity profile, patient and clinician preferences, patient convenience, and treatment costs. Osteoclast inhibition is often initiated at the time of detecting bone metastases and may be continued indefinitely. Short-term adverse events associated with osteoclast inhibition may include hypocalcemia, bone pain, and acute phase reactions. Long-term bone specific adverse events may include osteonecrosis of the jaw (ONJ) and atypical fractures.

Osteonecrosis of the jaw (ONJ)

ONJ is an uncommon event that occurs in individuals receiving potent osteoclast inhibition. ONJ consists of necrotic, exposed bone within the oral cavity that has not healed within 8 weeks after identification by a health

care provider [45]. ONJ is differentiated from osteoradionecrosis by the lack of exposure to radiation therapy to the maxillofacial region. ONJ has been reported in patients with metastatic bone disease treated with bisphosphonates and denosumab with a similar incidence of 1–2% at a median of 14 months of exposure of monthly osteoclast inhibition [46]. ONJ has been reported in patients receiving osteoclast inhibition for osteoporosis, as well as participants in adjuvant bisphosphonate clinical trials, although the incidence appears lower in these situations [45, 47]. The etiology of ONJ is presently unknown and is the subject of preclinical and clinical investigation. Risk factors for ONJ include an extended duration of osteoclast inhibition, dental extractions, and infection/inflammation [48]. Optimizing oral health and avoiding dental extractions during therapy with an osteoclast inhibitor may decrease the risk of ONJ. An observed reduction in the incidence of ONJ from 3.2% to 1.3%, when comparing pre- and post-implementation of preventive measures program, has been reported [49].

Atypical subtrochanteric femoral fractures

Atypical subtrochanteric femoral fractures have recently been reported in relation to bisphosphonate therapy [50]. These transverse femoral fractures most often occur with no or minimal trauma. Bisphosphonates may be associated with atypical subtrochanteric fractures, but causation has not been proven. It appears that these atypical fractures occur at a rate of approximately 31 per 10,000 patient years in patients treated with bisphosphonate, and at a rate of 6–13 per 10,000 patient years in untreated individuals [51].

Data on atypical fractures in patients with cancer are limited. A case report of a low trauma atypical femoral fracture of a man with renal cell carcinoma with skeletal involvement has recently been described after 18 months of intravenous zoledronic acid [52]. In a retrospective study of patients with metastatic bone disease, four patients, of a cohort of 327, were identified to have met radiographic criteria for atypical or stress fracture [53]. Three had breast cancer and one had myeloma, and they had received between 48 and 73 doses of bisphosphonates, primarily pamidronate. All experienced a prodrome of thigh pain. These investigators found no difference with regard to cumulative dose or duration of treatment of intravenous bisphosphonate between those with atypical fractures and those who did not. Thus, the incidence of these fractures appears to be low. However, prospective studies are required to determine if risk factors for atypical fractures can be elucidated.

SUMMARY

Patients with breast or prostate cancer likely exhibit a baseline risk of osteoporotic fractures due to advancing age and comorbid conditions; in addition, the management of their cancer may accelerate the risk for loss of BMD or fracture. Optimizing bone health practices through nutrition and/or supplements, weight-bearing exercises, and lifestyle modifications is essential. Clinical and radiographic assessment of fracture risk is a component of monitoring bone integrity. Pharmacologic interventions with bisphosphonates or denosumab are options to maintain BMD or reduce fracture in both the adjuvant and the metastatic setting. Participation in clinical trials is encouraged.

EPIDEMIOLOGY OF BONE CANCER PAIN

Pain is the most common presenting symptom in patients with skeletal metastases and is directly proportional to the patient's quality of life [1, 2]. Two main types of cancer pain exist: ongoing pain, and incident or breakthrough pain. Ongoing pain is typically described as a dull and aching pain that is constant in nature and progresses according to overall disease process. Incident or breakthrough pain is most commonly associated with bone metastases and is characterized by sharp pain, intermittent in nature, exacerbated by movement. Breakthrough pain is difficult to treat, but can be found in as high as 80% of patients with advanced disease [3, 4]. Significant insight into understanding bone cancer pain and the development of new therapeutic strategies for bone cancer pain are due to the development of novel animal models and recent clinical trials.

MECHANISMS OF BONE CANCER PAIN

Rodent and canine models of bone cancer pain have been described in the literature in the past decade. Each model differs in the route of inoculation of tumor cells, type of tumor, immunocompetency of the host, and species of host [5]. Despite these differences, a wealth of information has been generated regarding the pathophysiologic mechanisms that drive bone cancer pain. Ultimately, bone cancer pain is a multifactorial process that is initiated by a complex interaction between the host cells within the affected bone and the tumor cells.

Pain generally occurs during tissue damage as the result of release of neurotransmitters, cytokines, and other factors from damaged cells, reactive or activated inflammatory cells, adjacent blood vessels, and nerve terminals. Pain is transduced at the level of the primary afferent nerve fiber that innervates peripheral tissue. Bone is densely innervated by sensory nerve fibers within the bone marrow, mineralized bone, and periosteum (Fig. 87.1) [6]. Sensory and sympathetic neurons form a mesh-like network throughout the periosteum in association with blood vessels that can detect small distortions of skeletal integrity (Fig. 87.2) [7].

The majority of metastatic skeletal malignancies are destructive in nature and produce regions of osteolysis (bone destruction). This occurs via activation, recruitment, and proliferation of osteoclasts and is characterized by an increased number and size of osteoclasts found in tumor-bearing sites [8–11]. The activation and proliferation of osteoclasts is mediated by the interaction between receptor activator for nuclear factor-κB (RANK) expressed on osteoclasts with RANK ligand (RANKL) expressed on osteoblasts. An increased expression of both RANK and RANKL has been found in tumor-bearing sites. Selective inhibition of osteoclasts using either bisphosphonates or the soluble decoy receptor for RANKL, osteoprotegerin (OPG) results in inhibition of cancer-induced osteolysis, cancer pain behaviors, and neurochemical markers of peripheral and central sensitization [12–16].

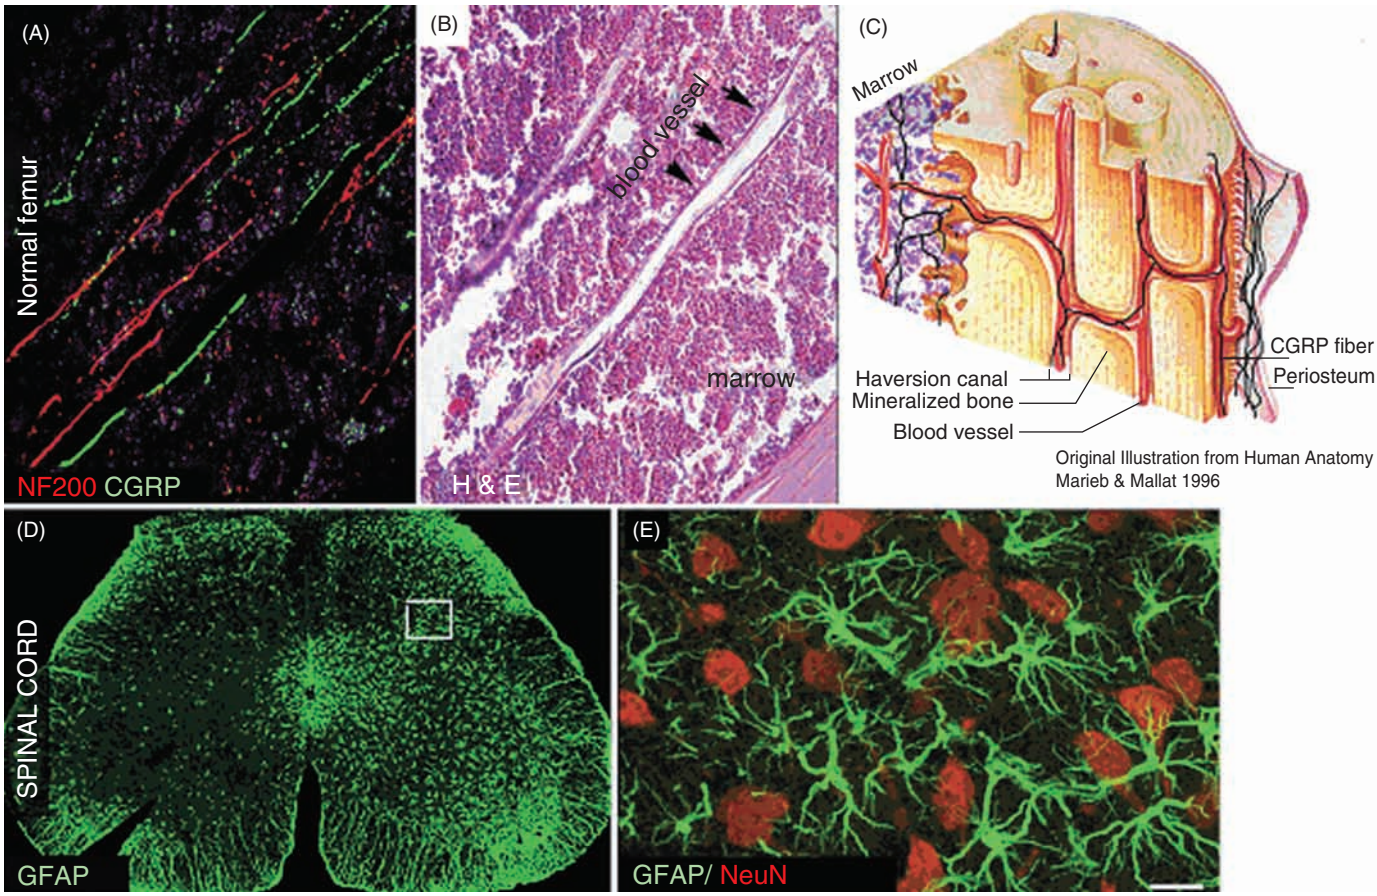

Fig. 87.1. Peripheral and central mechanisms of bone cancer. Histophotomicrographs of (A) confocal and (B) histologic serial images of (D and E) normal bone and confocal images of spinal cord of tumor-bearing mice. Note the extensive myelinated (red, NF 200) and unmyelinated (green, CGRP) nerve fibers within bone marrow that appear to course along blood vessels (arrowheads, B). (C) Schematic diagram demonstrating the innervation within periosteum, mineralized bone, and bone marrow. All three tissues may be sensitized during the various stages of bone cancer pain. (D) Confocal imaging of glial fibrillary acidic protein (GFAP) expressed by astrocytes in a spinal cord of a tumor-bearing mouse. Note increased expression only on the side ipsilateral to the tumorous limb. (E) High-power magnification of spinal cord showing hypertrophy of astrocytes (green) without changes in neuronal numbers (red, stained with neuronal marker, NeuN). NF200: neurofilament 200; CGRP: calcitonin gene-related peptide; GFAP: glial fibrillary acidic protein; NeuN: neuronal marker.

Tumor-derived cytokines, growth factors, and peptides have been shown to activate primary afferent nerve fibers that innervate bone. Prostaglandins, interleukins, protons, bradykinin, chemokines, tumor-necrosis factor-α, nerve growth factor (NGF), and endothelins are all examples of chemical mediators released from tumor cells, or the host inflammatory response, that sensitize nerve terminals resulting in cancer pain [5, 17–19]. Each mediator has a specialized receptor that converts the chemical to an electrical signal (Fig. 87.3). In bone cancer pain, chemical mediators are released that bind to respective receptors causing pain transduction. Neural sensitization occurs when constant nerve stimulation/activation leads to decreased excitation thresholds, upregulation of receptors in nerve terminals, or recruitment of previously silent pain receptors [20–23].

Central sensitization

Central sensitization is the heightened reactivity of nervous system in the face of sustained neural signals. Central sensitization can lead to allodynia, a painful condition where mechanical stimuli not normally perceived as noxious are painful. While central sensitization may occur anywhere along the central or peripheral nervous system, it is most effectively seen in the dorsal horn of the spinal cord. As verified by electrophysiologic and anatomic studies, a change in the activity and responsiveness of dorsal horn neurons occurs in response to persistent painful stimulation. Central sensitization is mediated in part by glutamate, substance P, prostaglandins, and growth factors [24].

Persistent stimulation of unmyelinated C fibers results in increased neural responsiveness of spinal neurons,

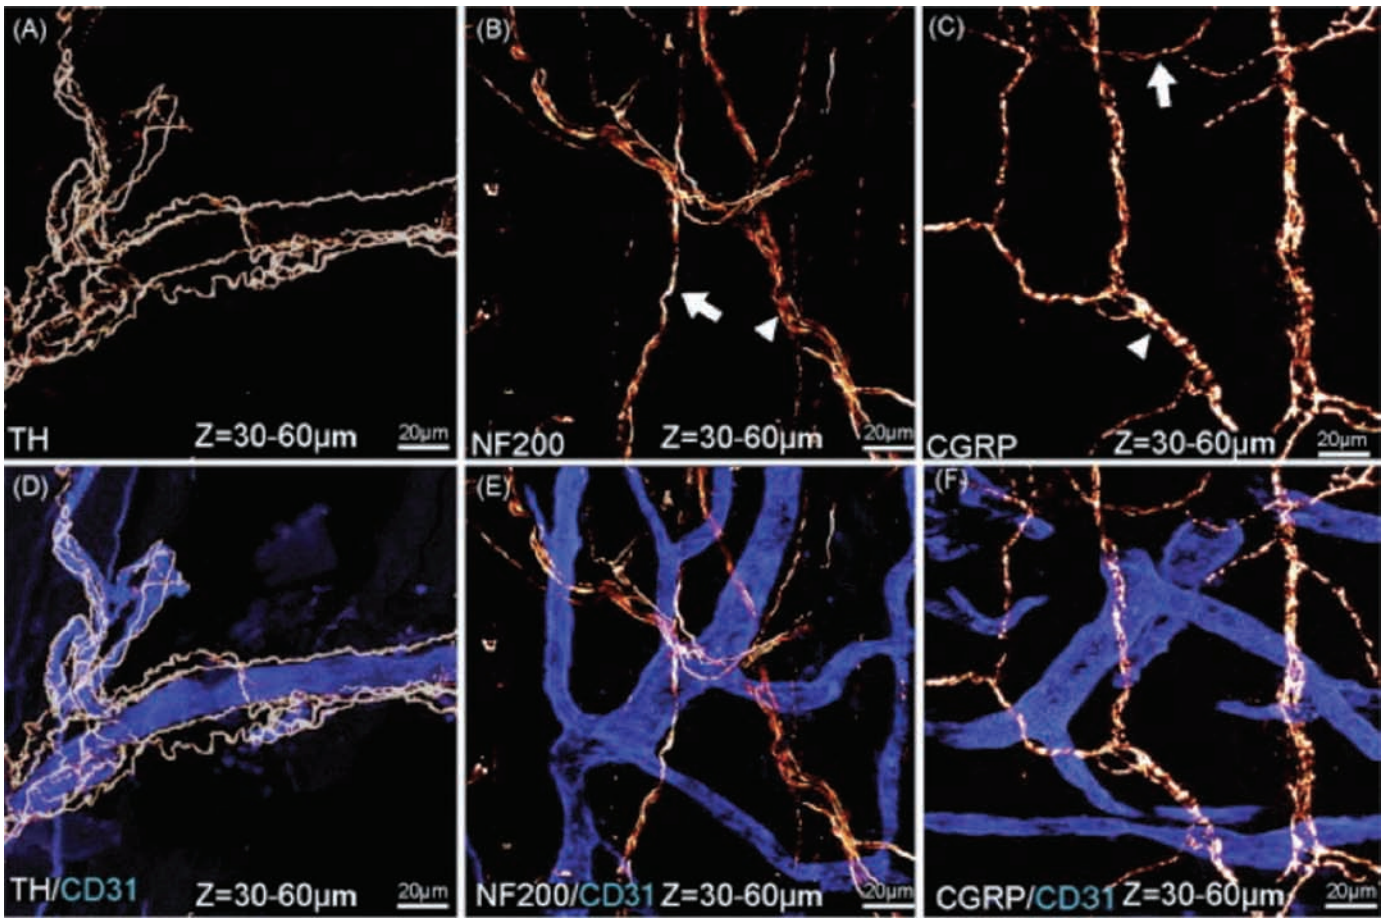

Fig. 87.2. Close association of sensory and sympathetic nerve fibers with blood vessels in the bone periosteum. High-power computed tomography scans of bone in cross section overlaid by confocal images. (A) Sympathetic nerve fibers wrapping around CD31 positive blood vessels of the periosteum (D). (B) NF200+ neurofilament positive and CGRP+ calcitonin gene-related peptide positive sensory nerve fibers (C) do not associate with CD31+ blood vessels [as seen in (E) and (F), respectively].

called "wind-up" [25]. Sensitization can also occur when persistent stimulation results in phenotypic changes in neurons that are adjacent to neurons receiving the persistent painful stimulation. Typically this adjacent sensitization occurs in A-beta fibers that normally do not transmit painful stimuli. Once sensitized, A-beta neurons are capable of transmitting both non-painful and painful information. The molecular understanding of the specific neural pathways involved in central sensitization is currently being investigated as a potential therapeutic option [26, 27].

Reorganization of peripheral and central nervous system in response to cancer pain

Several models of neural sensitization in bone cancer models exist [5, 20, 22]. In normal mice, the neurotransmitter substance P is synthesized by nociceptors and released in the spinal cord when noxious mechanical stress is applied to the femur. Substance P, in turn, binds to and activates the neurokinin-1 receptor that is expressed by a subset of spinal cord neurons, eliciting a response. In mice with bone cancer, the reorganization of nociceptive nerve fibers causes mechanical allodynia where non-painful level of mechanical stress induce the release of substance P, making the stimuli noxious [22].

Phenotypic alterations with extensive neurochemical reorganization in the innervation of tumor-bearing bones occur during the sensitization of peripheral nerves. Specific neural changes that may mediate pain include astrocyte hypertrophy and decreased expression of glutamate re-uptake transporters. The increased extracellular glutamate levels result in central nervous system excitotoxicity [28, 29]. Prolonged pain induces central sensitization, which leads to increased transmission of nociceptive information and allodynia [30].

Recently, progress has been made in understanding the pathophysiology of nociceptive nerve sprouting in prostate cancer [20]. Using a mouse model, fluorescently labeled prostate cancer cells were injected into the bone marrow of naive mice. Twenty-six days after injection,

nociceptive nerve fibers showed significant new sprouting with increased fiber density and appearance, forming a network of pathological nerve fibers (Fig. 87.4). These data suggest that pathological tumoral sprouting of nociceptive nerve fibers occurs early in the metastatic prostate disease process. To further evaluate the driving force for the new nociceptive fibers, RT-PCR (reverse transcriptase polymerase chain reaction) analysis for NGF showed the surrounding tumor-associated inflammatory, immune, and stromal cells are the major source of NGF in these painful tumors [20]. Proof of concept experiments showed that local anti-NGF therapy can block ectopic sprouting and pathological reorganization of these nociceptive fibers, suggesting that prophylactic treatment may be capable of preventing bone cancer pain [21].

THERAPEUTIC STRATEGIES: PAST, PRESENT, AND FUTURE

Pain research has significantly improved our understanding of acute and chronic pain mechanisms. By highlighting key molecular mechanisms involved in pain transmission, new drugs are currently being investigated as potential novel therapies. Currently available medications such as the opioids are fraught with side effects that limit their clinical efficacy. Research is now focused on targeting pain initiation sites within the nervous system to limit systemic complications.

Therapeutic targets: Ion channels

The transient receptor potential (TRPV1) family of ion channels is located on unmyelinated C fibers and spinal nociceptive neurons that mediate pain transmission. TRPV1 channels can be activated by heat, capsaicin, and acid; mice that lack the channel are unable to develop chronic pain states. Antagonists to TRPV1 administered orally or the intrathecal space significantly decrease chronic pain [18, 31, 32]. Activation of TRPV1 initially provokes a powerful afferent nerve irritant effect, followed by desensitization and long-term analgesia. In a canine model of bone cancer, intrathecal administration of resiniferatoxin, a potent capsaicin analog, resulted in pain reduction and selective destruction of small sensory neurons [33]. As TRPV1 is only expressed on nociceptive peripheral terminals, selective blockade of TRPV1 may provide analgesia with a limited side effect profile [34]. Recent work has focused the role of TRPV1 in the acidic microenvironment of bone metastasis that mediates

pain. Specifically, acid signals received by the sensory nociceptive neurons innervating bone stimulate intracellular signaling pathways of sensory neurons. Molecular blockade of the activated intracellular transcription factors in these signaling pathways has served as a method to inhibit pain transmission [19, 35].

Therapeutic targets: Cytokines and growth factors

NGF modulates inflammatory and neuropathic pain states. In chronic pain, NGF levels are elevated in peripheral tissues and neutralizing antibodies against NGF are effective in reducing and in some cases preventing chronic pain [36]. *In vitro* studies have shown that growth and differentiation of NGF-dependent sensory nerve cell lines can be inhibited by naturally neutralizing antibodies. More recently, these same antibodies have been shown to inhibit the *in vitro* migration and metastasis of prostate cancer cells [23]. In addition, pathological sprouting of nerve fibers in a prostate cancer model is modulated in a NGF-dependent fashion (Fig. 87.5) [20]. In animal models, anti-NGF antibodies reduce continuous and breakthrough pain by blocking the nociceptive stimuli associated with the sensitization in the peripheral or central nervous system [36].

In addition to NGF, two other growth factors have been implicated in cancer-related bone pain: glial-derived growth factor (GDNF) and brain-derived growth factor (BDNF). BDNF has been implicated in the modulation of central sensitization as its expression is increased in nociceptive neurons in models of chronic neuropathy. BNDF sensitizes C fiber activity, resulting in hyperalgesia and allodynia. Inhibition of BNDF and its cognate receptor, TrkB, results in decreased C fiber firing and a reduction in pain behaviors [37, 38]. GDNF is important in the survival of sensory neurons and supporting neural cells. Neuropathic pain behaviors commonly observed in animal models of chronic pain are prevented or reversed following GDNF administration. The analgesic effects of GDNF show strong temporal and molecular regulation. Specifically, the timing of administration of GDNF directly determines whether analgesia effects are observed [38, 39].

Endothelins are a family of vasoactive peptides that are expressed by several tumors, with levels that appear to correlate with pain severity. Direct application of endothelin to peripheral nerves induces activation of primary afferent fibers and pain-specific behaviors. As such, endothelins may contribute to cancer pain by directly sensitizing nociceptors [40]. Selective blockade of endothelin receptors blocks bone cancer pain-related behaviors and spinal changes indicative of peripheral and central sensitization [41, 42]. Endothelin antagonists are a pharmacological agent that may show significant promise in the management of cancer pain [40].

Therapeutic targets: Osteoclast

Osteoclasts play an essential role in cancer-induced bone loss and contribute to the etiology of bone cancer pain. Bisphosphonates act by disrupting the activity of osteoclasts, the principle bone cell responsible for bone resorption [43]. Currently, bisphosphonates have shown clinical success in treatment of both osteoporosis and tumor-

induced osteolysis. Recently, administration of bisphosphonates has shown a positive impact on overall skeletal health and quality of life in patients with breast and prostate skeletal metastasis [15, 16]. In addition, initiation of zoledronic acid thearpy prior to the development of skeletal metastasis has recently been shown to improve quality of life scores in patients with prostate cancer while decreasing measurements of clinical pain and skeletal related events such as pathological fracture [44]. The long-term beneficial effects of bisphosphonate treatment in reducing bone pain and skeletal related events (e.g. axial or appendicular pathologic fractures) and the patient reported improvement in overall quality of life are clear from clinical trials in lung, breast, and prostate cancer [44–46].

Tumor-induced osteolysis is stimulated by RANKL, and inhibited by OPG. While direct therapeutic targeting of OPG in humans has never been successful, recent work targeting RANKL has shown success in treating bone cancer pain and pathological fracture related complications. Specifically, denosumab (a human monoclonal antibody against RANKL) was recently evaluated against zoledronic acid (bisphosphonate) in a randomized clinical trial evaluating the prevention of skeletal-related events in patients with bone metastases from breast cancer. While both therapies were well tolerated and delayed or prevented skeletal-related events, denosumab trended toward superior reductions in patient reported pain and improved patient quality of life [47]. In addition to being effective in patients with breast cancer, recently, denosumab was compared to zoledronic acid in a phase III clinical trial for patients with metastatic prostate cancer. The results showed a greater decrease in skeletal-related events such as pathological fracture in patients taking denosumab than those patients taking zoledronic acid [48].

INTRODUCTION

Ionizing radiation is an effective cancer treatment modality. In recent decades, improvements in the diagnosis, planning, and delivery of radiotherapy (RT) have helped decrease mortality rates among some populations of cancer patients [1]. With this increase in overall long-term cancer survivorship, prevention of radiation-induced normal (noncancerous) tissue injury has received more attention. Skeletal complications, particularly fractures of the hip, represent particularly debilitating radiation late effects [2–6]. The incidental irradiation of normal skeletal tissues is not insignificant, as the dose absorbed by normal tissues in close proximity to the tumor can be substantial. For example, RT for gynecological malignancies commonly involves administration of 30 1.8 Gy fractions over 6 weeks, applying approximately a 54-Gy total dose to the tumor. Normal tissues in each hip can receive as much as half of each fraction, depending on tumor type and location. Advancements in surgical excision, concurrent chemotherapy, and modern RT procedures have helped to limit the dose absorbed by some adjacent normal skeletal elements. However, fractures that occur at irradiated skeletal sites, such as the hip and spine, remain a major source of morbidity and can have fatal consequences [7].

While radiation-induced fractures are well documented in the literature, recent animal and cellular work has helped to identify potential new mechanisms underlying these observations. Early loss of bone resulting from activation of osteoclasts likely contributes to the well-established reduction in vasculature and bone formation following irradiation [8, 9]. RT-induced osteoporosis, and the resulting increase in fracture risk, appears to result from a rapid but temporary period of bone resorption, followed by long-term suppression of bone turnover that ultimately prevents recovery of bone mass and can impair bone quality. In this review, we will outline the rationale for radiation-induced fractures as a clinical concern, as well as the current state of knowledge regarding *in vivo* and *in vitro* models of radiation-induced osteoporosis. Attention will be primarily directed toward acquired deficits in the appendicular skeleton and axial components of the trunk.

FRACTURES OF IRRADIATED BONES AFTER CLINICAL EXPOSURE

The increased incidence of pathologic fracture that occurs within the irradiated volume is largely associated with absorbed dose at or near the fracture location [10]. Patients receiving breast cancer RT exhibit rib fracture rates ranging from 1.8% [11] to 19% [12]. Similarly, patients receiving RT for various pelvic malignancies are at increased risk for fracture at pelvic skeletal locations that

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

absorb dose, including structures of the "hip" (notably the femoral neck, sacrum, and acetabular rim) [2, 13–16]. Among men treated for prostate cancer, fracture incidence was shown in one study to be approximately 6.8%, with a median time to diagnosis of 20 months [17].

In women treated for gynecologic malignancies, the prevalence and timing of these fractures varies among published reports. Kwon and colleagues evaluated pelvic magnetic resonance (MR) images of 510 uterine cancer patients before and after RT: 100 patients (20%) had insufficiency fractures in the pelvis [16], and of these 100 patients, 61% had multiple fractures. The 5-year fracture prevalence rate was 45%, with the cumulative prevalence increasing from 15%, 27%, 32% and 35% at 1-, 2- 3-, and 4-years post-RT, respectively. Only 0.4% of patients experienced avascular necrosis of the femoral head. Two other studies using computed tomography (CT), rather than MR, to diagnose radiographic pelvic fractures in patients with gynecological tumors identified fracture rates of 10% and 13% [15, 18]. In all three studies, a large majority of the insufficiency fractures were near the sacroiliac joint [15, 16, 18]. In the Kwon et al. study, there was no significant difference in the fracture rate of patients who underwent concurrent chemotherapy (17%) during RT and those who did not (21%) [16].

A comprehensive study used data from the National Cancer Institute-Surveillance Epidemiology and End Results–Medicare cancer registry to examine traumatic pelvic fracture rates in nearly 6,500 women over the age of 65 with nonmalignant anal, cervical, or rectal cancers [2]. Using a proportional hazards model, they determined that irradiation increased the hazard ratios for pelvic fractures to 3.16, 1.66, and 1.65 for anal, cervical, and rectal cancers, respectively, relative to patients who did not receive external beam RT as part of treatment at any time post diagnosis. Five-years after RT, fracture rates for non-RT vs RT patients were 7.5% vs 14% (anal cancer), 5.9% vs 8.2% (cervical cancer), and 8.7% vs 11.2% (rectal cancer) [2]. Fracture rates from the arm and vertebrae, which were located outside of the radiation field, were not significantly greater following RT. Anal cancer patients, with a three-times greater risk for pelvic fracture compared to non-RT protocols, have greater doses of irradiation to the femoral head (targeted at the inguinal lymph nodes), again supporting a hypothesis that local radiation effects are a primary contributor to increased fracture risk. While systemic or non-targeted radiation effects cannot be discounted [19], the deleterious clinical response appears to be limited to the irradiated volume.

RADIATION AND VASCULATURE

Damage that occurs to bone following irradiation has historically been considered to result from physiological changes occurring within the vasculature, as well as changes to bone cell number and function [13, 20–25]. Since the turn of the 20th century, radiation-induced bone damage (previously termed "osteitis") was thought to be initiated by a reduction in vascularity throughout the bone [26]. This vascular damage is characterized by swelling and vacuolization of endothelial cells within the osteon [20, 21, 25]. In addition, sclerotic connective tissue is deposited within the marrow cavity. Late fibrosis of the subintima also occurs, along with replacement of vascular smooth muscle cells with a hyaline-like material. These changes result in eventual constriction of the vessel lumen, resulting in localized hypoxia. Bones of the skull and jaw are considered especially at risk for vascular injury due to their superficial location and relative lack of blood vessels [14]. Indeed, loss of vasculature in both the marrow cavity and Haversian system has been identified within the bone of many animal models following radiation exposure [21, 27, 28].

RADIATION EFFECTS ON OSTEOBLASTS

Damage to osteoblasts following irradiation has long been recognized as the greatest contributor to the development of reduced bone mineral density [13, 20, 25, 29]. The overall decrease in the number and activity of osteoblasts following radiation exposure has been documented, along with attenuated matrix formation [9, 28]. *In vitro* and *in vivo* data show impaired bone formation following a decrease in osteoblast proliferation and differentiation, osteoblast cell-cycle arrest, reduced collagen synthesis, and increased apoptosis [24, 30–32]. Lowered levels of runt-related transcription factor 2 (RUNX2) in osteoblast cultures stimulated with bone morphogenic protein-2 (BMP-2) have been observed following irradiation [32]. Receptor activator of nuclear factor-κB ligand (RANKL) mRNA levels in osteoblasts tend to be elevated following irradiation with photons [33]. Additionally, osteoblast precursors appear damaged following exposure [8]. Mesenchymal stem cell (MSC) colony forming ability and overall numbers are lowered after radiation exposure [28]. It may be that oxidative stress contributes to this response [8, 28]. It is important to note, however, that other groups have shown no loss of MSC viability within irradiated bone. Instead, they suggest that damage occurs as a later effect, when terminal osteoblast differentiation occurs [34].

RADIATION EFFECTS ON OSTEOCYTES

While the effects of radiation on osteocyte viability remain unclear, evidence suggests that these cells may be less radiosensitive than osteoblasts. Several studies investigating the status of osteocytes following radiation exposure indicate that the cells remain viable for several months after acute exposures in both mice and rabbits [29, 35–37]. However, other studies have identified loss of osteocytes within irradiated bone [13, 20, 21]. Osteocyte death was confirmed within the cortical lamellar

and Haversian bone of monkey mandibles irradiated with 45 Gy [21]. Interestingly, osteocyte numbers were not affected within trabecular bone.

RADIATION EFFECTS ON OSTEOCLASTS

Research over the past decade has highlighted the substantial role that osteoclasts play in radiation-induced osteoporosis [8, 9]. Irradiation results in increased osteoclast number and activity within the first few days after exposure [9]. Serum tartrate-resistant acid phosphatase (TRAP5b) is increased as early as 24 hours after exposure to total-body X-rays. Osteoclast number and surface (normalized to bone surface) are both greater in rodent bones within the first 3 days after exposure [38]. This early increase in osteoclast number and activity precede a subsequent loss of bone within a week of treatment [8, 9]. However, the majority of the bone loss occurs when the number of osteoblasts and bone formation are unchanged relative to control [9]. The use of bisphosphonate antiresorptive agents (e.g., risedronate) to suppress osteoclast activity can effectively block both a radiation-induced increase in osteoclast activity and loss of bone at multiple skeletal sites [9]. The initial and early increase in osteoclast activity may then be followed by a prolonged decrease in osteoclast activity [39, 40]. A persistent reduction of both bone formation and resorption could sufficiently suppress bone remodeling as to result in damage to the material properties of skeletal tissue [41], which has been described in rodents [42]. A combination of an early yet acute increase in osteoclast activity leading to bone loss, followed by a lengthy reduction in bone formation, could compromise the structural integrity of bone as a late effect. The resulting reduction in turnover could, by lowering bone density and/or altering the mechanical or material properties of bone, lead to an increased incidence of fracture [43].

DETERIORATION OF BONE QUANTITY AND QUALITY AFTER IRRADIATION

Skeletal fractures are known to be a late effect resulting from direct irradiation. These fractures are thought to result from radiation-induced deterioration of both bone quantity and quality [2, 20, 44]. Several factors can influence the response of skeletal tissue to radiation exposure, including the total absorbed dose, radiation energy, dose per fraction, and developmental stage of the patient [12–14]. Osteopenia is often observed at 1-year after cancer RT [13, 25]. The radiation-induced deficits in bone that have been documented include demineralization, thinning, sclerosis, and loss of trabecular bone [13, 20, 25, 44]. However, trabeculae with abnormal, thickened morphology have been documented within the irradiated volumes of patients [14] and animal models [27, 45].

A more comprehensive study published nearly 20 years ago highlights substantial skeletal damage as an early response to RT. Eleven patients with cancer of the uterus/cervix underwent RT, with the third lumbar spine (L3) receiving dose as it was within the treatment field [46]. Twelve patients underwent a therapy regimen that did not include RT. CT scans were performed before treatment, at the end of RT (5 weeks), and at 3, 6, and 12 months post therapy. Quantitative computed tomography (QCT) analysis was performed to quantify L3 trabecular bone mineral content (BMC) values at each time point. Patients not receiving RT had no change in BMC over the course of the year; however, a dramatic loss of BMC was observed from the RT group. These patients experienced a loss of BMC of 32% at 5 weeks, 40% at 3 months, 47% at 6 months, and 49% at 12 months compared to the pre-RT scan [46]. During the period of RT, trabecular bone loss was exceptionally rapid (–6%/week), with significant loss continuing to 6 months without subsequent recovery. One patient experienced a compression fracture of L2 at 6 months after RT. The authors discuss radiation injury to both osteoblasts and osteoclasts, and state that "bone change due to irradiation is a type of low-turnover osteoporosis" [46]. However, the substantial loss of BMC at such early times after initiating RT supports the hypothesis that early activation of osteoclastic bone resorption has a causal role in radiation therapy-induced osteoporosis.

From animal models, acute deterioration of trabecular bone architecture has been identified following exposure to ionizing radiation. Loss of trabecular bone has been documented using microcomputed tomography (μCT) as little as 3 days after exposure to a 2-Gy dose of photons [8]. Trabecular bone microarchitecture and mass are eroded in the proximal tibia, distal femur, and throughout the fifth lumbar vertebrae of mice 1 week after exposure to a 2-Gy dose of radiation [9]. This early loss of trabecular bone appears to translate into prolonged deficits in bone quantity and quality; loss of trabecular bone persists for months after both photon and charged particle exposures [47, 48].

LOSS OF BONE STRENGTH IN ANIMAL MODELS AFTER IRRADIATION

Animal models are necessary to examine not only the mechanisms behind radiation-induced bone loss, but also to identify the cause, extent, and timing of strength reductions in bony elements. Compared with cortical bone, photon radiation appears to produce greater damage to the trabecular network [47]. However, at relatively low doses (i.e., 50 cGy), high linear energy transfer (LET) heavy ion radiation does appear to increase cortical bone porosity, cortical area, and polar moment of inertia [49]. To date, the most direct assessment of radiation-induced reduction in bone strength comes from rodent and rabbit models, although studies are limited. Reduced ultimate

strength of cortical bone from rabbit tibiae has been observed at 4 and 12 months after exposure to a 50-Gy total dose [36]. Compressive testing of mouse distal femora showed a reduction of strength at 12 weeks after 5- and 12-Gy acute doses of X-rays [42]. The subsequent loss of strength as determined by compressive testing and estimated by finite element analysis (FEA) occurred despite a transient increase in bone volume and a sustained elevation of cortical bone mineral content. That is, the bone appeared to be more brittle. Changes in bone strength after irradiation may be influenced by both architectural and material properties. Additionally, a 2-Gy dose of heavy ion radiation induces a loss of vertebral stiffness when tested by compression loading and determined by FEA [50].

CONCLUSION

Clinical RT can compromise the health of normal skeletal tissue, leading to fracture. However, limited research has defined the mechanisms underlying radiation-induced bone loss. Even fewer studies have identified the magnitude and extent of bone loss in patients following RT. Based on research using animal models and cell culture studies, radiation appears to cause an early increase in active bone resorption by somehow stimulating osteoclast activity, followed by a persistent reduction in bone formation. Strength may be further compromised by lowered overall bone density, impaired bone material properties resulting from a low-turnover state, a combination of the two, or other factors. Future research should be aimed at identifying the mediators of bone damage following radiation exposure in order to develop effective therapeutic countermeasures for radiation-induced fracture.

INTRODUCTION

With improvements in therapy more and more children are surviving childhood cancer. The 5-year survival rate for children with cancer is about 82%, and the rate for acute lymphocytic leukemia (ALL), the most common childhood cancer, is about 87% [1, 2]. Survivors of childhood cancer number about 270,000, and close to 1 in 640 people between 20 and 39 years of age have had childhood cancer [3, 4]. As more and more children with cancer are surviving, the number of adults with complications from cancer is increasing, and the cumulative incidence of a chronic health condition years after the cancer diagnosis is 73% [5]. The Childhood Cancer Survivor Study (CCSS) has generated data on the long-term outcomes of pediatric cancer survivors [6]. This chapter focuses on one of the long-term sequelae: deficits in bone mineral density (BMD).

During adolescence approximately 40% of peak bone mass is accumulated. Lack of adequate bone mineral acquisition during this period may compromise peak bone mass, leading to lifelong deficits in bone mineral and predisposing to fractures. In children with cancer, nutritional deficiencies and prolonged decreases in activity may compromise bone accrual. Hormonal deficiencies secondary to cranial irradiation causing growth hormone deficiency and/or central hypogonadism, or gonadal radiation leading to secondary hypogonadism, may further compromising bone accrual [7, 8]. Finally, chemotherapeutic agents, such as glucocorticoids and methotrexate, interfere with bone mineral accretion and skeletal development [7, 8] (see Ref. 7 for a review).

ACUTE LYMPHOCYTIC LEUKEMIA (ALL)

ALL is the most common childhood malignancy and much literature on the skeletal effects of cancer focuses on this population.

At diagnosis of ALL

The ALL disease process may affect bone acquisition; osteopenia (BMD Z-score <–1.0 SD) at diagnosis is reported in 10–46% of children with ALL [9–13]. Osteopenia and/or fractures are evident on radiographs in 13% and 10% of patients, respectively [9].Vertebral compression fractures can be seen at presentation (in 16% of ALL patients in one study [14]) and are associated with a lower BMD lumbar spine Z-score [14]. Bone formation is impaired and markers of bone formation are low [15], including osteocalcin, type I collagen carboxy-terminal propeptide (PICP), and bone-specific alkaline phosphatase (BSAP) [9, 10, 12, 13, 16–19]. Bone resorption may also be impaired [15]. Urinary N-telopeptide (NTX) is normal [10], and type I collagen carboxyl-terminal telopeptide (ICTP) is normal [12, 16] or reduced [13, 17, 18] in most, but not all [20], studies. The reduction in bone formation and resorption markers suggests a low bone turnover

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

state is present at diagnosis [17, 21]. 1,25-dihydroxy vitamin D is reduced in some patients in most [9, 12, 16, 19], but not all [11], studies.

During treatment of ALL

Treatment of ALL is associated with additional loss of bone in some patients [10–12, 16, 19, 20]. Using phalangeal ultrasound for skeletal assessment during treatment of ALL (at diagnosis, and at 6, 12, and 24 months), a rapid deterioration of bone properties was seen after the first 6 months of therapy with subsequent progressive uncoupling of the two quantitative ultrasound (QUS) parameters, which was worse in subjects who developed skeletal complications during treatment [22].

There is not a strong relationship between changes in growth velocity and BMD during therapy. Overall growth is not significantly compromised in most children undergoing cancer treatment, which may explain why the findings of studies using areal BMD do not differ significantly from those of studies using BMAD (apparent volumetric BMD) or quantitative computed tomography (QCT) to correct for size differences [12].

Chemotherapy is associated with a decrease in BMD, and BMD is decreased in patients treated with only chemotherapy [12]. Glucocorticoids and methotrexate are known to predispose to osteopenia and fractures (see Refs. 7 and 23 for a review), and higher cumulative doses of methotrexate [16] and higher doses of glucocorticoids [10] are associated with a lower BMD. Glucocorticoids decrease bone formation, decrease intestinal absorption of calcium, and increase renal calcium excretion. Methotrexate may also inhibit new bone formation and fracture healing (see Ref. 23 for a review). Cranial irradiation is associated with a drop in BMD Z-score during treatment [11]. Lifestyle factors such as calcium intake and physical activity are not correlated with BMD during therapy [12].

Accumulation of normal bone mass may be impaired during therapy. Although induction therapy with prednisolone and methotrexate is associated with a further decrease in bone formation markers, with discontinuation of prednisolone, bone formation markers increase to normal [10, 12, 13, 15–17]; the increase is less in children who received high-dose methotrexate [17]. During induction therapy with prednisolone and methotrexate, bone resportion markers (pyridinoline, ICTP) also decrease and then increase after prednisolone is discontinued [17] to normal or elevated levels [12, 15, 16, 18], suggesting resorption is increased [21]. High doses of methotrexate are associated with an even greater increase in bone resorption markers [17, 20]. These findings suggest that osteoblast and osteoclast activity are suppressed secondary to the actions of glucocorticoids on bone, and that high doses of methotrexate continue to inhibit osteoblast proliferation but increase osteoclast activity [17]. Higher levels of bone formation markers at diagnosis (osteocalcin) and at 1 year (PICP) have been correlated with a higher BMD at 1 year [16]. The levels of 1,25-dihydroxyvitamin D have been reported to be reduced [10, 16, 24] or normal [11, 12]. In one study [12], although 1,25-dihydroxyvitamin D levels were within the normal range, the levels increased significantly in the first 32 weeks of treatment, and the increase was positively correlated with the change in lumbar spine BMD over that period of time [12]. 25-hydroxyvitamin D has been reported to be reduced [16, 24] or normal [10].

Up to 40% of patients sustain a fracture [10, 19, 20]. Fracture rates have been reported to be increased sixfold [12] and tend to occur during or shortly after discontinuation of chemotherapy [25]. Fractures are associated with osteopenia that develops during therapy [15]; children who fracture have a greater decrease in BMD Z-score than children who do not fracture [12, 16]. A decrease in BMD Z-score during treatment is a positive predictor [9, 19], and an increase in bone mineral content (BMC) a negative predictive [9], of subsequent fracture. In one study, an increase in NTX was correlated with the occurrence of a fracture [10].

There have been trials to impact on the loss of BMD with therapy. Pilot studies of oral alendronate during therapy in children with ALL [26, 27] show an increase in the BMD Z-score in most patients treated for 6 to 24 months. No placebo-controlled trials have been carried out, and many issues remain, most notably what the criteria for treatment should be. A randomized exercise intervention trial during treatment of childhood ALL showed no difference in BMD between groups that received the intervention and those who did not, although lack of compliance may have been a factor [28].

After treatment of ALL

In most studies of ALL survivors, the low BMD persists [12, 29–38] although a few studies find that BMD normalizes [39, 40]. Bone formation and resorption markers normalize [41]. In one study after remission of childhood ALL or non-Hodgkin's lymphoma, a decreased BMD was associated with dexamethasone treatment, cranial irradiation, bone marrow transplant, and total body irradiation (TBI) [38].

Most studies find some "catch-up" in the BMD after discontinuation of therapy, and the length of time since cessation of therapy is associated with a higher BMD or BMC [34, 36]. In the short term (0–3 years after discontinuation of ALL therapy), a greater increase in total body BMD is seen in patients compared to controls [41]. In a longitudinal QCT study of ALL survivors at an average of 11 years after ALL diagnosis, the mean lumbar spine BMD Z-score increased with time, although the percentage of individuals with a BMD Z-score <–1.0 SD increased over time [42], suggesting that in a subgroup of patients, catch-up growth in BMD does not occur. Thus, although there may be catch-up in the BMD after the discontinuation of therapy, peak bone mass may not be achieved.

Risk factors associated with a lower BMD in follow-up include Caucasian race [29, 35, 42]; older age at diagnosis

of ALL [23, 42]; poor nutritional status [42]; alcohol consumption [42]; male gender [29, 33, 35, 42]; endocrine abnormalities including growth disturbance, growth hormone deficiency, and hypogonadism [37]; and low physical activity, including exercise capacity (as measured by peak oxygen consumption) [34], a low activity level [33, 34], and muscle strength in the extremities [43]. These physical activity findings are particularly notable as there is evidence that long-term ALL survivors are less likely to meet the Centers for Disease Control and Prevention physical activity recommendations and are more likely to report no leisure-time physical activity compared to the general population [44].

The relative contribution of chemotherapy versus cranial irradiation, with the subsequent hormonal deficiencies, on BMD is not clear. Patients who received chemotherapy in the absence of cranial irradiation have a low BMD in some [13, 25, 33], but not all [25] studies. Previous exposure to methotrexate is associated with a reduction in BMC at the spine [34], and higher doses of methotrexate have been associated with a lower BMD [33, 42]. A history of cranial irradiation has been associated with a low BMD [29, 35, 42, 45], and BMD is inversely correlated with the cranial irradiation dose [35]. Others have found that the use of cranial irradiation status did not predict BMD [36] and that the decrease in BMD seen in adults after treatment for ALL is not dependent on the severity of growth hormone deficiency secondary to cranial irradiation [30]. These findings, taken together, suggest that although chemotherapy and cranial irradiation likely play a role in the low BMD in long-term survivors, additional factors likely adversely affect BMD.

Fracture rates are increased in long-term survivors of ALL. From the time of diagnosis of ALL through the subsequent 5 years, fractures rates are reported to be double that of controls [41]. In one study, the 5-year cumulative incidence of fractures was 28% [46]. Factors associated with a higher risk of fractures include the diagnosis of ALL during adolescence [23, 46], male sex [46], and treatment with dexamethasone versus prednisone [46]. In one study, a history of cranial irradiation was not associated with fracture rate [47].

Children undergoing stem cell transplant (SCT) may be at particularly high risk for deficits in bone mass. A low BMD post transplant has been reported in 36–47% of survivors [48–50]; although in children transplanted at younger than 3 years of age, the prevalence is lower (23.5%) [51]. In children who have undergone SCT, risk factors for osteopenia include female sex [48, 49]; total body irradiation (TBI) [48], and the presence of secondary effects of TBI including delayed pubertal growth, growth hormone deficiency, hypogonadism, or chronic renal insufficiency [48, 49]. Fat mass index is positively correlated with BMD in children who have undergone bone marrow transplant [52].

Nutritional factors may play a role in the bone mineral deficits. Less than 30% of ALL survivors at least 5 years after completion of therapy met the recommended dietary intakes for vitamin D and calcium [53]. Investigators at St. Jude Children's Research Hospital have initiated a placebo-controlled double-blind randomized longitudinal study to compare the effects of nutritional counseling, 800 IU/day vitamin D, and 1,000 mg/day elemental calcium to nutritional counseling with a placebo on changes in BMD and serum and urine markers of bone metabolism in participants at least 5 years after completion of ALL therapy who have a BMD Z-score below 0 [54].

OTHER CANCERS

Survivors of solid tumors also show bone mineral deficits years after therapy. Children with brain tumors may be particularly susceptible to osteopenia due to growth hormone deficiency and hypogonadism following cranial irradiation. Children who survive with a brain tumor have a decreased BMD [55–60], and cranial irradiation may be associated with an even higher prevalence of low BMD [61]. The degree of osteopenia in brain tumor patients is correlated with a reduction in health-related quality of life [57, 61], and children with osteopenia reported more pain that significantly limited physical activity [57].

In pediatric patients with bone sarcomas, bone mineral deficits may not be present initially but may develop with time. Patients with newly diagnosed Ewing sarcoma and osteosarcoma show no deficits in lumbar spine (LS) BMD after completion of neoadjuvant chemotherapy, although in patients with a lower extremity tumor, local deficits are seen and the BMD is lower in the affected compared to the non-affected femoral neck [62]. However, at an average of over 5 years after remission, bone mineral deficits are seen in bone sarcoma survivors, including survivors of Ewing sarcoma and osteosarcomas [63–66], and in other soft tissue sarcomas (rhabdomyosarcoma and non-rhabdomyosarcoma soft tissue sarcomas) [65]. Risk factors for a low BMD included younger age at diagnosis [64, 65], male sex [64], and higher cumulative dose of cyclophosphamide [65].

In a study of children with neuroblastoma, 11.1% (3/27) presented with a BMD Z-score below –2.0, suggesting that neuroblastoma can affected BMD prior to the start of therapy [67]. Low intake of vitamin D and low physical activity, as well as treatment with methotrexate, ifosfamide, bleomycin, and cisplatin, may contribute [63].

There is evidence that Hodgkin's disease survivors have bone mineral deficits. In one series, 34% of survivors of Hodgkin's disease and non-Hodgkin's lymphoma had low ultradistal radius trabecular volumetric BMD by peripheral quantitative computed tomography (pQCT), and 45% had osteopenia (Z-score <–1.0 SD) by dual energy X-ray absorptiometry (DXA), which was negatively correlated with the cumulative dose of corticosteroid administered [68]. In another report, the proportion of Hodgkin's disease survivors with a BMD below the

mean did not differ from the general population, although the proportion with a BMD Z-score <–1.5 SD was 14.7%, significantly greater than the 6.7% reported in the general population [69]. In this study, male gender was associated with an increased risk for a low BMD [69]. A third group found that among patients treated in childhood with chemotherapy alone for Hodgkin's disease, a low total body BMD and LS BMAD were found in women only, but not in men [70].

Nutritional factors may play a role in the bone mineral deficits seen in pediatric patients with a variety of solid tumors. In one study, an average of 14 months after treatment for a pediatric solid tumor (primarily cerebral tumors, Ewing sarcomas, and osteosarcomas) calcium intake was inadequate in 75% of patients, and vitamin D levels were less than 20 ng/ml in 61.5% and less than 10 ng/ml in 11.5% of patients [71]. Lack of physical activity may play a greater role in the low BMD seen in pediatric solid tumor survivors than in other cancers. In the CCSS cohort, the highest prevalence of physical performance limitations was seen in survivors of brain tumors (36.9%), bone tumors (26.6%), and Hodgkin's disease (23.3%) [72, 73].

CONCLUSIONS

An important long-term consequence of childhood cancer is deficits in bone mass accrual that often persist into adulthood, thereby increasing the risk of osteoporosis and fractures. The chemotherapies and radiation therapies used to treat these cancers are in large part responsible for the increased risk of a low BMD. However, there are a number of modifiable contributing factors. In recognition of the long-term morbidities associated with treatment of pediatric malignancies, including the bone mineral deficits the Children's Oncology Group (COG) has produced the 2006 COG long-term follow-up guidelines [7, 15, 74, 75]. Guidelines for the management of the bone morbidity that occurs after treatment of childhood cancer include recommendations directed at modifiable factors that may contribute, including exercise, adequate calcium, and vitamin D intake, and a baseline bone density scan 2 or more years after therapy has been completed [75]. In addition, early identification of growth hormone deficiency and hypogonadism may improve bone health in pediatric cancer survivors. The hope is that the early detection of bone mineral deficits and treatment of the modifiable factors will improve the prognosis in survivors of childhood cancer.

Treatment and Prevention of Bone Metastases and Myeloma Bone Disease

Jean-Jacques Body

Clinical Aspects 741
Bisphosphonates and Denosumab in Tumor Bone Disease 742
References 750

CLINICAL ASPECTS

According to various large series, up to 80–90% of patients with advanced cancer will develop bone metastases. The skeleton is the most common site of metastatic disease. It is also the most frequent site of first distant relapse in breast and prostate cancers.

Breast cancer

Metastatic bone disease causes considerable distress to breast cancer patients. Because of the long clinical course breast cancer may follow, morbidity due to tumor bone disease also makes major demands on resources for health care provision. The term "skeletal-related events" (SREs) refers to four major objective complications of tumor bone disease: pathological fractures, need for radiotherapy, need for bone surgery, and spinal cord compression [1]. Hypercalcemia is not counted as an SRE in most trials because it is generally easily treated with a bisphosphonate, and it is often of paraneoplastic origin. Such major complications will be observed in up to one-third of the patients whose first relapse is in bone.

Bone pain can be the source of great suffering, causing the most patient concern and physician visits [2]. A recent prospective study suggests that patients with osteolytic lesions, as evaluated by a computed tomography (CT) scan of the most painful lesions, have the highest mean pain score and analgesic consumption, and the least mean scores for quality of life as compared with patients who have mixed or sclerotic lesions [3]. This distinction between osteolytic and osteosclerotic actually represents two extremes of a continuum in which dysregulation of the normal bone remodeling process occurs. Hypercalcemia classically occurs in 10–15% of the cases, spinal cord compression in 5–10%, and, when long bones are invaded, fractures will occur in 10–20% of the cases [4, 5]. Pathological fractures are a dramatic consequence of tumor bone disease. They occur with a median onset of 11 months from the initial diagnosis of bone involvement. Solitary skeletal metastases carry a better prognosis than multiple metastases and are associated with an earlier stage and a more favorable histology. Interestingly, the sternum was the most commonly involved bone in a series of 289 patients with solitary skeletal metastasis [6].

Across all tumor types, patients with breast cancer have the highest incidence of skeletal complications. Taken from data in placebo groups of randomized bisphosphonates trials, the mean skeletal morbidity rate, i.e., the mean number of SREs per year, varies between 2.2 and 4.0 [4, 5, 7–9]. Patients who have metastases only in the skeleton have a higher rate of SREs than patients who also have bone and visceral metastases, e.g., a two- to threefold increase in pathological fractures. Survival from diagnosis of bone metastases is longest for patients with only bone metastases (median survival 24 months) and least for patients with bone and liver metastases

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

(5.5 months) [9]. The occurrence of SREs has a marked detrimental effect on survival in patients with bone metastases [10].

Prostate cancer

The most common sites of bone metastases are throughout the axial skeleton, whereas long bones are invaded much less often. Pain is the most common symptom. Surprisingly, there are only a few studies documenting the frequency and the nature of bone metastatic complications in patients with hormone-refractory prostate cancer [11–13]. The incidence of SREs can be best estimated by analyzing the placebo group of the large scale zoledronic acid-controlled trial [12, 13]. Inclusion criteria required that patients had at least one bone metastasis and an augmentation of prostate-specific antigen (PSA) levels while on hormonal therapy. During a follow-up period of 2 years, nearly one-half of the patients developed one or more SREs, which, in this study, also included a change in antineoplastic therapy to treat bone pain. The two most frequent complications were the need for radiation therapy and the occurrence of pathological fractures. These fractures appeared more frequently at peripheral than at vertebral sites. The median time to the first SRE was 10.5 months, whereas the mean skeletal morbidity rate per year was nearly 1.5. The median survival was 9.5 months [13].

Multiple myeloma

Bone pain is a presenting feature in three-fourths of the patients with multiple myeloma. Back pain correlates with the presence of vertebral fractures that are present in more than half the patients at diagnosis. Extensive osteolytic lesions are frequent in this aggressive bone disease, and, typically, they do not heal despite successful antineoplastic treatment. Diffuse osteoporosis can also be a presenting and misleading feature. The increased fracture rate seems to be especially high around the time of diagnosis. In a large retrospective cohort study, fracture risk was increased 16-fold in the year before diagnosis and 9-fold thereafter. Fractures of the vertebrae and ribs were the most frequent [14].

BISPHOSPHONATES AND DENOSUMAB IN TUMOR BONE DISEASE

Mode of action of bisphosphonates and denosumab: Clinical relevance

The mechanisms of action of these two classes of inhibitors of osteoclast-mediated bone resorption are reviewed in other chapters of the *Primer* and in a recent exhaustive review article [15]. Contrasting differences in the mode of action are relevant for the prevention and the treatment of bone metastases.

Bisphosphonates are widely used for the treatment and the prevention of SREs in patients with cancer and bone metastases. They concentrate in the skeleton, primarily at active remodeling sites. They are embedded in bone where they can remain inactive for years. They are released in the acidic environment of the resorption lacunae under active osteoclasts and are taken up by them. Bisphosphonates will then interrupt the "vicious cycle" of tumor-mediated osteolysis by inhibiting the activity of bone-resorbing osteoclasts and inducing their apoptosis [16].

An increased expression and secretion of receptor activator of nuclear factor-κB (RANK) ligand (RANKL) plays a key role in the pathogenesis of tumor-induced bone destruction by stimulating osteoclast formation and function [15]. Osteoclast formation and activity are regulated via RANK through the coordinated expression of RANKL and osteoprotegerin. Denosumab, a new treatment option, is a fully human monoclonal antibody against human RANKL. By binding to RANKL, denosumab affects the key signaling pathway involved in bone remodeling and disrupts the "vicious cycle" of bone destruction stimulated by the metastasized tumor cells. Denosumab inhibits the formation and the activity of osteoclasts, which probably contributes to a larger inhibitory effect on bone resorption than what is achieved with bisphosphonates (see below). On the other hand, unlike bisphosphonates, denosumab shows no evidence of sustained binding to bone surfaces and is not incorporated into the bone matrix. The inhibitory action of denosumab on bone resorption is thus more transient, and a possible rebound effect is a concern, at least theoretically, if the treatment is stopped. These considerations have evident implications for the long-term treatment of patients with bone metastases since denosumab should probably not be stopped in patients with active tumor bone disease.

Cancer hypercalcemia

Bisphosphonates were first successfully used in tumor-induced hypercalcemia. This use is reviewed in another chapter of the *Primer*.

Prevention of skeletal-Related events

Breast cancer

Bisphosphonates can relieve metastatic bone pain, decrease the frequency of SREs, and improve patient functioning and quality of life [17]. Treatment and prevention of metastatic bone pain are now part of the long-term management of metastatic bone disease with bisphosphonates. Randomized placebo-controlled trials have shown that intravenous pamidronate, clodronate, ibandronate, and zoledronic acid exert useful pain relief

[5, 18]. In a phase III trial of patients with breast cancer, pain and analgesic scores were reduced to a similar extent after 1 year with zoledronic acid and pamidronate [19]. In phase III trials of intravenous and oral ibandronate, bone pain was reduced and similarly maintained below baseline for 2 years [7, 20]. There were also significant improvements in global quality of life and physical functioning with intravenous or oral ibandronate versus placebo [20]. However, bisphosphonates have to be considered as co-analgesics, and they cannot replace opioids for the treatment of severe bone pain. In recent comparative trials, the delay in the requirement of opioids to control bone pain has actually become a measure of the relative efficacy of inhibitors of bone resorption.

Bisphosphonates constitute an effective therapeutic means for the prevention of skeletal complications secondary to bone metastases in breast cancer. Several placebo-controlled trials and fewer comparative trials against another bisphosphonate have been performed. Assessment of treatment effects has often used the first-event analyses, such as the proportion of patients with at least one SRE or time to the first event. These are quite objective and conservative end points but they do not take into account all subsequent events that occur in any given patient. From a clinical perspective, an aggregate score of symptomatic SREs is more relevant. Skeletal morbidity rate (SMR) or skeletal morbidity period rate (SMPR, the number of periods with at least 1 SRE) take into account the occurrence of multiple SREs. More recently, multiple-event analyses have been increasingly used, as they are able to model all events and the time between events. They allow the calculation of a hazard ratio that indicates the relative risk of skeletal events between two treatment groups.

Clinical trials of the bisphosphonates clodronate, in Europe, and pamidronate, in the United States and Europe, have established their effectiveness in breast cancer patients with bone metastases [8, 21–23]. Clodronate is less effective than other bisphosphonates for the prevention of SREs, as demonstrated in a limited comparative trial against pamidronate [24, 25]. Two double-blind randomized placebo-controlled trials comparing 90 mg pamidronate infusions every 4 weeks to placebo infusions for up to 2 years in addition to chemo- or hormonal therapy in large series of breast cancer patients with at least one lytic bone metastasis demonstrated that bisphosphonates can reduce SMR by more than one-third, increase the median time to the occurrence of the first SRE by almost 50%, and reduce the proportion of patients having any SRE [8, 23]. More convenient and possibly more effective aminobisphosphonates have emerged. Zoledronic acid is now widely used for patients with bone metastases from various tumors [13, 19, 26–28], and ibandronate has also been approved in many countries, but not the U.S., for the prevention of skeletal events in patients with breast cancer and bone metastases.

Three randomized, double-blind, multicenter trials assessed the efficacy of zoledronic acid in patients with breast cancer and multiple myeloma, in prostate cancer, and in lung or other solid tumors. The primary efficacy end point was the proportion of patients with at least one SRE. Secondary end points included time to first SRE, SMR, and Andersen-Gill multiple-event analysis. Patients with breast cancer or multiple myeloma (n = 1648) were randomized to a 15-minute infusion of 4 or 8 mg of zoledronic acid or a 2-hour infusion of pamidronate 90 mg every 3–4 weeks [19, 26]. The proportion of patients with at least one SRE was similar in all treatment groups and the preestablished criterion for non-inferiority of zoledronic acid to pamidronate was thus met. Zoledronic acid 8 mg was not more effective than the 4-mg dose but was associated with an increased frequency of renal adverse events, explaining why all patients in that treatment arm were switched to the lower dose of zoledronic acid during all phase III trials. Median time to the first SRE was approximately 1 year in the three treatment groups, and SMRs were also not significantly different. A preplanned multiple-event analysis, according to the Andersen-Gill model, showed, however, that 4 mg of zoledronic acid reduced the risk of developing a skeletal complication by an additional 20% over that achieved by pamidronate 90 mg in the breast cancer subgroup ($P < 0.05$) (Fig. 90.1, top panel) [26]. The short infusion time (15 minutes compared with 1 or 2 hours for pamidronate) offers a quite convenient therapy. Zoledronic acid is still viewed as the standard treatment for metastatic bone disease in breast cancer [29]. Moreover, limited data suggest that switching from either pamidronate or clodronate to second-line zoledronic acid after an SRE or progression of bone metastases can significantly improve pain control and reduce bone turnover markers [29].

In the U.S., only zoledronic acid and pamidronate, and more recently denosumab, are approved to treat patients with bone metastases. However, the efficacy of intravenous and oral ibandronate has been demonstrated in randomized double-blind, placebo-controlled studies [7, 30]. Breast cancer patients were randomized to ibandronate 6 mg or placebo infused over 1–2 hours every 3–4 weeks in the intravenous trial, whereas oral ibandronate 50 mg was given once daily, 1 hour before breakfast. The primary efficacy end point was the skeletal morbidity period rate (SMPR), defined as the number of 12-week periods with skeletal complications (vertebral fractures, nonvertebral fractures, radiotherapy to bone and surgery to bone) divided by the total observation time. Secondary end points also included a multiple-event analysis. Intravenous and oral ibandronate significantly reduced SMPR compared with placebo ($P < 0.005$ for both). Multiple-event Poisson regression analysis showed that intravenous ibandronate led to a statistically significant 40% reduction in the risk of SREs compared with placebo (Fig. 90.1, lower panel; $P < 0.005$). The effect of oral ibandronate 50 mg on the risk of SREs was similar (Fig. 90.1, lower panel; 38% reduction versus placebo, $P < 0.0001$).

Bisphosphonates may be associated with renal toxicity, which can complicate the use of these agents in

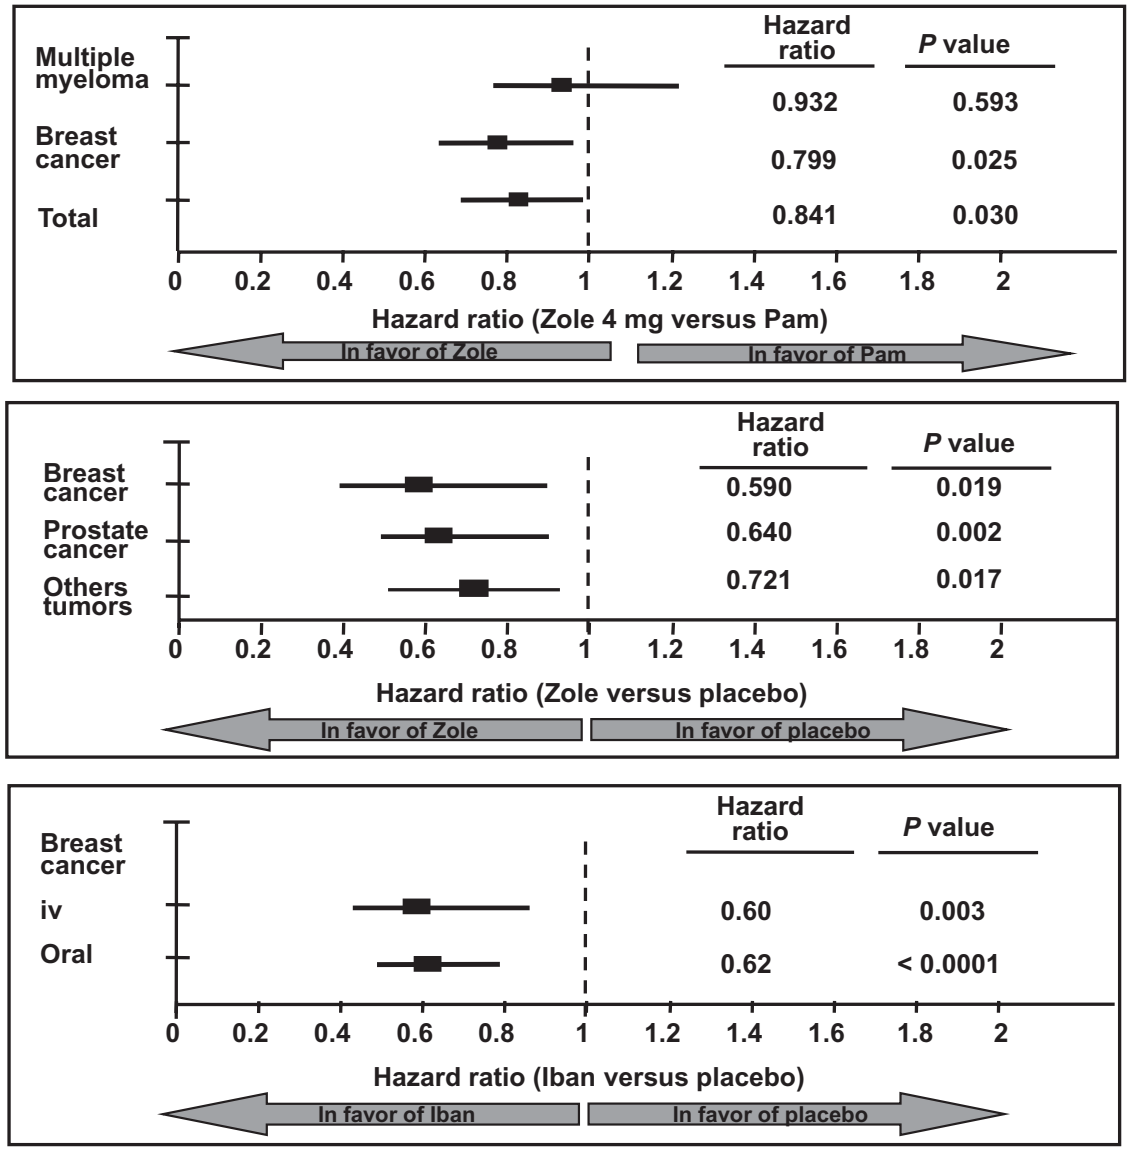

Fig. 90.1. Effects of long-term therapy with bisphosphonates on the risk of developing a skeletal complication in patients with bone metastases. Data are summarized by a multiple-event analysis (Andersen-Gill model for zoledronic acid and Poisson regression analysis for ibandronate). Hazard ratios (and 95% CI) are shown in the left part of each graph with corresponding P values indicated in the right parts. The upper graph is taken from Ref. 26; data in the middle graph are from Refs. 18, 13, and 44; data in the lower graph relate to ibandronate and are taken from Refs. 7 and 30.

patients with renal insufficiency; this is especially important in elderly patients who often have impaired renal function. Creatinine clearance should be monitored during treatment, and for zoledronic acid at least, dosing should be withheld if renal function deteriorates [31, 32]. Denosumab represents a new treatment option for the prevention of SREs in patients with bone metastases from solid tumors. Denosumab is not eliminated by the kidneys and monitoring of renal function is not necessary. Although recent American Society for Clinical Oncology (ASCO) guidelines suggest there is insufficient evidence to recommend one bone modifying agent over another in the management of metastatic bone disease in breast cancer [33], pivotal phase III trials indicate that denosumab has improved efficacy over the widely used bisphosphonate, zoledronic acid [34].

The treatment schedule of denosumab used in comparative phase III trials has been selected from two phase II studies. The first trial included women with breast cancer–related bone metastases who had not received prior intravenous bisphosphonate treatment [35, 36]. In all, 255 women were randomized to one of five denosumab regimens or open-label intravenous bisphosphonate for 24 weeks. All doses of denosumab reduced the

levels of uNTx/Cr within 1 week after the first treatment dose, and this was sustained throughout the treatment period. At study week 13 (the primary end point), there was a median percentage reduction of 71% in uNTx/Cr in the pooled denosumab groups compared with a reduction of 79% with bisphosphonate therapy [35]. Similar changes in uNTx/Cr were seen at week 25 [36]. In the second phase II trial, denosumab efficacy was assessed in patients with bone metastases who had received prior intravenous bisphosphonate therapy. In this study, 111 patients with breast cancer, prostate cancer, or other solid tumors were randomized to subcutaneous denosumab 180 mg every 4 weeks or every 12 weeks, or continued intravenous bisphosphonate therapy for 25 weeks [37]. The patients had to have elevated uNTx levels at screening despite ongoing bisphosphonate therapy, and so were not considered to be responding adequately to bisphosphonates. At week 13, the proportion of patients achieving normal uNTx levels was significantly greater among individuals who received denosumab every 4 weeks (78%) and every 12 weeks (64%) than in those treated with bisphosphonates (29%). More denosumab-treated patients maintained normalized uNTx levels over 25 weeks compared with bisphosphonate-treated patients [37].

Further analysis of these two phase II studies showed that denosumab provided similar median percentage reductions in uNTx/Cr at week 25 in bisphosphonate-naïve patients (75%) and those previously treated with bisphosphonate (80%) [38]. The median time to reach uNTx levels less than 50 nmol/L BCE/mM creatinine with denosumab treatment was 9 days for both bisphosphonate-naïve and previously treated patients. This compares with 8 days for intravenous bisphosphonate therapy in naïve patients and 65 days in previously treated patients. Denosumab also provided substantially greater median percentage reductions in tartrate-resistant acid phosphatase (TRAP-5b, a surrogate marker of osteoclast number) at week 25 than intravenous bisphosphonate therapy (73% vs 11%) in patients previously treated with intravenous bisphosphonates. This suggests that functioning osteoclasts are still present in patients showing an inadequate response to bisphosphonate therapy and that switching to denosumab may help suppress their activity. This finding confirms the different mechanism of action of denosumab compared with bisphosphonates and suggests that denosumab may prove to be especially effective in patients who respond poorly to bisphosphonate therapy.

The effects of denosumab and zoledronic acid on SREs in breast cancer patients with bone metastases have been recently compared in a randomized, active-controlled, double-blind, double-dummy study including over 2,000 patients [39]. Patients were randomized equally to receive subcutaneous denosumab 120 mg and an intravenous placebo every 4 weeks, or intravenous zoledronic acid 4 mg (dose adjusted for creatinine clearance) and a subcutaneous placebo every 4 weeks. Patients were strongly recommended to take daily supplemental calcium and vitamin D. The primary end point was the time to the first on-study SRE (classically defined as pathologic fracture, radiation or surgery to bone, or spinal cord compression) assessed for treatment non-inferiority; if non-inferiority was proven, treatment superiority was tested as a secondary end point. Denosumab increased the time to first on-study SRE by 18% compared with zoledronic acid [hazard ratio (HR): 0.82; P = 0.01 for superiority; Fig. 90.2, left panel]. The median time to the first on-study SRE was 26.4 months for the zoledronic acid group and had not been reached for the denosumab treatment group. Denosumab also significantly delayed the time to the first and subsequent on-study SREs by 23% compared with zoledronic acid (multiple-event analysis, P = 0.001). The mean skeletal morbidity rate was also significantly lower with denosumab than with zoledronic acid (0.45 vs 0.58 events per patient per year; P = 0.004), which represents a reduction of 22% with denosumab. Median reductions in bone turnover markers at week 13 were greater with denosumab than with zoledronic acid. Overall survival and disease progression were similar in the two treatment groups.

It is now recommended to start bisphosphonates (or denosumab) as soon as bone metastases are diagnosed in order to delay the first SRE and to reduce the complication rate of metastatic bone disease. ASCO guidelines recommend that, once initiated, intravenous bisphosphonates should be continued until there is a substantial decline in the patient's general performance status [33]. However, criteria are lacking to determine if and how long an individual patient benefits from the administration of bisphosphonates. Promoting lifelong therapy is in contradiction with the paucity of data regarding the usefulness and the safety of treatment durations beyond 2 to 3 years. Stopping zoledronic acid therapy, at least temporarily, or reducing the frequency of the infusions (e.g., an infusion every 3 months) is often considered in patients whose bone disease is not "aggressive" and is well controlled by the antineoplastic treatment. However, no data or specific guidelines are available yet to give firm support to intermittent zoledronic acid treatments or a reduction in the frequency of infusions [40]. The pharmacokinetics of denosumab argues against intermittent treatments. Unlike bisphosphonates, denosumab is not stored in bone and interrupting its administration is probably not without risks, at least if the bone disease is not controlled by the antineoplastic treatment. A reduction in the frequency of denosumab injections, guided by the evolution of metastatic bone disease, is probably a better alternative than intermittent treatments. Long-term studies with denosumab are ongoing and should give more information on the balance between efficacy and risks of prolonged therapy.

Prostate cancer

Skeletal metastases from prostate cancer are typically osteoblastic. Therefore, it was traditionally not believed that this form of bone metastasis might respond to

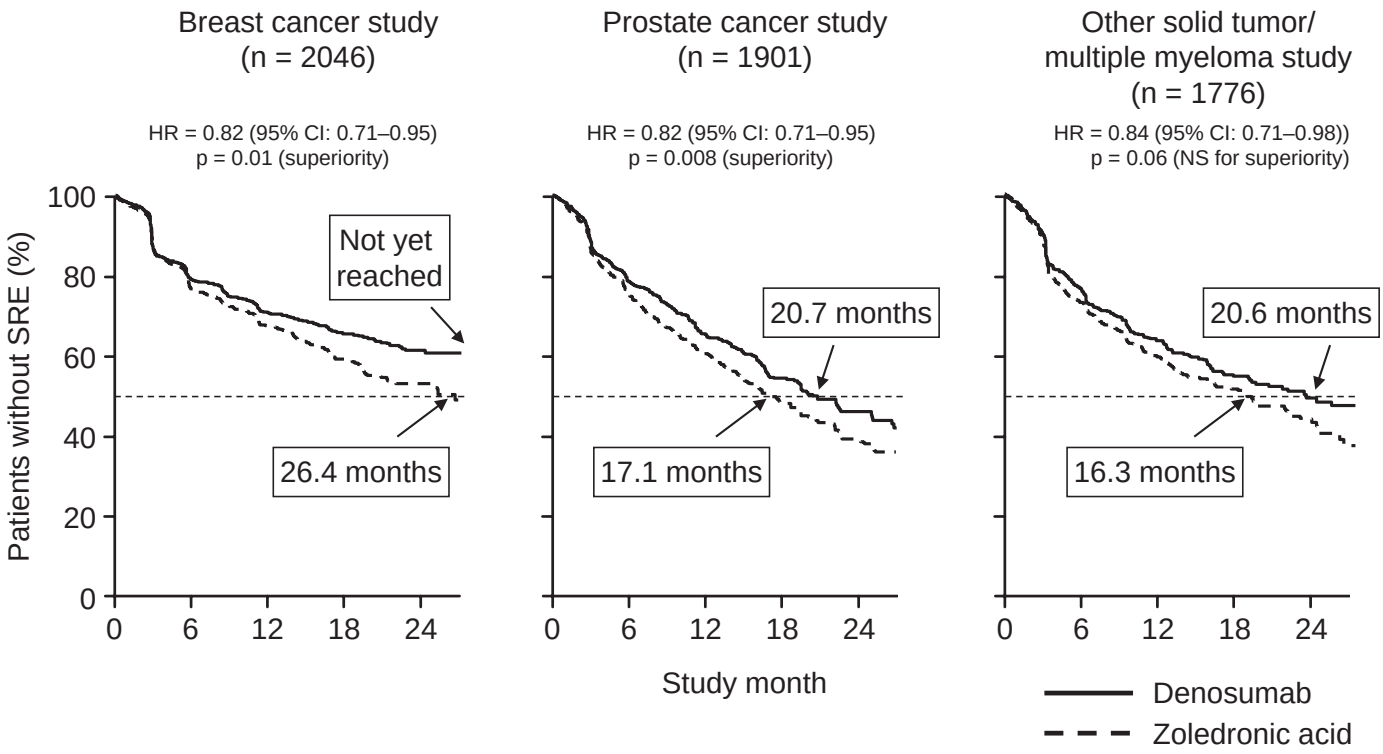

Fig. 90.2. Kaplan–Meier estimates of time to first on-study SRE with denosumab and zoledronic acid in three double-blind, double-dummy phase III clinical trials. Hazard ratios (and 95% CI) are shown above each graph with corresponding P values for superiority testing. (Adapted from Ref. 34.)

antiresorptive therapy. Meanwhile, histomorphometric analyses of bone biopsies and studies on biochemical markers of bone turnover demonstrated that enhanced bone formation in osteoblastic lesions is accompanied by a marked increase in the bone resorption rate [41].

Initial uncontrolled trials with bisphosphonates were often positive, while subsequent placebo-controlled studies were usually negative, whether for clodronate or for pamidronate [11]. The primary objective of the pivotal placebo-controlled study of zoledronic acid of 643 men with bone metastases and progressive prostate cancer after androgen deprivation therapy was to demonstrate a reduction in the frequency of objective SREs following bisphosphonate therapy. Castrate-refractory prostate cancer patients with bone metastases were randomized to receive intravenous zoledronic acid 8 mg or 4 mg or placebo every 3–4 weeks [12, 13]. As mentioned above, the group receiving 8 mg was switched during the trial to 4 mg because of renal toxicity. This trial established zoledronic acid as the first bone-modifying agent to benefit men with castrate-resistant prostate cancer and bone metastases. At the end of the core trial, there was a relative reduction of 25% in the number of patients presenting an objective bone complication. The time to the first SRE was also improved with zoledronic acid. In a multiple-event analysis, 4 mg of zoledronic acid significantly decreased the risk of developing skeletal complications by 36% compared with placebo ($P < 0.005$) (Fig. 90.1, middle panel). Other secondary end points, including the time to the first SRE or the percentage of patients who presented a fracture, were also significantly reduced in the 4-mg zoledronic acid group. One can speculate that part of the favorable effects of zoledronic acid, especially on the fracture rate, could be due to effective therapy of castration-induced osteoporosis. The effect on bone pain appeared to be less impressive than in breast cancer. A favorable pain response, defined as a 2-point difference on the 11-point scale of the BPI assessment, was observed in 33% of the zoledronic acid-treated patients compared with 25% for patients receiving a placebo [42].

Denosumab was recently shown to be superior to zoledronic acid in reducing the risk of SREs in a study that involved more than 1,900 men with castrate-resistant prostate cancer and bone metastases [43]. Denosumab delayed the time to the first on-study SRE by 18% compared with zoledronic acid (Fig. 90.2, middle panel; HR: 0.82; $P = 0.008$ for superiority). The median time to the first on-study SRE was 3.6 months longer with denosumab compared with zoledronic acid. Denosumab also significantly delayed the time to the first and subsequent on-study SREs by 18% compared with zoledronic acid ($P = 0.008$). As for the breast cancer study, overall survival and disease progression did not differ significantly between the treatment groups. At week 13, denosumab

provided significantly greater median reductions than zoledronic acid in levels of the bone markers uNTx/Cr and serum bone alkaline phosphatase (BAP).

On the basis of these studies, zoledronic acid or denosumab should be recommended for all patients with castrate-refractory prostate cancer and bone metastases, especially when they are symptomatic. It is often tempting to start bone-modifying agents earlier in the course of the disease, especially if the bone disease causes clinically significant pain or after an SRE has occurred. One should wait, however, for the results of an ongoing prospective trial in patients with metastatic castration-sensitive prostate cancer.

Other solid tumors

In a phase III placebo-controlled study conducted in patients with lung and other solid tumors, zoledronic acid produced less impressive results than in other cancers, partly because of the short survival of lung cancer patients [44]. There was no significant effect on bone pain or quality of life. At 9 months, the primary end point (percentage of patients with an SRE) was not significantly lower with zoledronic acid 4 mg than with placebo, but a multiple-event analysis indicated a favorable effect (Fig. 90.1, middle panel). Retrospective subset analysis of patients with kidney cancer suggested a marked efficacy in that particular tumor.

Zoledronic acid was more recently compared to denosumab in 1,800 patients with bone metastases and solid tumors other than prostate or breast, or with multiple myeloma [45]. Approximately 40% of patients in that study had non-small-cell lung cancer, and 10% had multiple myeloma. Denosumab was non-inferior to zoledronic acid in delaying the time to the first on-study SRE (Fig. 90.2, right panel; HR = 0.84). However, after adjustment for multiple comparisons, the difference between the groups was not statistically significant for treatment superiority ($P = 0.06$). Analysis for multiple events showed a nonsignificant difference in the time to first and subsequent on-study SREs between both compounds. In tumor types other than breast, prostate, or myeloma, it is reasonable to start bisphosphonates (or denosumab) if the skeleton is one of (or the) predominant symptomatic metastatic site(s) and expected survival time is at least 3–6 months.

Multiple myeloma

A systematic review of the various therapeutic options for the management of multiple myeloma has considered the introduction of bisphosphonates as one of the two most important therapeutic advances for this disease (the other one being the use of high-dose chemotherapy) [46]. ASCO guidelines recommend starting bisphosphonates in patients with lytic disease on plain X-rays or imaging studies, or with spine compression fracture(s) from osteopenia. The panel still considers it "reasonable" to start bisphosphonates in patients with osteopenia based on plain radiographs or bone mineral density (BMD) measurement but does not recommend them in patients with solitary plasmacytoma or smoldering or indolent myeloma [47]. The recommendations of the European Myeloma Network are similar, although they firmly recommend starting bisphosphonates also upon detection of severe osteopenia or osteoporosis [48].

The Cochrane Myeloma Review Group has reported a meta-analysis based on 11 trials. This review concluded that both pamidronate and clodronate reduce the incidence of hypercalcemia, the pain index, and the number of vertebral fractures in myeloma patients [49]. In the largest placebo-controlled trial, the proportion of patients developing any SRE was significantly ($P < 0.001$) smaller in the pamidronate than in the placebo group, and, at the end of a second year extension of the trial, the mean number of skeletal events per year was 1.3 in the pamidronate group versus 2.2 in the placebo group [50]. The newer, more potent bisphosphonate zoledronic acid has been shown to have a comparable efficacy to pamidronate in a randomized phase III trial including myeloma patients (Fig. 90.1, upper panel) [26]. Although there is no direct comparative trial between clodronate and pamidronate or zoledronic acid, the ASCO Panel recommends only intravenous pamidronate or zoledronic acid in light of the use of the time to the first event as the primary end point and a more complete assessment of bony complications [47]. The European Myeloma Network also advises to use the intravenous route and underlies that zoledronic acid and pamidronate are equally effective in terms of reducing SREs [48]. European guidelines advise that bisphosphonates should be given for 2 years and continued if there is evidence of active myeloma bone disease [48], whereas ASCO recommends to seriously consider the discontinuation of bisphosphonates in patients with responsive or stable disease after 2 years of therapy. Bisphosphonates should then be resumed upon relapse with new-onset SREs [47]. A consensus from the Mayo Clinic advises decreasing the frequency of the infusions to every 3 months if bisphosphonates are continued after 2 years [51]. Even if this is a reasonable recommendation in order to reduce the risk of osteonecrosis of the jaw, there are no prospective trials data to support it.

Denosumab has only been studied in a limited number of myeloma patients; they comprised only 10% of patients in the phase III study [45]. There was an unfavorable trend for denosumab seen in an *ad hoc* analysis of overall survival in the subgroup of patients with myeloma. However, the denosumab and zoledronic acid arms were not well balanced for clinical subgroups of myeloma patients, so it is risky to draw conclusions from these limited data. This probably contributed to the reasoning behind why the U.S. FDA and the European Medicines Agency have so far approved denosumab in patients with solid tumors only and not in those with multiple myeloma. A randomized, double-blind study of denosumab versus zoledronic acid in newly diagnosed patients with myeloma is ongoing and should provide a clearer indication of the effects of denosumab in myeloma. Zoledronic acid has been shown to reduce the risk of SREs in

patients with multiple myeloma with similar efficacy to pamidronate, and it is likely that this will also be the case for the comparison between denosumab and zoledronic acid.

Safety aspects

Although generally well tolerated, bisphosphonates and denosumab are occasionally associated with adverse events that are reviewed more extensively in other chapters of the *Primer*. Hypocalcemia is a side effect that may occur with all bisphosphonates, but especially in vitamin D-deficient patients. It is advisable to administer calcium and vitamin D to all patients on prolonged bisphosphonate or denosumab therapy to avoid hypocalcemia and the deleterious consequences of chronic secondary hyperparathyroidism. Hypocalcemia was reported more frequently with denosumab than with zoledronic acid in the integrated analysis of the three phase III studies (9.6% vs 5.0%) [52]. The findings are consistent with the more marked inhibition of bone resorption with denosumab suggested by the larger decrease in bone resorption markers. The majority of hypocalcemia events after zoledronic acid or denosumab administration are transient and asymptomatic, but some may be severe.

The reported incidence of renal function deterioration in clinical trials of zoledronic acid was 10.7% in patients with multiple myeloma or breast cancer, not significantly different from the pamidronate figures in that trial [19]. Rare cases of renal failure with zoledronic acid have been subsequently reported, and renal monitoring is now recommended before each infusion of zoledronic acid. The product label advocates stepwise dose reductions when baseline creatinine clearance is 30–60 ml/min [31]. Zoledronic acid is not recommended in patients with severe renal deterioration or those taking nephrotoxic medications. Prolonged use of intravenous ibandronate in patients with breast cancer has shown a low incidence of renal adverse events that is comparable to placebo [7]. The monitoring of renal function is not necessary with denosumab, as the drug is not excreted by the kidney. However, denosumab has not been studied in cancer patients with creatinine clearance less than 30 ml/min.

Osteonecrosis of the jaw (ONJ) is the most feared side effect of prolonged bisphosphonate or denosumab therapy [34, 53, 54]. Although sometimes devastating, ONJ can also present as an asymptomatic bony exposure. Its definition, early diagnosis, and follow-up have been reviewed by an American Society for Bone and Mineral Research (ASBMR) task force [54]. According to the series, its prevalence varies between 1% and 10% in patients on prolonged bisphosphonate therapy, with higher rates in myeloma than in solid tumors. It typically occurs after dental extraction but can also occur spontaneously. The prolonged inhibition of bone remodeling with lack of repair of physiologic microfractures due to constant stress from masticatory forces probably plays a key role in the development of ONJ, while the decreased intraosseous blood flow, and infections in the maxilla and/or mandible play a contributory role. The risk appears to be higher after zoledronic acid than after pamidronate, but is essentially linked to the duration of therapy. In the comparative trials between zoledronic acid and denosumab, there were numerically more cases of ONJ in the denosumab groups but the integrated analysis of the three comparative trials showed that the cumulative incidence of confirmed ONJ after 3 years was not significantly different between denosumab and zoledronic acid treatments (1.8% vs 1.3%; p = 0.13) [55]. Tooth extraction was reported for 62% of those patients. Management was mostly conservative and healing occurred in 36% of patients [55]. Patients should receive a comprehensive dental examination before treatment with bisphosphonates or denosumab to treat dental problems that may require surgical or invasive dental procedures. After therapy initiation, invasive dental procedures should be avoided if possible. Recent studies in patients with myeloma or solid tumors showed that the frequency of ONJ could be lowered by at least one-half by implementation of a preventive dental program, including a detailed assessment of dental status, regular dental care, and avoidance of invasive dental procedures during treatment with zoledronic acid [56–58].

Bisphosphonates as adjuvant therapy

Another potential major role for bisphosphonates is the prevention or at least a delay in the development of bone metastases. Bisphosphonates have the potential to reduce tumor burden in bone, whether indirectly, by decreasing bone turnover, or directly, by one or several antitumor effects [59]. Initial adjuvant studies were conducted with clodronate, but the results were contradictory. The only double-blind placebo-controlled trial involving more than 1,000 unselected breast cancer patients after surgery treated for 2 years with 1,600 mg clodronate or a placebo indicates that clodronate could reduce the incidence of bone metastases (by 31% at 5 years, P = 0.043) and may prolong survival (P = 0.048) [60]. The recently published trial of the National Surgical Adjuvant Breast Project (NSABP) B-34, conducted in 3,323 women assigned in a 1:1 ratio to either clodronate or placebo for 3 years, showed no differences in DFS or overall survival between groups. However, DFS was significantly prolonged in women age 50 years or older on study entry (61).

In early breast cancer, zoledronic acid and denosumab have been studied in the adjuvant setting for preventing aromatase inhibitor-induced bone loss (reviewed in Chapter 86 of the *Primer*). The phase III Austrian Breast & Colorectal Cancer Study Group (ABCSG)-12 trial investigated the adjuvant use of zoledronic acid 4 mg every 6 months in 1,800 premenopausal patients with hormone receptor-positive breast cancer receiving ovarian suppression for 3 years in combination with either tamoxifen or anastrozole. At a median follow-up of 4 years, the addition of zoledronic acid not only prevented hormone therapy-induced bone loss but also resulted in significant improvement in recurrence-free survival (HR = 0.65; P = 0.01) and

disease-free survival (DFS, HR = 0.64; P = 0.01) compared with no zoledronic acid. Fewer patients who received zoledronic acid had distant disease recurrence at bone and non-bone sites, including visceral metastases, locoregional recurrences, and contralateral breast disease. A preplanned analysis showed that, in patients who were 40 years or younger at baseline, zoledronic acid did not significantly reduce the relative risk of DFS events (HR = 0.94), whereas in patients who were older than 40 years at baseline, the risk reduction (HR = 0.58) with zoledronic acid was significant. Although all patients got ovarian suppression, patients older than 40 years at baseline likely achieved more substantial estrogen deprivation. There was also a trend toward improved overall survival [61, 62]. At a median follow-up of 62 months, more than 2 years after completion of therapy, the addition of zoledronic acid to endocrine therapy produced a durable improvement in DFS overall (HR = 0.68; P = 0.009) and a trend toward improved survival (HR = 0.67; P = 0.09). Recently presented data at 68 months follow-up indicate a significant overall survival advantage. There were no reports of renal failure or ONJ [63].

The multicenter studies Zometa-Femara Adjuvant Synergy Trial, Z-FAST and ZO-FAST, are two similarly designed trials that evaluate the efficacy of zoledronic acid in preventing bone loss induced by the aromatase inhibitor letrozole in postmenopausal women with breast cancer. Patients were randomized to receive with adjuvant letrozole either upfront or delayed zoledronic acid. A combined analysis showed lower recurrence rates in the group receiving upfront zoledronic acid and the 3-year follow-up results of the ZO-FAST trial (n = 1,065) showed a significant 41% relative risk reduction for DFS events (P = 0.03) in the upfront group compared to the delayed therapy group [64]. Lastly, the Adjuvant Zoledronic acid Recurrence (AZURE) trial is a randomized open phase III trial of 3,360 patients with stage II/III breast cancer that evaluates the effect of zoledronic acid for 5 years, given at a more intensive dosing schedule than that used in ABCSG-12, in addition to standard therapy on disease-related outcomes. A subgroup analysis of that trial indicates that zoledronic acid in combination with neoadjuvant chemotherapy might confer an antitumor effect as compared to patients who did not receive zoledronic acid [65]. The final results of the AZURE trial have been recently published. For the overall study population, DFS, overall survival, and recurrence type (local, regional, or distant) did not differ between groups. The cumulative incidence of ONJ was 1.1% in the zoledronic acid group [66]. In a planned subset analysis, women who were older than 60 years of age or known to be postmenopausal for longer than 5 years had a significant improvement in DFS (HR = 0.76; P < 0.05) and overall survival (HR = 0.71; P < 0.05) with the addition of zoledronic acid. The group of postmenopausal women in the AZURE trial had very low estrogen concentrations within bone, which must also be the case for the women more than 40 years old in the ABCSG-12 or in the ZO-FAST trials [66]. This supports the hypothesis that adjuvant bisphosphonates might be most effective at reducing breast cancer recurrence in a low-estrogen, high-bone resorptive environment [67]. However, the data are not sufficiently compelling to support routine use of zoledronic acid in adjuvant therapy. Other ongoing trials are actively evaluating the role of adjuvant bisphosphonates in early breast cancer. Denosumab has also been shown to prevent aromatase inhibitor-induced bone loss and a placebo-controlled adjuvant trial in early breast cancer is ongoing.

In patients with prostate cancer, there is no evidence that bisphosphonates are useful in the adjuvant setting besides preventing bone loss induced by androgen deprivation therapy. The results of a large (n = 1,432), randomized, placebo-controlled study in patients with nonmetastatic, castration-resistant prostate cancer at high risk of developing bone metastases on the basis of PSA levels (8 ng/ml or higher) or PSA doubling time (10 months or less), have shown that denosumab (120 mg every 4 weeks) significantly improves bone metastasis-free survival by a median of 4.2 months compared with placebo; the hazard ratio was 0.85 (P = 0.028). Denosumab was also associated with increased time to first symptomatic bone metastasis. Overall survival did not differ between groups. Denosumab was associated with increased incidence of hypocalcemia and ONJ (4% at the end of year 3) [68].

Conclusions and perspectives

Bisphosphonates, especially zoledronic acid, constitute an important part of our therapeutic armamentarium to reduce the skeletal morbidity rate in patients with bone metastases and to preserve bone health in patients with early stage breast cancer [69]. Monthly infusions reduce the complications of established tumor bone disease by about 40%. Recent phase III studies have demonstrated the superiority of denosumab to zoledronic acid for delaying the time to the first SRE in patients with breast or prostate cancer and bone metastases. Non-inferiority was shown in the trial including other solid tumors and multiple myeloma. The overall burden of the disease (as assessed by an analysis of multiple events and yearly skeletal morbidity rate) was also significantly reduced in the breast and the prostate cancer studies, and in the prespecified integrated analysis that included all three studies. Denosumab is conveniently administered by subcutaneous injections and is devoid of renal toxicity. However, ONJ could be more frequent than with zoledronic acid and cost-effectiveness analyses should be performed to demonstrate that this incremental efficacy benefit is not of debatable value because of the increased expense.

Treatment with these potent inhibitors of bone resorption should be progressively "individualized.". Tailoring therapy to individual tumor and patient characteristics is increasingly accomplished in modern oncology. In metastatic breast cancer, ASCO still recommends to start bone-modifying agents as soon as metastatic bone disease is diagnosed by a radiological technique and to continue their administration until "evidence of substantial

decline in a patient's general performance status" [33]. These recommendations contrast with the paucity of data beyond 2 years of treatment duration. As our understanding improves of the pathophysiology of the different steps of tumor bone destruction, and more sensitive and specific markers of cancer-induced changes in bone turnover and metabolism are developed, it is likely that future studies will enable treatment to be refined. Such studies will better define the place of intermittent treatments, according to individual disease characteristics, such as "aggressiveness" characteristics of the bone metastases, early estimation of the responsiveness to systemic therapy, and the use of biochemical parameters to monitor the influence of tumor secretory products on bone marrow, bone cells, and bone matrix. Treatments tailored to the individual patient are likely to decrease the occurrence of toxic effects, notably ONJ, and to improve the cost-effectiveness ratio of new compounds.

Tumor bone disease in breast cancer and in multiple myeloma is most often accompanied by an inhibition or disorganization of osteoblast proliferation and activity. The most promising agent to date that has been shown to increase osteoblast proliferation is a monoclonal anti-sclerostin antibody. Increased bone density and strength of non-fractured bones have been reported in animal models [70], and clinical studies have started in postmenopausal osteoporosis. Combination or sequencing therapies with denosumab and an anti-sclerostin antibody should be fruitful areas of investigation in the future. For prostate cancer, endothelin-A receptor antagonists, proto-oncogene tyrosine-protein kinase (SRC) inhibitor dasatinib, tyrosine kinase inhibitor cabozantinib, and alpha-emitting radium-223 are all under active investigation [71].

Lastly, the prevention of bone metastases is a key goal in the management of cancer patients. It appears that zoledronic acid can prevent bone metastases in estrogen-deprived patients, as suggested by the ABCSG-12 study in premenopausal women who were medically castrated and older than 40 years old, and by analysis of the subset of postmenopausal women in the adjuvant AZURE breast cancer study. These initial results are quite encouraging but bisphosphonates cannot be recommended yet in the adjuvant setting. Placebo-controlled adjuvant studies with denosumab in early breast cancer have started, and the results of a large placebo-controlled study in patients with nonmetastatic, castrate-resistant prostate cancer at high risk of developing bone metastases have shown that denosumab significantly improves bone metastasis-free survival compared with placebo. The prevention of bone metastases by "bone modifying agents" is an exciting objective for the years to come. Identifying predictors of bone metastases will allow selective use of bone-modifying agents in patients who would benefit from them most, while avoiding adverse effects and cost in patients unlikely to benefit. Recent data suggest that high serum CTX levels before initiation of adjuvant endocrine therapy are predictive for bone-only relapse [72]. Because of its importance for the growth of cancer cells in bone, the stem cell niche is another potential pharmaceutical target. Agents that stimulate normal hematopoiesis or bone formation could reduce colonization of bone by tumor stem cells and prevent metastatic progression [73].

Introduction 754
External Beam Radiotherapy 754
Bone-Seeking Radiopharmaceuticals 756
References 757

INTRODUCTION

Bone is the most common site of symptomatic cancer metastasis. Two-thirds to three-quarters of patients with advanced disease from breast and prostate carcinomas have skeletal metastases, and lung, thyroid, and renal carcinoma metastasize to bone in approximately 30% to 40% of cases [1]. Pain is the most common symptom [1, 2]. Additionally, clinical implications of skeletal metastases include pathological fracture, nerve entrapment and/or spinal cord compression (SCC), bone marrow insufficiency, and hypercalcaemia. Hence, bone metastases have a devastating impact on a patient's quality of life [1, 3]. SCC is of particular concern to cancer patients with a long expected survival, e.g., those with breast cancer and the diagnosis of skeletal metastasis as the first and sole metastatic event [4].

Optimal management combines medical treatment, radiation therapy, surgery, bone-targeted radiopharmaceuticals, bisphosphonates, and denosumab, depending on the biology of the disease, extent of the skeletal involvement, and the life expectancy of the patient.

EXTERNAL BEAM RADIOTHERAPY

Skeletal metastases are the single most frequent indication for palliative radiotherapy. External beam radiotherapy (EBRT) effectively relieves pain from localized sites of skeletal metastases [5, 6]. However, the lack of tumor-only selectivity limits its clinical use. Furthermore, since skeletal metastases usually are multiple and distributed throughout the axial skeleton [1, 2, 4], larger or multiple fields of irradiation are often necessary. Table 91.1 outlines factors to be considered when prescribing palliative radiotherapy for bone metastases.

Pain palliation

Solid empirical evidence has clearly documented that single-fraction (SF) EBRT provides equivalent pain relief compared with multi-fraction (MF) EBRT for uncomplicated bone metastases documented by more than 25 randomized clinical trials (RCTs) and three recent meta-analyses [6–8].

One of the first RCTs was conducted by the Radiation Therapy Oncology Group [9]. Ninety percent of patients experienced some degree of pain relief, and 54% achieved complete pain palliation. The trial initially concluded that the low-dose, short-course schedules were as effective as the high-dose protracted programs. However, this study was criticized for using physician-based pain assessment. A reanalysis of the same set of data grouped solitary and multiple bone metastases and used the end point of pain relief, taking analgesia intake into account as well as the need for re-treatment. The authors then concluded that the number of radiation fractions was significantly related to complete combined relief (absence of pain and use of narcotics) and that protracted dose-

Table 91.1. Factors to be Considered When Prescribing Palliative Radiotherapy (EBRT) for Bone Metastases

EBRT—Single fraction (SF)	EBRT—Fractionated (MF)
Indication: "pain relief"	Indication: "local tumor control"
Short life expectancy	Expected long-term survival
Concomitant visceral metastases	Predominantly bone or bone-only metastasis
Poor performance status	Good performance status
Inflammatory pain	Neuropathic pain
Aspects of cost and inconvenience	Spinal cord compression
	Postoperative EBRT following an orthopedic procedure in selected cases
	Impending fractures where surgery is not indicated

fractionation schedules were the most effective [10]. This was contrary to the initial report and highlights that the choice of end points will influence the outcome [11].

More recently, results from several large-scale prospective RCTs have been published. The UK Bone Pain Trial Working Party randomized 765 patients with bone metastases to either an SF or MF regimen [12]. There were no significant differences in the time to first improvement in pain, time to complete pain relief, time to first increase in pain at any time up to 12 months after randomization, and no differences in the incidence of nausea, vomiting, SCC, or pathological fracture between the two groups. Re-treatment was, however, twice as common after SF than after MF radiotherapy. The study concluded that an SF of 8 Gy is as safe and effective for the palliation of metastatic bone pain for at least 12 months with greater convenience and lower cost than MF treatment.

The large Dutch Bone Metastases Study included 1,171 patients and confirmed the results mentioned above [13]. In this trial, the re-treatment rates were 25% in the single 8 Gy arm, 7% in the MF arm, and more pathological fractures were observed in the SF group but the absolute percentage was low. In a cost-utility analysis of this RCT, there was no difference in life expectancy or quality-adjusted life expectancy. The estimated cost of radiotherapy, including re-treatments and nonmedical costs, was significantly lower for the SF than for the MF schedule [14].

A Scandinavian RCT planned to recruit 1,000 patients with painful bone metastases randomized to single 8 Gy or 30 Gy (3 Gy in 10 fractions) [15]. The data monitoring committee recommended closure of the study after 376 patients had been recruited because interim analyses indicated that the treatment groups had similar outcomes. Equivalent pain relief within the first 4 months was experienced, and no differences were found for fatigue, global quality of life, and survival between the groups [15].

Two meta-analyses published in 2003 each showed no significant difference in complete and overall pain relief between SF and MF EBRT for bone metastases [6, 7]. Results were remarkably similar, with the Wu et al. paper reporting a complete response rate (absence of pain) of 33% and 32% after SF and MF EBRT, respectively, compared to 34% and 32% for Sze et al. Overall response rates from the two meta-analyses were 62% and 59% [7], compared to 60% and 59% [6], for SF and MF, respectively. When restricted to evaluable patients, overall response rates became 73% for each arm [7]. Most patients experienced pain relief in the first 2 to 4 weeks after EBRT [7]. Side effects were similar and generally consisted of nausea and vomiting.

An updated meta-analysis reviewed 16 RCTs that compared SF and MF schedules [8] involving a total of 2,513 randomizations to SF arms and 2,487 to MF arms. The overall response rate to SF EBRT was 58%, and the complete response rate was 23%, not significantly different from the 59% and 24% experienced by patients randomized to MF EBRT. No differences in acute toxicity, pathological fracture (3.2% of patients fractured after SF vs 2.8% after MF) or SCC incidence were found, thus confirming the conclusions of the 2003 systematic reviews. Recent therapeutic guidelines for the treatment of bone metastases from the American College of Radiology Appropriateness Criteria Expert Panel on Radiation Oncology also endorsed the findings [16, 17].

Palliative radiotherapy is not without side effects. Patients treated either with a single 8 Gy or multiple fractions reported a pain flare incidence of around 40% [18]. Dexamethasone as prophylaxis of radiation-induced pain flare after palliative radiotherapy for symptomatic bone metastases has been reported in a phase II study [19].

Neuropathic pain and spinal cord compression

There is some evidence that certain groups of patients would benefit from a protracted schedule. In a comparison of a single 8 Gy vs 20 Gy (4 Gy in five fractions) for 272 patients with a neuropathic pain component [20], it was found that SF was not as effective as MF; however, it was also not significantly worse. The authors recommended MF as standard radiotherapy for patients with neuropathic pain. However, in patients with short survival or poor performance status, as well as when cost/inconvenience of MF is relevant, SF could be used instead [20].

In the treatment of neoplastic SCC, one RCT has studied the outcome in patients with SCC and an estimated outcome of 6 months or less with no indication for primary surgery [21]. However, two EBRT-schedules not commonly used were compared; i.e., 16 Gy in two fractions over 1 week or a split course of 15 Gy in three

fractions, followed by 4 days of rest, and the additional 15 Gy in five fractions. No significant differences were reported between the two arms [21]. More recent trials have included a single 8 Gy and concluded that SCC patients achieve palliation with minimal toxicity and inconvenience with a single fraction [22, 23]. Longer-course radiotherapy is associated with better local control of SCC [23]. Hence, patients with more favorable survival expectancy should be considered for a protracted course of radiotherapy. On the other hand, similar functional outcomes can be achieved with short-course radiotherapy. Patients with limited survival may be better served with a single fraction [24].

Until the results from a recently published RCT comparing surgery and postoperative EBRT and EBRT alone [25] were presented in favor of primary surgery, the common view was that the outcome did not differ between EBRT and surgery for patients with vertebral metastases and SCC [26].

Impending fracture and risk prediction

An impending fracture has a significant likelihood of fracture under normal physiological stresses. Although some physicians believe that all patients with proximally located femoral metastases should undergo preventive surgery, this would result in a large number of unnecessary surgical procedures [27]. Furthermore, a proportion of patients will not be candidates for an operative procedure or will refuse surgical intervention. Often, a minimum life expectancy (6–12 weeks), a reasonable performance status, manageable comorbidities, and adequate remaining bone to support the implanted hardware are required in order to justify the morbidity and mortality risk [28].

If an orthopaedic intervention is not appropriate, patients may receive EBRT alone. Although EBRT can provide pain relief and tumor control, it does not restore bone stability, and remineralization will take weeks to months [29]. Patients should be warned of the increased risk of fracture in the peri-radiation period due to an induced hyperemic response at the periphery of the tumor that temporarily weakens the adjacent bone. Pain relief may allow the patient to be more mobile and, hence, at greater risk for fracture. As such, measures to reduce anatomic forces across the lesion (crutches, a sling, or a walker) are routinely introduced during this time.

Although there is no consensus on appropriate dose fractionation, most authors recommend an MF course of EBRT in a patient with an impending or established fracture [30]. One retrospective series analyzed 27 pathologic fractures in various sites treated with doses of 40–50 Gy over 4–5 weeks. Healing with remineralization was seen in 33%, with pain relief in 67% [30]. Koswig and Budach reported in a prospective randomized trial that the recalcification showed a significant difference between patients treated with 30 Gy in 10 fractions (173%) and those treated with a single 8 Gy (120%, $p < 0.0001$) [31]. In practice, 20–40 Gy for established pathologic fracture is generally given over 1–3 weeks. In patients with an apparently solitary, histologically confirmed metastasis, especially after a long disease-free interval, some clinicians may wish to give even a higher dose, e.g., 40–50 Gy, under the assumption that this will provide long-term control.

Re-irradiation

Subsets of patients with metastatic disease have longer life expectancies than in the past due to advances in systemic therapy and may therefore outlive the duration of benefit provided by their initial palliative EBRT. This may require consideration of re-irradiation of previously treated sites at a later date [32].

The clinical indications, optimal dose and fractionation, and techniques for re-treatment are controversial [33] due to lack of precise quantitative data on the time course, magnitude, and tissue specificity of long-term occult radiation injury recovery [34].

Re-treatment rates after SF EBRT varied from 18% to 25% compared to 7% to 9% after MF EBRT [12, 13, 15, 35]. Sande et al. recently updated their randomized multicenter trial that patients in the single 8 Gy arm received significantly more re-irradiations as compared to the 30 Gy in 10 fractions arms (27% vs 9%, $p = 0.002$) [36]. The Dutch Bone Metastases Study Group recently reanalyzed their data to specifically report the efficacy of re-irradiation [37]. Of patients not responding to initial radiation, 66% who initially received a single 8 Gy responded to re-treatment, compared to 33% of patients who initially received a MF course. Re-treatment in patients after pain progression was successful in 70% of those who received SF initially, compared with 57% of those who received more than one fraction. Overall, re-irradiation was effective in 63% of all such treated patients. Jeremic et al. also noticed the efficacy of the second single 4 Gy re-irradiation for patients with painful bone metastases who had already twice received SF radiation [38].

Hence, it is important to consider re-irradiation of sites of metastatic bone pain after initial EBRT, particularly when this follows an initial period of response. There is also evidence that a proportion of initial nonresponders will respond. The preferred dose schedule, however, is at present unknown, but a large, prospective, randomized intergroup study employing common re-irradiation schedules has been launched [39].

BONE-SEEKING RADIOPHARMACEUTICALS

Treatment with intravenous (IV) injected bone-seeking radiopharmaceuticals (BSRs) is an intriguing alternative that selectively delivers ionizing radiation to targeted areas of amplified osteoblastic activity and targets multiple (symptomatic and asymptomatic) metastases simul-

taneously. The target is Ca–OH–apatite particularly abundant in sclerotic metastases from prostate cancer but also present, although more heterogeneously distributed, in mixed sclerotic/osteolytic metastases from breast cancer. This is evident from the biodistribution image common to all BSRs—exemplified as "hot-spots" visualized on a routine diagnostic bone-scan (by ^{99m}Tc-MDP; a radiolabeled bisphosphonate). BSRs effectively relieve pain and have been thoroughly reviewed [40–44]. In the commercially available formulations, the radioisotopes involved are beta-emitters: strontium-89 dichloride (Metastron, GE Healthcare, Chalfont St. Giles, UK) and ^{153}Sm-EDTMP (Quadramet, Schering AG, Berlin, Germany, and Cytogen Co., Princeton, NJ, USA).

Because of the mm-range of the emitted electrons, the cross-irradiation of the bone marrow represents an ever-present concern. Following IV injection of a beta-emitting BSR, bone marrow is an innocent bystander and the dose-limiting organ. Furthermore, disease-associated bone-marrow suppression already present in these patients often results in delayed and unpredictable recovery. This severely limits the usefulness of beta-emitting BSRs, especially when dosages are increased to deliver potential antitumor radiation levels and/or repeated treatments are attempted. Few clinical studies to date have reported on the feasibility of combining BRSs and chemotherapy [45–48].

Due to short particle track length and potent cell killing, an alpha-emitting BSR could be an intriguing alternative [49]. In contrast to the beta emitters, the alpha-particle emitters deliver a much more energetic and localized radiation that produce densely ionizing tracks and predominantly non-reparable double DNA-strand breaks. In a phase I study of single-dosage administration of escalating amounts of the natural bone-seeker ^{223}Ra in 25 patients with bone metastases from breast and prostate cancer [50], dose-limiting hematological toxicity was not observed. Mild and reversible myelosuppression occurred; with only grade 1 toxicity for thrombocytes at the two highest doses. A phase II RCT of external beam radiation plus either saline or ^{223}Ra injections (given four times at 4-week intervals) in patients with bone metastases from castrate-resistant prostate cancer resulted in a statistically significant decrease from baseline compared with placebo both in bone alkaline phosphatase and prostate-specific antigen [51]. A favorable adverse event profile was observed with minimal bone-marrow toxicity for patients who received ^{223}Ra. Importantly, survival analyses from this phase II trial showed a significant overall survival benefit for ^{223}Ra [51]. Enrollment of 900 patients in a phase III RCT has, by January 1, 2011, been completed (see www.algeta.com).

The combination of radiotherapy or radionuclide therapy with bisphosphonates has recently been reviewed [52]. A significant response in terms of pain relief and improvement of quality of life and performance status better than either therapy alone is shown, but this needs to be vigorously tested in phase III randomized settings. There is a strong theoretical basis for synergistic activity between the two modalities [52], with enhanced healing in metastatic disease in animal studies resulting in better biochemical strength, stability, and bone microarchitecture.

INTRODUCTION

Over 1.5 million people are diagnosed with cancer each year [1], and approximately 50% of those will develop bone metastasis. As treatments improve for primary and metastatic disease, patients are living longer with their disease. This often causes them to experience the morbidities of related bone disease. Although the most worrisome clinical problem is progressive disease in the skeleton, patients can also experience treatment-related osteoporosis. Additional physiologic disruptions in patients with bone metastasis include anemia and hypercalcemia. The bone lesions themselves can cause extreme pain and put the patient at risk for pathologic fractures. Patients become less mobile and may function at a lower level. Prolonged immobilization due to pain or risk of fracture creates potential problems with thromboembolic disease or decubitus ulcers. Lesions in the vertebral region can cause progressive neurologic deficits. Overall quality of life is often markedly diminished.

Comprehensive treatment of bone metastasis is beyond the scope of this chapter, but advances in chemotherapy, targeted biologic therapy, and vaccines have been variably effective for the underlying primary cancer. Different forms of radiation are used to target metastatic cancer cells within the bone to provide palliative pain relief and potentially abrogate the need for surgical intervention. Minimally invasive treatments such as radio-frequency ablation, cryoablation, and kyphoplasty are effective at relieving pain when surgery is not feasible. This chapter focuses on treatment that affects the neoplastic process as well as the bone microenvironment. A brief review of the molecular events related to metastatic bone disease will be discussed. The use of bisphosphonate therapy as well as surgical stabilization in these settings will be summarized.

BIOLOGY OF METASTATIC BONE LESIONS

Tumor–bone interactions

Upon arrival in bone, tumor cells begin a reciprocal (bilateral) interaction with the bone microenvironment. This interaction fosters tumor growth while offsetting the normally balanced process of bone remodeling toward either net bone destruction or formation, causing significant morbidity [2–7] (Fig. 92.1). The majority of research aimed at elucidating tumor–bone interactions has been performed in the field of breast cancer bone metastasis, a predominantly osteolytic disease. Studies using mouse models have provided evidence of a "vicious cycle" of tumor growth and bone destruction driven by transforming growth factor-β (TGF-β). In the course of normal bone remodeling, TGF-β is released, stimulating breast cancer cells to secrete parathyroid hormone-related protein (PTHrP) [8]. PTHrP then stimulates osteoblast precursors to increase receptor activator for nuclear factor-κB ligand (RANKL), which increases osteoclast differentiation. An increased number of active osteoclasts then destroy more

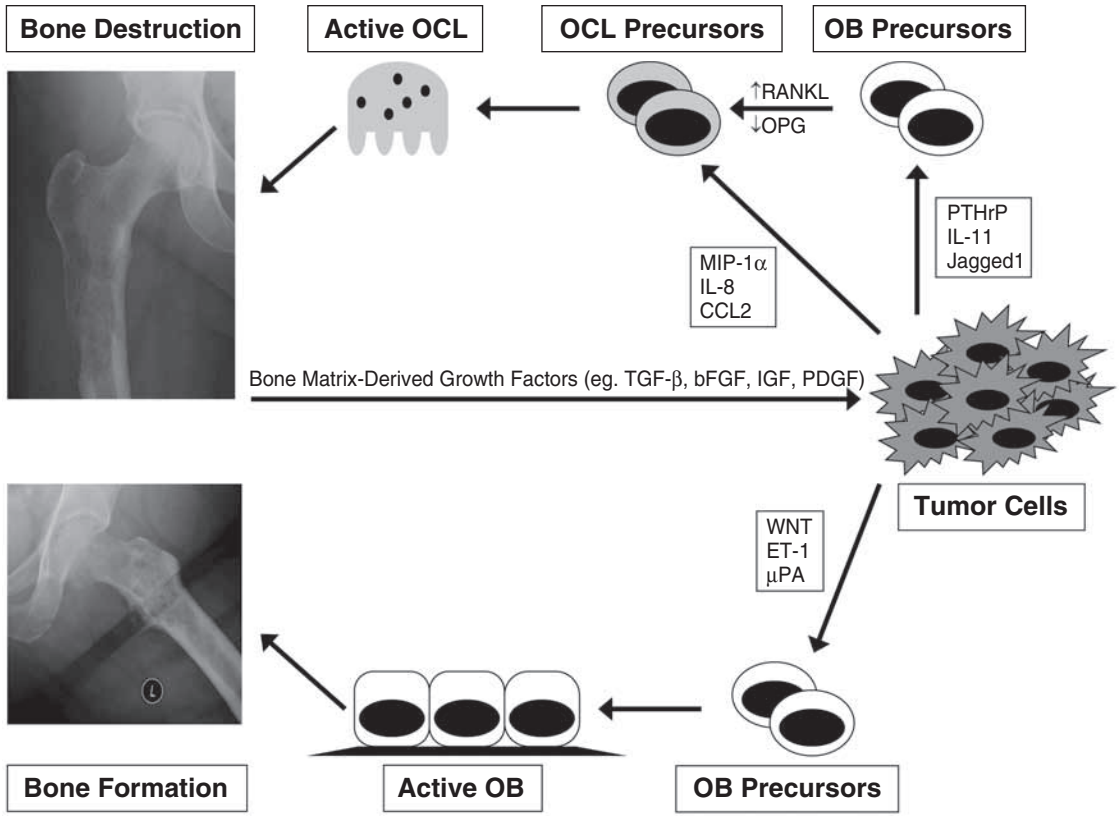

Fig. 92.1. This schematic illustrates the general cycle of bone destruction (osteolytic metastasis—lung cancer) and bone formation (osteoblastic metastasis—breast cancer).

bone. This releases numerous growth factors in addition to TGF-β, including basic fibroblast growth factor (bFGF), insulin-like growth factor (IGF), and platelet-derived growth factor (PDGF), fueling tumor growth and restarting the cycle.

Strikingly, along with PTHrP, numerous other TGF-β-regulated genes have been shown to promote osteolytic bone metastasis including IL-11, CTGF, COX-2, Jagged1, and ADAMTS1 [9–12]. Given its widespread effect on bone metastasis, the TGF-β signaling pathway has become the target of various experimental therapeutic drugs, several of which are in clinical trials [13]. In addition to TGF-β-regulated genes, studies indicate that the chemokines IL-8, CCL2, and MIP-1α promote osteolytic metastasis using mouse models of breast cancer and myeloma [14–16]. Rather than increasing osteoclast numbers via effects on osteoblasts, these factors exert direct effects on osteoclast precursors, stimulating their recruitment and differentiation into mature osteoclasts.

As opposed to other common cancer types affecting the skeleton, prostate cancer causes predominantly osteoblastic lesions in bone. Utilizing mouse models of prostate cancer, several tumor-produced paracrine factors that stimulate osteoblasts to form new bone have been identified. Endothelin-1 (ET-1) has been shown to directly stimulate the proliferation and differentiation of osteoblast precursors [17]. In addition to its direct effects, ET-1 enhances the activation of Wnt signaling in osteoblast precursors by decreasing expression of the WNT inhibitor, Dickkopf homolog 1 (Dkk1) [17]. Urokinase plasminogen activator (uPA) has also been reported to influence prostate cancer bone metastasis, wherein it induces proteases capable of performing multiple functions including the degradation of PTHrP and liberation of IGF-I from its inhibitory binding proteins, thus favoring osteoblast differentiation and activity [18, 19].

Role of bisphosphonates and a RANKL inhibitor

The use of bisphosphonates to treat patients with metastatic disease significantly decreases the incidence of skeletally related events such as pathologic fractures [20]. These compounds bind preferentially to bone matrix and are known to inhibit osteoclastic bone resorption. Bisphosphonates are separated into two classes: nitrogen-containing and non-nitrogen-containing, each having a different mechanism of action. Non-nitrogen-containing bisphosphonates cause osteoclast apoptosis following breakdown into metabolites that compete with adenosine triphosphate (ATP) during energy metabolism. Nitrogen-containing bisphosphonates target the mevalonate

pathway, specifically the enzyme farnesyl diphosphate synthase (FPPS), and cause osteoclast inactivation by interfering with geranylgeranylation.

Bisphosphonates have been used with published success to treat bone pain and hypercalcemia in breast and prostate cancer and are most efficacious when used as an adjunct to systemic cancer therapies. They are a routine treatment for most patients with metastatic bone disease or multiple myeloma [21]. The most commonly used drugs in the United States are zoledronic acid (Zometa) and pamidronate (Aredia) given as intravenous injections. Based on a review of 30 randomized controlled trials of patients treated with oral or intravenous bisphosphonates for metastatic disease, these drugs are associated with a significant reduction in all skeletal morbidity end points with the exception of spinal cord compression [20]. They are given when bone metastasis are first diagnosed, as they significantly increase the time to the first skeletal-related event. Osteonecrosis of the jaw is a rare but serious complication in patients with bone metastasis on bisphosphonates and is estimated to occur with a frequency of 0.6–6.2% [22]. It is recommended that patients have a routine dental examination before starting on bisphosphonates, and risk factors include high cumulative doses, poor oral health, and a history of dental extractions.

Denosumab is a RANKL inhibitor that is approved for treatment of patients with bone metastasis and shown to be both safe and effective [23]. In a phase 3 study of patients with castration-resistant prostate cancer, denosumab was more effective than Zometa at preventing skeletally related events [24].

SURGICAL TREATMENT OF METASTATIC BONE DISEASE

Impending fractures

As patients with bone metastasis are unlikely to be surgically cured, the primary focus of orthopedic oncologists is to improve quality of life. If a bone lesion is discovered at an early stage, radiation or systemic medical treatment may prevent further destruction and allow surgery to be avoided. However, if a lesion progresses despite nonsurgical treatment or is initially discovered after there has been extensive cortical destruction and pain, surgical stabilization should be considered [25]. Patients who have prophylactic fixation of their extremity have a shorter hospitalization, quicker return to pre-morbid function, and less hardware complications [26]. Elective stabilization also allows the medical oncologist and surgeon to coordinate operative treatment and systemic chemotherapy. The difficulty lies in reliably determining which bone lesions will eventually cause a fracture. Several classifications have been proposed which involve determination of pain, cortical destruction, and/or size of the bone lesion [27, 28]. Computed tomography based structural rigidity analysis to predict vertebral fracture risk in patients with metastatic breast cancer is 100% sensitive but only 20% specific in a recent study [29].

Surgical treatment

The goals of surgical treatment of patients with bone metastasis are to improve function and decrease pain. Treatment of impending or actual fractures secondary to metastatic bone disease utilizes different principles than those used for routine traumatic fractures [25]. The underlying bone quality is often poor, and the patient may have progressive osseous destruction despite treatment.

Upper extremity bone metastases are less common than those in the lower extremity and can often be treated nonoperatively. However, if patients require their upper extremities for weight bearing (i.e., have lower extremity lesions that cause pain or inability to bear weight without assistive devices), then surgical treatment should be considered in order to improve mobility. Lesions in the scapula and clavicle are generally treated nonoperatively with radiation or minimally invasive options, as most surgical options do not improve function in these areas. Extensive bone destruction in the proximal humerus is either treated by a proximal humeral prosthetic replacement or an intramedullary device with or without supplemental methylmethacrylate if secure fixation can be achieved (Fig. 92.2). Diaphyseal humeral lesions are treated with intramedullary devices or occasionally intercalary metal spacers [30, 31]. Distal humeral lesions are less common and are stabilized with crossed intramedullary pins, dual plating, or segmental distal humeral prosthetic reconstruction. Bone metastases distal to the elbow are extremely rare and are treated on an individual basis.

Lower extremity metastases are more common than those found in the upper extremities and have a larger impact on quality of life due to the need for weight bearing. Pelvic lesions are usually treated nonoperatively or with minimally invasive techniques if the acetabulum is not affected. Acetabular lesions are treated according to specific classification schemes depending on the extent and location of bone loss [32]. Patients with severe bone loss in the acetabulum should have a reasonably long predicted lifespan and good performance status in order to make the procedure and recovery worthwhile. Metastases to the femoral neck are common and often lead to hip fractures [33]. The treatment is either a bipolar hemiarthroplasty or a total hip replacement depending on the status of the acetabulum [34] (Fig. 92.3). Internal fixation with plates and screws is not indicated, as there is a high risk of hardware failure with disease progression in this area. In the intertrochanteric and subtrochanteric regions, options for prosthetic reconstruction or intramedullary fixation are available depending on the extent and location of bone loss as well as the tumor histology. Tumors that are less responsive to systemic treatment or

Fig. 92.2. (A) A radiograph of the right proximal humerus in a 61-year-old man with metastatic renal cell carcinoma reveals an osteolytic lesion in the metaphysis at high risk for pathologic fracture and likely to progress despite radiation and systemic treatment. There were no additional lesions in the remaining humerus. (B) Postoperative radiograph showing the stabilization of the humerus with an intramedullary nail supplemented with additional proximal screw fixation and methyl methacrylate.

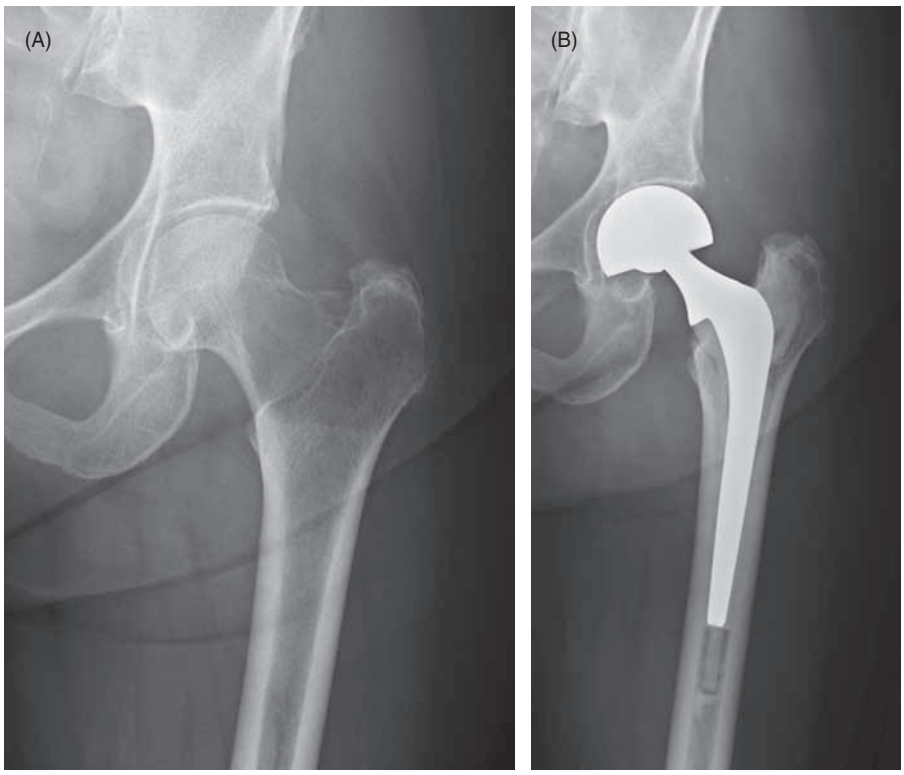

Fig. 92.3. (A) A radiograph of the left hip in a 66-year-old woman with metastatic breast cancer shows an osteolytic lesion in the intertrochanteric region at high risk for pathologic fracture. She had prior radiation to the area with progression of disease and pain. (B) Postoperative radiograph after a cemented bipolar hemiarthroplasty of the hip. There were no additional lesions in the remaining femur.

radiation (ie renal cell carcinoma) are often treated more aggressively with surgical resection. Femoral diaphyseal lesions are treated with intramedullary fixation [34]. It is important that the intramedullary device includes stabilization of the femoral neck to avoid a future hip fracture. Distal femoral lesions are treated by intramedullary fixation, plate fixation, or prosthetic reconstruction. Lesions distal to the knee are uncommon and treated on an individual basis.

The most common site of bone metastasis is the thoracic spine. If patients are neurologically intact and there are no fracture fragments impinging on the spinal cord, radiation is often the treatment of choice. If patients have intractable pain, progressive neurologic deficits or deformity progression, surgical stabilization should be considered [35, 36].

Minimally invasive options

In selected patients, minimally invasive procedures provide an alternative to surgery and can produce long-lasting pain relief. Kyphoplasty and vertebroplasty are commonly used techniques for patients who have osteolytic spine metastasis without neurologic compromise. Both techniques can be performed safely, stabilize the collapsed vertebral body, and yield quick pain relief [37, 38]. Radio-frequency ablation (RFA), cryoablation, or similar techniques are used to treat metastasis in multiple bony sites with most patients achieving some measure of pain relief [39]. Cyberknife treatment is a type of minimally invasive oupatient radiosurgery used for spine metastasis. A comparison with external beam radiation (EBRT) showed that EBRT was more cost effective but with more acute toxicities and need for further subsequent interventions at the same vertebral level [40].

INTRODUCTION

Osteosclerosis and hyperostosis refer to trabecular and cortical bone thickening, respectively. Increased skeletal mass is caused by many rare (often hereditary) osteochondrodysplasias, as well as by a variety of dietary, metabolic, endocrine, hematologic, infectious, or neoplastic disorders (Table 93.1).

OSTEOPETROSIS

Osteopetrosis (OMIM: 166600, 259700, 259710, 259720, 259730, 607634, 611490, 611497) [1, 2], sometimes called "marble bone disease," was first described in 1904 by Albers-Schönberg [3]. Traditionally, two major clinical forms are discussed [4]: the autosomal dominant adult (benign) type that is associated with relatively few symptoms [5], and the autosomal recessive infantile (malignant) type that is typically fatal (if untreated) in early childhood [6]. Additional more rare types have included an "intermediate" form that presents during childhood where the impact on life expectancy is poorly understood [7]. Osteopetrosis with renal tubular acidosis and cerebral calcification is the inborn error of metabolism, carbonic anhydrase II deficiency [4]. Neuronal storage disease with malignant osteopetrosis has been considered a distinct entity [8]. Osteopetrosis, lymphedema, anhydrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID) is an X-linked condition that affects boys [9]. Other unusual forms of osteopetrosis have been called "lethal," "transient infantile," and "post infectious" [4]. Drug-induced osteopetrosis was first described in 2003 in a boy who received high cumulative doses of pamidronate [10]. However, revelation of the genetic defects (see below) responsible for most cases of osteopetrosis has greatly clarified this nosology while further illuminating osteoclast biology [11].

Although defects in multiple genes cause osteopetrosis [11], all true forms are due to failure of osteoclast-mediated resorption of the skeleton [4]. Consequently, primary spongiosa (calcified cartilage deposited during endochondral bone formation) persists and is the histopathological hallmark. Understandably, "osteopetrosis" has been used generically to describe radiodense skeletons yet lacking this finding. Now it is crucial to appreciate

that therapeutic approaches for genuine osteopetroses, for which this pathogenesis is documented, may be inappropriate for other sclerosing bone disorders [4].

Clinical presentation

Infantile osteopetroses manifest during the first year of life [6]. Nasal stuffiness caused by underdevelopment of the mastoid and paranasal sinuses is an early symptom. Cranial foramina do not widen, and optic, oculomotor, and facial nerves may become paralyzed. Hearing loss is common. Blindness can also be caused by retinal degeneration or raised intracranial pressure [12]. Some patients develop hydrocephalus or sleep apnea. Eruption of the dentition is delayed, and there is failure to thrive. Bones are dense but fragile. Recurrent infection and spontaneous bruising and bleeding follow myelophthisis caused by the excessive bone, abundant osteoclasts, and fibrous tissue that crowd marrow spaces. Hypersplenism and hemolysis may exacerbate the anemia. Physical findings include short stature, macrocephaly, frontal bossing, "adenoid" appearance, nystagmus, hepatosplenomegaly, and *genu valgum*. Untreated patients usually die in the first decade of life from hemorrhage, pneumonia, severe anemia, or sepsis [6].

Intermediate osteopetrosis leads to short stature, cranial nerve deficits, ankylosed teeth that predispose to osteomyelitis of the jaw, recurrent fractures, and mild or occasionally moderately severe anemia [7].

Adult osteopetrosis features radiographic abnormalities that appear during childhood. In some kindreds, "carriers" show no disturbances [5, 13]. The long bones are brittle and may fracture. Facial palsy, compromised vision or hearing, psychomotor delay, osteomyelitis of the mandible [13], carpal tunnel syndrome, slipped capital femoral epiphysis, and osteoarthritis are potential complications. Two principal types of adult osteopetrosis have been proposed [14], but so-called autosomal dominant osteopetrosis, type 1 (ADO 1) proved to be the high bone mass phenotype caused by *LRP5* gene activation (see below), whereas ADO 2 is a genuine osteopetrosis better called Albers-Schönberg disease or chloride channel 7 deficiency osteopetrosis [4].

Neuronal storage disease with osteopetrosis features especially severe skeletal manifestations with epilepsy and neurodegeneration [8]. Lethal osteopetrosis manifests *in utero* and causes stillbirth [4]. Transient infantile osteopetrosis inexplicably resolves during the first months of life [4]. Dysosteosclerosis presents during early childhood as an "osteoclast-poor" form of osteopetrosis.

Radiological features

Generalized, symmetrical increase in bone mass is the major radiographic finding [15]. Trabecular and cortical bone appear thickened. In the severe forms, all three

components of skeletal development are disrupted: growth, modeling, and remodeling. Increased density is typically uniform, but alternating sclerotic and lucent bands may appear in the iliac wings and metaphyses. Metaphyses become widened and can develop a club shape or "Erlenmeyer flask" deformity (Fig. 93.1). Rarely, distal phalanges in the hands are eroded (common in pycnodysostosis). Pathological fracture of long bones is not rare. Rachitic-like changes in growth plates may occur [16] because of hypocalcemia with secondary hyperparathyroidism. The skull is usually thickened and dense, especially at the base, and the paranasal and mastoid sinuses are underpneumatized. Vertebrae can show, on lateral view, a "bone-in-bone" (endobone) configuration. Albers-Schönberg disease especially thickens the skull base with a "rugger jersey" appearance of the spine [14]. Skeletal scintigraphy helps show fractures and osteomyelitis. Magnetic resonance imaging (MRI) can assess bone marrow transplantation, because successful engraftment will enlarge medullary spaces [17]. Cranial computed tomography (CT) and MRI findings have been detailed for pediatric patients [18].

Laboratory findings

In infantile osteopetrosis, failure of bone resorption can lead to hypocalcemia because circulating calcium levels are increasingly dependent on dietary intake [19]. Secondary hyperparathyroidism with elevated serum levels of calcitriol is common. In Albers-Schönberg disease, this disturbance is mild [14]. Increased serum acid phosphatase and the brain isoenzyme of creatine kinase (BB-CK) are biomarkers for osteopetrosis [20]. Both enzymes seem to originate from the excessive or defective osteoclasts [20, 21]. Serum levels of LDH isoenzymes and sometimes AST levels are elevated in Albers-Schönberg disease [20].

Histopathological findings

The radiographic features of the osteopetroses [15] can be diagnostic; however, osteoclast failure during endochondral bone formation provides a pathognomonic histological finding because remnants of primary spongiosa persist as "islands" or "bars" of calcified cartilage within trabecular bone (Fig. 93.2). Osteoclasts may be increased, normal, or, rarely, decreased in number [22]. In infantile osteopetrosis, they are usually abundant on bone surfaces. Nuclei are especially numerous, and ruffled borders or clear zones are absent [23]. Fibrous tissue often crowds marrow spaces [23]. Adult osteopetrosis may show increased osteoid and few osteoclasts also lacking ruffled borders, or osteoclasts can be especially numerous and large [24]. Immature "woven" bone is common. Rounded, hypermultinucleated osteoclasts are transiently off of bone surfaces in bisphosphonate-induced osteopetrosis [10].

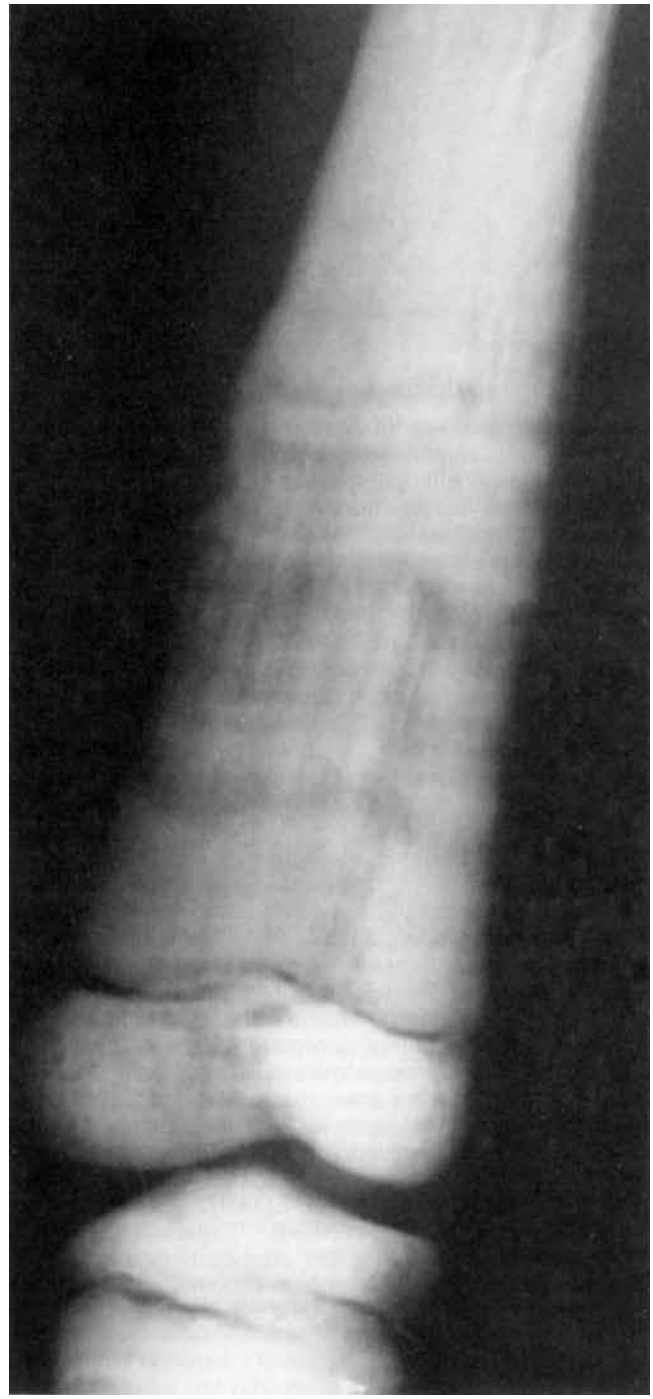

Fig. 93.1. Osteopetrosis. Anteroposterior radiograph of the distal femur of a 10-year-old boy shows a widened metadiaphysis with characteristic alternating dense and lucent bands. [Reprinted with permission from Whyte MP, Murphy WA. 1990. Osteopetrosis and other sclerosing bone disorders. In: Avioli LV, Krane SM (eds.) *Metabolic Bone Disease, 2nd Ed.* Philadelphia: Saunders. p. 618].

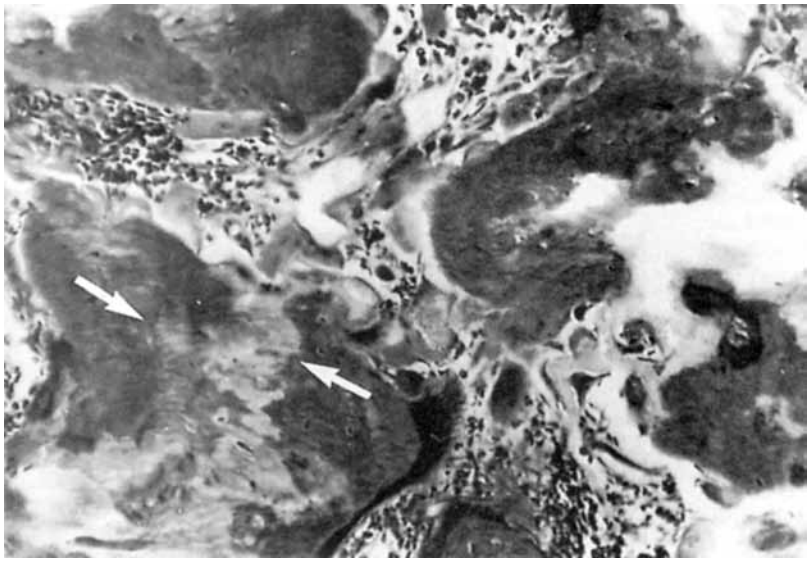

Fig. 93.2. Osteopetrosis. A characteristic area of lightly stained calcified primary spongiosa (arrows) is found within darkly stained mineralized bone.

Etiology and pathogenesis

The potential causes of osteopetrosis are many and complex [4]. Defects could involve primarily the stem cell for osteoclastogenesis or its microenvironment, mononuclear precursor cell, or mature heterokaryon. Furthermore, an osteoblast defect has been reported [25]. In theory, the bone matrix could resist resorption [4]. In osteopetrosis with neuronal storage disease (featuring accumulation of ceroid lipofuscin), lysosomes could be defective [8]. Virus-like inclusions of uncertain significance have been found in the osteoclasts of a few cases of mild osteopetrosis [26]. Synthesis of an abnormal parathyroid hormone (PTH) or defective production of interleukin (IL)-2 or superoxide have been considered [4]. In fact, leukocyte function in infantile osteoporosis may be abnormal [27]. Ultimately, impaired skeletal resorption causes bone fragility because unresorbed cartilage accumulates, collagen fibers do not interconnect osteons, woven bone remodels poorly to compact bone, and microcracks fail to heal.

The molecular basis for osteopetrosis is now known for the majority of patients [11]. Deficiency of chloride channel 7 activity caused by heterozygous mutations in *CLCN7* causes Albers-Schönberg disease [28]. Autosomal recessive infantile osteopetrosis most often involves mutations in *TCIRG1* (*ATP6I*) encoding the *a3* subunit of the vacuolar proton pump [29]. *CLCN7* defects can also cause autosomal recessive malignant or intermediate osteopetrosis [30]. Deactivation of *CA* II explains carbonic anhydrase II deficiency [4]. Accordingly, mutation of these genes that regulate acidification by osteoclasts explains osteopetrosis in most patients. Loss-of-function of the GL (grey-lethal) gene encoding "osteopetrosis associated transmembrane protein 1" (*OSTM1*) causes especially severe osteopetrosis [31]. OL-EDA-ID is caused by inactivation of a key modulator of NF-κB [9]. Especially, rare infants with osteopetrosis featuring few osteoclasts (who fail bone marrow transplantation) suffer from deactivation of the gene that encodes receptor activator of nuclear factor-κB ligand (RANKL) [22]. In others, RANK may be deactivated.

Treatment

Because the cause and outcome differ among the osteopetroses, a precise diagnosis is crucial before therapy is attempted. Diagnosis has depended on careful evaluation of the disease complications and progression, as well as investigation of the family, but now a diagnosis can be made by mutation analysis offered in commercial laboratories [11].

Bone marrow transplantation

Bone marrow transplantation (BMT) from HLA-identical donors has remarkably improved some patients with infantile osteopetrosis [32]. Nevertheless, BMT may not be beneficial for all patients [4], because the causal defect is sometimes extrinsic to the osteoclast lineage (e.g,, RANKL deficiency) [22]. Hypercalcemia can occur as osteoclast function begins [33]. Severe, acute, pulmonary hypertension is a frequent complication of stem cell transplantation [34]. Patients with severely crowded medullary spaces seem less likely to engraft. Histomorphometric study of bone helps to predict the outcome of BMT, and this procedure early on seems best [32]. BMT from HLA-nonidentical donors must be improved. Administration of progenitor cells in blood from HLA-haploidentical parents has been effective [35].

Hormonal and dietary therapy

Some success has been reported with a calcium-deficient diet. Conversely, calcium supplementation may be nec-

essary for hypocalcemia that accompanies severe osteopetrosis [16]. High doses of calcitriol to stimulate quiescent osteoclasts, while dietary calcium is limited to prevent absorptive hypercalciuria and hypercalcemia, may improve infantile osteopetrosis [36]. Nevertheless, some patients seem to become resistant to this treatment. The observation that leukocytes produce less superoxide led to recombinant human interferon γ-1b treatment for malignant osteopetrosis. High-dose glucocorticoid treatment stabilizes pancytopenia and hepatomegaly. Prednisone and a low-calcium/high-phosphate diet have been discussed as an alternative to BMT [37]. One case report describes reversal of malignant osteopetrosis after prednisone treatment [38].

Supportive

Hyperbaric oxygenation can be helpful for osteomyelitis of the jaw. Surgical decompression of the optic and facial nerves and auditory canal [39] may benefit some patients. Joint replacement is challenging but possible [40]; internal fixation may be necessary for femoral fractures. Radiographic studies occasionally detect malignant osteopetrosis late in pregnancy. Early prenatal diagnosis by sonography has generally been unsuccessful. Mutation analysis is increasingly feasible, with most severe cases caused by *TCIRG1* and *CLCN7* mutations.

CARBONIC ANHYDRASE II DEFICIENCY

In 1983, the autosomal recessive syndrome of osteopetrosis with renal tubular acidosis (RTA) and cerebral calcification was identified as carbonic anhydrase II (CA II) deficiency (OMIM: 611492) [41].

Clinical presentation

There is considerable clinical variability [42]. In infancy or early childhood, patients can suffer fractures, failure to thrive, developmental delay, short stature, optic nerve compression with blindness, and dental malocclusion. Mental subnormality is common, but not inevitable. RTA may explain the hypotonia, apathy, and muscle weakness that troubles some patients.

Periodic hypokalemic paralysis can occur. Recurrent long bone fractures, although unusual, can cause significant morbidity [42]. Life expectancy does not seem threatened, but the oldest published cases have been young adults [43]. Autopsy studies have not been reported [43].

Radiological features

CA II deficiency resembles other osteopetroses radiographically, except that cerebral calcification appears between the ages of 2 and 5 years, and the osteosclerosis and modeling defects diminish over the years. Skeletal radiographs are typically abnormal at diagnosis, although findings can be subtle at birth. The cerebral calcification resembles this finding in idiopathic hypoparathyroidism or pseudohypoparathyroidism, increases during childhood, and affects cortical and basal ganglia gray matter.

Laboratory findings

Metabolic acidosis manifests as early as the neonatal period. Both proximal and distal RTA have been described [43]; distal (type I) RTA seems better documented. Any anemia is generally mild.

Etiology and pathogenesis

CA accelerates the first step in the reaction $CO_2 + H_2O$ <-> H_2CO_3 <-> $H^+ + HCO_3^-$. CA II is present in many tissues, including brain, kidney, erythrocytes, cartilage, lung, and gastric mucosa [44]. Deactivating mutations in the gene encoding CA II cause this disorder and reveal significance for CA II in bone, kidney, and perhaps brain. [45] In heterozygous carriers, CA II levels in erythrocytes are approximately 50% of normal [41, 43]. There is a CA II knockout mouse model [45].

Treatment

Transfusion of CA II-replete erythrocytes for one patient did not improve the systemic acidosis [46]. The RTA has been treated with HCO_3^-, but the long-term impact is unknown. BMT has corrected the osteopetrosis and slowed the cerebral calcification but not altered the RTA [47].

PYCNODYSOSTOSIS

Pycnodysostosis is the autosomal recessive disorder that perhaps affected painter Henri de Toulouse-Lautrec (1864–1901) [48].

More than 100 patients have been described since 1962 [49]. Parental consanguinity is recorded in fewer than 30% of cases. Most reports are from Europe or the United States, but some come from Israel, Indonesia, India, and Africa. Pycnodysostosis seems to be especially prevalent in the Japanese [50].

Clinical presentation

Pycnodysostosis is typically diagnosed during infancy or early childhood because of disproportionate short stature and a relatively large cranium, fronto-occipital prominence, small facies and chin, obtuse mandibular angle, high-arched palate, dental malocclusion with retained deciduous teeth, proptosis, and a beaked and pointed

nose [51]. The anterior fontanel and other cranial sutures are usually open. Fingers are short and clubbed from acro-osteolysis or aplasia of terminal phalanges, and the hands are small and square. The thorax is narrow and there may be *pectus excavatum*, kyphoscoliosis, and increased lumbar lordosis. Sclerae can be blue. Recurrent fractures typically involve the lower limbs and cause *genu valgum*. Rickets has been described. Adult height ranges between 4′ 3″ and 4′ 11″. Mental retardation affects fewer than 10% of cases [51]. Recurrent respiratory infections and right heart failure may occur from chronic upper airway obstruction caused by micrognathia.

Radiographic features

Pycnodysostosis resembles osteopetrosis because uniform osteosclerosis becomes apparent in childhood and increases with age, and there are recurrent fractures. The calvarium and base of the skull are sclerotic, and the orbital ridges are radiodense. However, the marked modeling defects of osteopetrosis do not occur, although long bones have narrow medullary canals. Additional findings include delayed closure of cranial sutures and fontanels (prominently the anterior), obtuse mandibular angle, wormian bones, gracile clavicles with hypoplastic ends, partial absence of the hyoid bone, and hypoplasia of the distal phalanges and ribs [52]. Endobones and radiodense striations are absent [15].

Laboratory findings

Serum levels of calcium, inorganic phosphate, and alkaline phosphatase are usually unremarkable. There is no anemia.

Electron microscopy has suggested that degradation of bone collagen might be defective [53]. In chondrocytes, inclusions have been described.In the osteoclasts of brothers, virus-like inclusions have been reported [54]. Diminished growth hormone secretion and low serum insulin-like growth factor 1 levels have been reported in five of six affected children [55].

Etiology and pathogenesis

In 1996, loss-of-function mutation within the gene that encodes cathepsin K was discovered to cause pycnodysostosis [50]. Cathepsin K, a lysosomal cysteine protease, is highly expressed in osteoclasts [56]. Impaired collagen degradation seems to be a fundamental defect [57] and compromises bone quality [58].

Treatment

There is no established medical therapy. BMT has not been reported. Fractures of long bones are typically transverse and heal at a satisfactory rate, although there can be delayed union and massive callus formation. Internal fixation of long bones or extraction of teeth is difficult because of skeletal hardness. Jaw fracture has occurred. Osteomyelitis of the mandible may require antibiotics and surgery.

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN DISEASE)

Progressive diaphyseal dysplasia (PDD; OMIM: 131300) was characterized by Cockayne in 1920 [59]. Camurati recognized the autosomal dominant inheritance. Engelmann described the severe form in 1929. In 2001, mutations were identified within a specific region of the gene that encodes transforming growth factor-β1(TGF-β1) [60].

All races are affected. Clinical severity is quite variable [61]. Hyperostosis occurs gradually on both the periosteal and endosteal surfaces of long bones. In severe cases, the axial skeleton and skull are also involved. Some carriers have no radiographic changes, but bone scintigraphy is abnormal.

Clinical presentation

PDD typically presents during childhood with limping or a broad-based and waddling gait, leg pain, muscle wasting, and decreased subcutaneous fat in the extremities mimicking a muscular dystrophy [62]. Severely affected individuals also have a characteristic body habitus that includes a large head with prominent forehead, proptosis, tall stature, and thin limbs exhibiting thickened painful bones and little muscle mass. Cranial nerve palsies may develop when the skull is involved. Puberty is sometimes delayed. Raised intracranial pressure can occur. Physical findings include palpable widened bones and skeletal tenderness. Some patients have hepatosplenomegaly, Raynaud's phenomenon, and other findings suggestive of vasculitis [63].

Although radiological studies typically show progressive skeletal disease, the clinical course is variable, and spontaneous improvement sometimes occurs during adult life [64].

Radiological features

Hyperostosis of major long bone diaphyses involves both the periosteal and endosteal surfaces [15]. The thickening is fairly symmetrical and gradually spreads to include metaphyses, yet typically spares epiphyses (Fig. 93.3). Diaphyses slowly widen and develop irregular surfaces. The tibias and femurs are most commonly affected; less frequently, the radii, ulnas, humeri, scapulae, clavicles, and pelvis, and, occasionally, short tubular bones are involved. Age-of-onset, rate of progression, and degree of

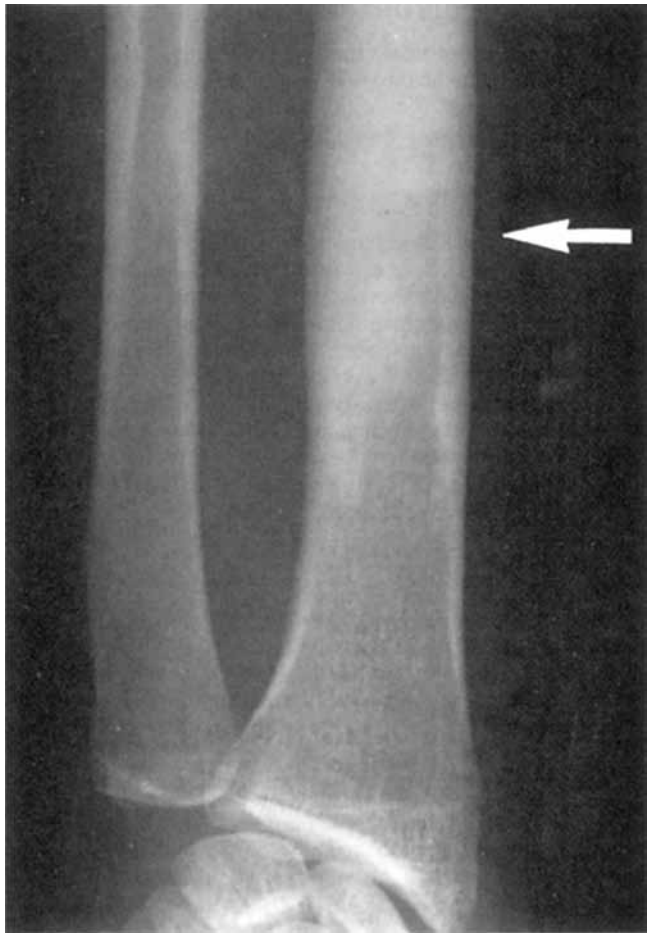

Fig. 93.3. Progressive diaphyseal dysplasia (Camurati-Engelmann disease). The distal radius of this 20-year-old woman has characteristic patchy thickening (arrow) of the periosteal and endosteal surfaces of the diaphysis.

bony change are highly variable. With relatively mild PDD, especially in adolescents or young adults, radiographic and scintigraphic abnormalities may be confined to the lower limbs. In severely affected children, regional osteopenia is possible.

Clinical, radiographic, and scintigraphic findings are generally concordant. Bone scanning typically shows focally increased radionuclide accumulation [65]. In some patients, however, advanced and metabolically quiescent disease features unremarkable bone scintigraphy [65]. Conversely, markedly increased radioisotope accumulation with minimal radiographic findings can represent early skeletal disease [65]. MRI and CT have delineated the cranial findings [66].

Laboratory findings

Serum alkaline phosphatase and urine hydroxyproline are elevated in some PDD patients. Modest hypocalcemia and significant hypocalciuria sometimes occur with severe disease, probably because of markedly positive calcium balance [64].

Other biochemical parameters of bone and mineral metabolism are typically normal. Mild anemia and leukopenia and elevated erythrocyte sedimentation rate have been reported [63]. Histopathology shows new bone formation along diaphyses with nascent woven bone undergoing centripetal maturation and then incorporation into the cortex. Electron microscopy of muscle has shown myopathic and vascular changes [62].

Etiology and pathogenesis

PDD is caused by mutation within one region of the gene that encodes transforming growth factor-β1 (TGF-β1) (*TGFβ1*). A latency-associated peptide remains bound to TGF-β1, keeping it active in skeletal matrix [67]. Mild PDD can reflect variable expressivity. PDD has been described as more severe in ensuing generations ("anticipation") [68]. Furthermore, there does seem to some locus heterogeneity [69]. The clinical and laboratory features and responsiveness to glucocorticoid treatment have suggested severe PDD is a systemic disorder (i.e., an inflammatory connective tissue disease) [63].

Treatment

PDD is somewhat unpredictable. Symptoms may remit during adolescence or adult life. Prednisone given in small doses on alternate days is effective for bone pain and can correct histological abnormalities of bone [70]. Resection of a cortical bone window has relieved localized pain. Bisphosphonate therapy may be helpful but has transiently increased symptoms [71].

ENDOSTEAL HYPEROSTOSIS

In 1955, van Buchem and colleagues described *hyperostosis corticalis generalisata* [72]. Subsequently, this and additional disorders were characterized as types of endosteal hyperostosis. The autosomal dominant relatively mild form is called Worth disease [73], and a second autosomal recessive severe form is sclerosteosis [74].

Van buchem disease

Van Buchem disease (OMIM: 239100) is a severe, autosomal recessive disorder. [72]

Clinical presentation

Progressive asymmetrical enlargement of the jaw occurs during puberty, causing marked thickening and a wide angle but without prognathism. Dental malocclusion is

uncommon. Carriers of the gene defect may be symptom-free; however, recurrent facial nerve palsy, deafness, and optic atrophy from narrowing of cranial foramina are common and can begin as early as infancy. Long bones may be painful with applied pressure but are not fragile, and joint range-of-motion is unaffected. Sclerosteosis (see below) differs because of excessive height and syndactyly [74].

Radiological features

Endosteal thickening produces a dense diaphyseal cortex with narrow medullary canal [15]. The hyperostosis is selectively endosteal; long bones are properly modeled. However, osteosclerosis also affects the skull base, facial bones, vertebrae, pelvis, and ribs. The mandible enlarges.

Laboratory findings

Serum alkaline phosphatase activity may be increased because of high levels of the skeletal isoform, whereas calcium and phosphate concentrations are unremarkable. Van Buchem and colleagues suggested that the excessive bone was essentially of normal quality [72].

Etiology and pathogenesis

Van Buchem disease and sclerosteosis were predicated to be allelic disorders, with their differences reflecting modifying genes [74]. Actually, loss-of-function mutations in *SOST*, the gene encoding sclerostin, cause sclerosteosis [75], whereas van Buchem disease involves a 52-kb deletion that lessens downstream enhancement of *SOST* [76]. Sclerostin binds to LRP5/6, antagonizes canonical Wnt signaling [77], and promotes osteoblast apoptosis [78].

Treatment

There is no specific medical therapy. Decompression of narrowed foramina may help cranial nerve palsies [79]. Surgery has been used to recontour the mandible [80].

Sclerosteosis

Sclerosteosis (cortical hyperostosis with syndactyly; OMIM: 269500), like van Buchem disease, is an autosomal recessive endosteal hyperostosis that affects primarily Afrikaners or others of Dutch ancestry [74]. Initially, sclerosteosis was distinguished from van Buchem disease by excessive height and syndactyly. In fact, the genetic defects differ [75, 76].

Clinical presentation

At birth, only syndactyly may be noted. During early childhood, affected individuals become tall and heavy with skeletal overgrowth, especially involving the skull. This causes facial disfigurement. Deafness and facial palsy are prominent problems. The mandible has a square configuration. Raised intracranial pressure and headache may result from a small cranial cavity. The brainstem can be compressed. Syndactyly from either cutaneous or bony fusion of the middle and index fingers is typical, but of variable severity. Patients are resistant to fracture. Life expectancy is often shortened [81].

Radiological features

Except for syndactyly, the skeleton appears normal in early childhood. Then, progressive bone acquisition widens the skull and mandible [82]. Long bones develop thickened cortices. Vertebral pedicles, ribs, tubular bones, and pelvis may also appear dense. Auditory ossicles may fuse and the internal canals and cochlear aqueducts become narrow [83].

Histopathological findings

Dynamic histomorphometry of one affected skull showed an increased rate of bone formation with thickened trabeculae and osteoidosis, whereas resorption appeared quiescent [84].

Etiology and pathogenesis

Loss-of-function mutations in *SOST* cause sclerosteosis [75].

Enhanced osteoblast activity with failure of osteoclasts to compensate causes the dense bone of sclerosteosis [84]. No abnormality of calcium homeostasis or of pituitary gland function has been documented [85].

The pathogenesis of the neurological defects has been described [84].

Treatment

There is no established medical treatment. Surgery for syndactyly is difficult if there is bony fusion. Management of the neurological complications has been reviewed [84].

OSTEOPOIKILOSIS

Osteopoikilosis ("spotted bones") is an autosomal dominant radiographic curiosity. With accompanying connective tissue nevi, *dermatofibrosis lenticularis disseminata*, the disorder is the Buschke-Ollendorff syndrome [86]. In 2004, deactivating mutations in the *LEMD3* gene were identified [87].

Clinical presentation

Osteopoikilosis (OMIM: 166700) is usually an incidental finding. The bony lesions are asymptomatic, but if not understood can precipitate investigation for metastatic disease to the skeleton [88]. Family members at risk should be screened with a radiograph of a wrist and knee in early adult life. Joint contractions and limb length

Fig. 93.4. Osteopoikilosis. The characteristic feature is the spotted appearance shown here in the pelvis and metaepiphyseal regions of the femora. [Reproduced with permission from Whyte MP. 1995 Rare disorders of skeletal formation and homeostasis. In: Becker KN (ed.) *Principles and Practice of Endocrinology and Metabolism, 2nd Ed.* Philadelphia: Lippincott-Raven Publishers. p. 598.]

inequality can occur, especially in individuals with accompanying changes of melorheostosis. The nevi usually involve the lower trunk or extremities and are small asymptomatic papules. Sometimes they are yellow or white discs or plaques, deep nodules, or streaks [86].

Radiological Features

There are numerous, small, usually round or oval, foci of osteosclerosis [15]. Commonly affected sites are the ends of the short tubular bones, metaepiphyses of long bones, and tarsal, carpal, and pelvic bones (Fig. 93.4). Lesions are unchanged for decades. Bone scanning is not abnormal [88].

Histopathological studies

Dermatofibrosis lenticularis disseminata consists of unusually broad, markedly branched, interlacing elastin fibers in the dermis; the epidermis is normal [86]. Foci of osteosclerosis are thickened trabeculae that merge with surrounding normal bone or are islands of cortical bone that include Haversian systems. Mature lesions appear to be remodeling slowly.

OSTEOPATHIA STRIATA

Osteopathia striata (OMIM: 166500) features linear striations at the ends of long bones and in the ileum [15]. Like osteopoikilosis, it is usually a radiographic curiosity, but it can also occur in a variety of important disorders including osteopathia striata with cranial sclerosis (OMIM: 300373) [89] and osteopathia striata with focal dermal hypoplasia (OMIM: 305600) [90].

Clinical presentation

Osteopathia striata alone is an autosomal dominant trait. Symptoms that may have led to the diagnosis are probably unrelated. With sclerosis of the skull, however, cranial nerve palsies are common [89], and this is due to WTX gene mutation [91]. Osteopathia striata with focal dermal hypoplasia (Goltz syndrome) is a serious condition of males, transmitted as an X-linked recessive trait, that features widespread linear areas of dermal hypoplasia through which adipose tissue can herniate and a variety of bony defects in the limbs [90].

Radiological features

Gracile linear striations are found in cancellous bone, particularly within metaepiphyses of major long bones and the periphery of the iliac bones [15]. Carpal, tarsal, and tubular bones of the hands and feet are less often and more subtly affected. The striations appear unchanged for years. Radionuclide accumulation is not increased during bone scanning [88].

Treatment

Histopathological studies of bone have not been described. Although unlikely to be misdiagnosed, radiographic screening during the young adult life of family members

at risk seems prudent. Osteopathia striata with cranial sclerosis has been detected prenatally by sonography.

MELORHEOSTOSIS

Melorheostosis (OMIM: 155950), from the Greek, refers to "flowing hyperostosis." The radiographic appearance resembles wax that has dripped down a candle. About 200 cases have been published [92] since the first description in 1922 [93]. Melorheostosis occurs sporadically, including when it accompanies osteopoikilosis.

Clinical presentation

Melorheostosis typically presents during childhood. Monomelic involvement is usual; bilateral disease is characteristically asymmetrical. Cutaneous changes may overlie the skeletal lesions and include linear scleroderma-like patches and hypertrichosis. Fibromas, fibrolipomas, capillary hemangiomas, lymphangiectasia, and arterial aneurysms can also occur [94]. Soft tissue abnormalities are often noted before the hyperostosis. Pain and stiffness are the major symptoms. Affected joints may contract. Leg length inequality can follow premature fusion of epiphyses. Bone lesions seem to advance most rapidly during childhood. In adult life, melorheostosis may or may not progress [95]. Nevertheless, pain is more frequent when there is continuing subperiosteal bone formation.

Radiological features

Dense, irregular, and eccentric hyperostosis of both periosteal and endosteal surfaces of a single bone, or several adjacent bones, is the hallmark of melorheostosis (Fig. 93.5) [15, 92]. Any bone may be affected, but the lower extremities are most commonly involved. Bone can also develop in soft tissues near skeletal lesions, particularly near joints. Melorheostotic bone is hyperemic and "hot" during bone scanning.

Laboratory findings

Serum calcium, inorganic phosphate, and alkaline phosphatase levels are normal.

Histopathological findings

Melorheostosis features endosteal thickening during growth and periosteal new bone formation during adult life [92]. Affected bones are sclerotic with thickened, irregular lamellae. Marrow fibrosis may be present [92]. In the skin, unlike in true scleroderma, the collagen of the scleroderma-like lesions appears normal and has therefore been called linear melorheostotic scleroderma [96].

Fig. 93.5. Melorheostosis. Characteristic patchy osteosclerosis is most apparent in the radius and second metacarpal of this 8-year-old girl.

Etiology and pathogenesis

The distribution of the bone and soft tissue lesions in sclerotomes, myotomes, and dermatomes suggests a segmentary, embryonic defect [96]. Linear scleroderma may represent the primary abnormality that extends into the skeleton. In affected skin, there may be altered expression of several adhesion proteins [97]. The germline, loss-of-function mutations in *LEMD3* that cause osteopoikilosis and the Buschke-Ollendorff syndrome do not explain sporadic melorheostosis [98].

Treatment

Surgical correction of contractures can be difficult; recurrent deformity is common. Distraction techniques seem promising [99].

AXIAL OSTEOMALACIA

Axial osteomalacia (OMIM: 109130) features coarsening of trabecular bone in the axial, but not the appendicular,

skeleton [100]. Fewer than 20 patients have been described. Most have been sporadic cases, but an affected mother and son have been reported [101].

Clinical presentation

Most patients have been middle-age or elderly men. Radiographic manifestations are probably detectable earlier [102]. Dull, vague, chronic, axial bone pain (often in the cervical spine) usually prompts the radiographic discovery.

Radiological features

Abnormalities are confined essentially to the spine and pelvis where the coarsened trabecular pattern resembles osteomalacia [103]. The appendicular skeleton is unremarkable. However, Looser's zones (characteristic of osteomalacia) are not reported. The cervical spine and ribs seem most severely affected. Several patients have had features of ankylosing spondylitis [102].

Laboratory studies

Serum alkaline phosphatase (bone isoform) may be increased. In a few patients, inorganic phosphate levels tended to be low [103]. For others, osteomalacia occurred despite normal levels of calcium, phosphate, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D.

Histopathological findings

Iliac crest specimens have distinct corticomedullary junctions, but the cortices can be especially wide and porous. Total bone volume may be increased. There is excess osteoid, but collagen has a normal lamellar pattern. Tetracycline labeling shows defective skeletal mineralization [102]. Osteoblasts are flat "lining" cells, but stain intensely for alkaline phosphatase. Changes of secondary hyperparathyroidism are absent [102].

Etiology and pathogenesis

Axial osteomalacia may be caused by an osteoblast defect [104].

Treatment

Effective medical therapy has not been reported, but the natural history seems relatively benign. Methyltestosterone and stilbestrol or vitamin D_2 (as much as 20,000 U/day for 3 years) have not been helpful [104]. Slight improvement in skeletal histology, but not in symptoms, was described after calcium and vitamin D_2. Long-term follow-up of one patient showed that symptoms and radiographic findings did not change [104].

FIBROGENESIS IMPERFECTA OSSIUM

Fibrogenesis imperfecta ossium was identified in 1950. Approximately 10 cases have been reported [105]. Radiographic studies suggest generalized osteopenia, but coarse and dense appearing trabecular bone explains its designation as an osteosclerotic disorder. The clinical, biochemical, radiological, and histopathological features have been carefully contrasted with axial osteomalacia [100].

Clinical presentation

Presentation occurs during middle age or later. Both sexes are affected. Characteristically, gradual onset of intractable skeletal pain is followed by rapid deterioration. The course is debilitating with progressive immobility. Spontaneous fractures are prominent. Physical examination shows marked bony tenderness.

Radiological features

Skeletal changes affect all but the skull. Initially, there may be osteopenia only and a slightly abnormal appearance of trabecular bone [105]. Subsequently, the findings are more consistent with osteomalacia with further alterations of the trabecular bone pattern, heterogeneous bone density, and cortical thinning. Corticomedullary junctions become indistinct. Areas of the skeleton may have a mixed lytic and sclerotic appearance [105]. Remaining trabeculae appear coarse and dense in a "fish-net" pattern. Pseudofractures may develop. Some patients have a "rugger jersey" spine. Diaphyses may show periosteal reaction. The radiographic features can distinguish fibrogenesis imperfecta ossium from axial osteomalacia (generalized versus axial, respectively). The histopathological findings are also different [100].

Laboratory findings

Serum calcium and inorganic phosphate levels are normal, but alkaline phosphatase is increased. Urine hydroxyproline may be normal or elevated [105]. Typically, there is no renal tubular dysfunction. Acute agranulocytosis and macroglobulinemia have been reported.

Histopathological findings

The osseous lesion is an osteomalacia [105]. Collagen lacks birefringence where there is defective mineralization. Electron microscopy reveals thin and randomly organized collagen fibrils in a "tangled" pattern. Cortical

bone in the femurs and tibias may show the least abnormality. Osteoblasts and osteoclasts can be abundant. In some regions, matrix structures of 300–500 nm diameter have been observed [106]. Unless bone is viewed with polarized-light or electron microscopy, fibrogenesis imperfecta ossium can be mistaken for osteoporosis or other forms of osteomalacia [106].

Etiology and pathogenesis

This is an acquired disorder of collagen synthesis in lamellar bone. The etiology is unknown. Genetic factors have not been implicated.

Treatment

There is no recognized therapy. Temporary improvement can occur. Treatment with vitamin D (or an active metabolite), calcium, salmon calcitonin, or sodium fluoride has not helped [105]. In fact, ectopic calcification has complicated high dose vitamin D therapy. Treatment with melphalan and prednisolone seemed to benefit one patient.

PACHYDERMOPERIOSTOSIS

Pachydermoperiostosis (hypertrophic osteoarthropathy: primary or idiopathic; OMIM: 167100) causes clubbing of the digits, hyperhidrosis and thickening of the skin especially on the face and forehead (*cutis verticis gyrata*), and periosteal new bone formation particularly in the distal extremities. Autosomal dominant and recessive inheritance with variable expression is established [107, 108]. In 2008, autosomal recessive pachydermoperiostosis was explained by loss-of-function mutation within the gene that encodes 15-hydroxyprostaglandin dehydrogenase [108].

Clinical presentation

Men seem to be more severely affected than women and blacks more commonly than whites. Age at presentation is variable, but usually it is during adolescence [107, 108]. All principal features (clubbing, periostitis, and pachydermia) trouble some patients; others have just one or two. Clinical manifestations emerge over a decade and can then abate [108]. Progressive enlargement of the hands and feet may cause a paw-like appearance, and there may be excessive perspiration. Acro-osteolysis can occur. Fatigue and arthralgias of the elbows, wrists, knees, and ankles are common. Stiffness and limited mobility of both the appendicular and the axial skeleton may develop. Compression of cranial or spinal nerves has been described. Cutaneous changes include coarsening, thickening, furrowing, pitting, and oiliness of the skin, especially the scalp and face. Myelophthisic anemia with extramedullary hematopoiesis may occur. Life expectancy is not compromised.

Radiological features

Severe periostitis thickens tubular bones distally: typically the radius, ulna, tibia, and fibula, and sometimes the metacarpals, tarsals/metatarsals, clavicles, pelvis, skull base, and phalanges. Clubbing is obvious, and acro-osteolysis can occur. The spine is rarely involved. Ankylosis of joints, especially in the hands and feet, may trouble older patients [15]. The major challenge in differential diagnosis is secondary hypertrophic osteoarthropathy (pulmonary or otherwise). Here, however, the radiographic features are somewhat different, featuring periosteal reaction that is typically smooth and undulating [109]. In pachydermoperiostosis, periosteal proliferation is exuberant, irregular, and often involves epiphyses. Bone scanning in either condition reveals symmetrical, diffuse, regular uptake along the cortical margins of long bones, especially in the legs, causing a "double stripe" sign.

Laboratory findings

Nascent periosteal bone roughens cortical bone surfaces and undergoes cancellous compaction so that centrally it can be difficult to distinguish histopathologically from the original cortex. There may also be osteopenia of trabecular bone from quiescent formation [15]. Mild cellular hyperplasia and thickening of blood vessels is found near synovial membranes, but synovial fluid is unremarkable [110]. Electron microscopy shows layered basement membranes.

Etiology and pathogenesis

A controversial hypothesis had suggested that some circulating factor in pachydermoperiostosis acts on vasculature to cause hyperemia, thereby altering soft tissues; later, blood flow is reduced [111].

Treatment

There is no established treatment. Painful synovial effusions may respond to nonsteroidal anti-inflammatory drugs. Colchicine reportedly helped one patient. Contractures or neurovascular compression by osteosclerotic lesions may require surgical intervention.

HEPATITIS C-ASSOCIATED OSTEOSCLEROSIS

In 1992, a new disorder featured severe, generalized osteosclerosis and hyperostosis in former intravenous drug abusers infected with the hepatitis C virus [112]. Approximately 20 cases have been reported, and hepatitis C virus infection proved common to all patients. Perios-

teal, endosteal, and trabecular bone thickening occurs throughout the skeleton, except the cranium. During active disease, the forearms and legs are painful. Dual energy X-ray absorptiometry (DXA) shows values 20–300% above control means. Remodeling of good quality excessive bone seems accelerated during active disease and may respond to antiresorptive therapy. Gradual, spontaneous remission with decreases in DXA values can occur. The IGF system features distinctive increases in circulating levels of IGF binding protein 2 and "big" IGF II [113].

HIGH BONE MASS PHENOTYPE

Certain activating mutations of the LRP5 gene (OMIM: 607636) encoding low-density lipoprotein receptor-related protein 5, inherited as an autosomal dominant trait, increase skeletal mass with good quality bone [114]. Enhanced Wnt signaling stimulates osteoblasts [114]. Some patients have *torus palatinus* [114], cranial nerve palsies, and oropharyngeal exostoses [115]. LRP6 gene activation can also cause high bone mass.

OTHER SCLEROSING BONE DISORDERS

Table 93.1 lists the many conditions that cause focal or generalized increases in skeletal mass. Sarcoidosis characteristically causes cysts within coarsely reticulated bone. However, sclerotic areas occasionally appear in the axial skeleton or long bones. Although multiple myeloma typically features generalized osteopenia and discrete osteolytic lesions, among indolent forms widespread osteosclerosis can occur. Lymphoma, myelofibrosis, and mastocytosis may also increase bone mass. Metastatic carcinoma, especially from the prostate, can cause dense bones. Diffuse osteosclerosis is also frequent in secondary, but not primary, hyperparathyroidism (e.g., renal disease).

INTRODUCTION

Fibrous dysplasia of bone (FD) (OMIM#174800) is an uncommon skeletal disorder with a broad spectrum of clinical presentation. On one end of the spectrum, patients may present in later life with an incidentally discovered, asymptomatic radiographic finding that is of no clinical consequence. On the other end of the spectrum, patients may present early in life with a disabling disease. The disease may involve one bone (monostotic FD), multiple bones (polyostotic FD), or the entire skeleton (panostotic FD) [1–3]. FD may be associated with extraskeletal manifestations, the most common of which is areas of cutaneous hyperpigmentation commonly referred to as café au lait macules. These lesions vary widely in size but have characteristic features that include jagged, "coast of Maine" borders, some relationship with the midline, and sometimes follow the developmental lines of Blaschko [Fig. 94.1(A)–(C)]. FD can also be associated with hyperfunctioning endocrinopathies, including precocious puberty, hyperthyroidism, growth hormone (GH) excess, and Cushing syndrome. FD in combination with one or more of the extraskeletal manifestations is known as McCune-Albright syndrome (MAS) [4–7]. A renal tubulopathy, which includes renal phosphate wasting, is one of the most common extraskeletal dysfunctions associated with polyostotic disease [8]. More rarely, FD may be associated with myxomas of skeletal muscle (Mazabraud's syndrome) [9] or dysfunction of the heart, liver, pancreas, or other organs within the context of the MAS [10].

ETIOLOGY AND PATHOGENESIS

FD is caused by missense mutations of the *GNAS* complex locus on chromosome 20q13.3 [11–13]. *GNAS* encodes the alpha subunit of the stimulatory G protein ($G_s\alpha$), a unit of a trimeric protein complex involved in the cyclic adenosine monophosphate (cAMP)-dependent signaling pathway. In the majority of FD patients, the mutation replaces the arginine 201 of $G_s\alpha$ with a histidine (R201H) or a cysteine (R201C); more rarely, other amino acid substitutions are observed at the same position [14] or in other codons (Q227) [15]. In all cases, the mutation impairs the intrinsic GTPase activity of $G_s\alpha$, leading to persistent stimulation of adenylyl cyclase and aberrant production of cAMP (gain-of-function mutations) [16]. Mutations of *GNAS* associated with FD and related disorders are never inherited and could theoretically occur at any time during post-zygotic development. However, the mechanism by which the two most common amino acid replacements are established, which is aberrant methylation of the CpG dinucleotide in the R201 codon, indicates that for the majority of FD patients a restricted time window, i.e., the phase of active methylation of the genome that takes place in the inner cell mass, is the period during which the mutational event occurs [17]. This implies the involvement of a pluripotent cell as the initial target of the disease, thus explaining how the mutation can be transmitted to derivatives of all three germ layers and be broadly distributed in patients with severe forms of the disease. At the same time, differences in the size and viability of the clone

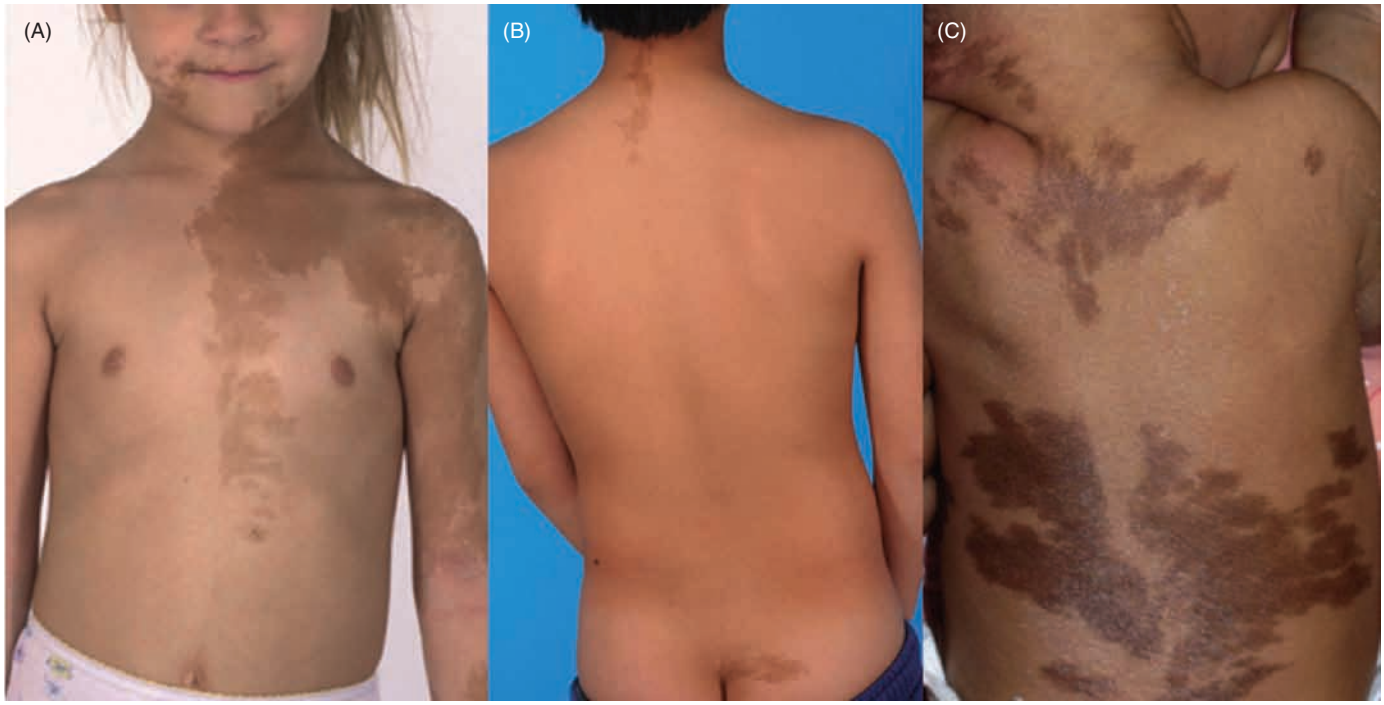

Fig. 94.1. Café au lait skin pigmentation. (A) A large pigmented macule with a classical appearance on the face, chest, and arm of a 5-year-old girl with McCune-Albright syndrome that demonstrates jagged "coast of Maine" borders, and the tendency for the lesions to respect the midline. (B) Small but typical lesions that are often found on the nape of the neck and crease of the buttocks are shown, which also show a relationship to the midline. (C) Extensive lesions on the back of an infant that follow the developmental lines of Blaschko.

arising from the original mutated pluripotent cell could account for the variability of the clinical phenotype observed in the majority of FD patients [18].

The pathology of FD (Fig. 94.2) is characterized by the development of fibro-osseous lesions that replace normal skeletal structures and impair normal skeletal functions. The fibrotic tissue is typically devoid of hematopoiesis and adipose marrow. The bony part consists of trabeculae that are abnormal in amount, distribution, and shape. Different site-specific histological patterns of the disease have been recognized (Chinese writing, sclerotic pagetoid, and sclerotic hypercellular). However, at all affected sites, recurrent subtle histopathological features (stellate-shaped osteoblasts, Sharpey fibers) can be observed as diagnostic hallmarks of the disease, distinguishing it from other skeletal fibro-osseous diseases [19]. Previous work indicated that the histology of FD results from the abnormal differentiation of postnatal multipotent skeletal stem cells and from the abnormal function of mutated osteoblasts brought about by the *GNAS* mutation [20, 21, 22]. Indeed, recent studies showed that normal human skeletal stem cells transduced with the mutated $G_s\alpha$ sequence display impaired adipogenic differentiation and deranged expression of osteogenic markers [23]. Furthermore, the selective downregulation of the mutated allele by specific RNA-interfering sequences reverts the molecular phenotype (normalization of cAMP production) and restores adipogenic differentiation [23]. Most of the histopathological features of FD emanate from the osteogenic nature of the lesional tissue. The severe osteomalacic change of the FD bone [13,24], which plays a major role in the skeletal morbidity of the disease, is related to excess production of the phosphaturic hormone, FGF23, by the expanded osteogenic tissue [25]. The inappropriate osteoclastogenesis observed within the FD tissue is dependent on osteogenic cells through secretion of interleukin-6 (IL-6) [26] and likely, as recently shown in transduced cells, through the upregulation of receptor activator of nuclear factor-κB ligand (RANKL) caused by the *GNAS* mutation [23]. Multiple determinants contribute to the establishment, evolution, and natural history of each FD lesion. The local number of mutated cells likely plays the major role in the development of the disease. However, unexpected epigenetic and nongenetic mechanisms have emerged along the way as potential adjunctive modulators of the clinical expression of the disease. The expression of the two $G_s\alpha$ alleles in clonogenic osteoprogenitor cells is asymmetric and random [27]. This implies that different skeletal sites with an equal number of mutated cells can have different levels of expression of the mutated allele and therefore a different likelihood of developing the disease. Furthermore,

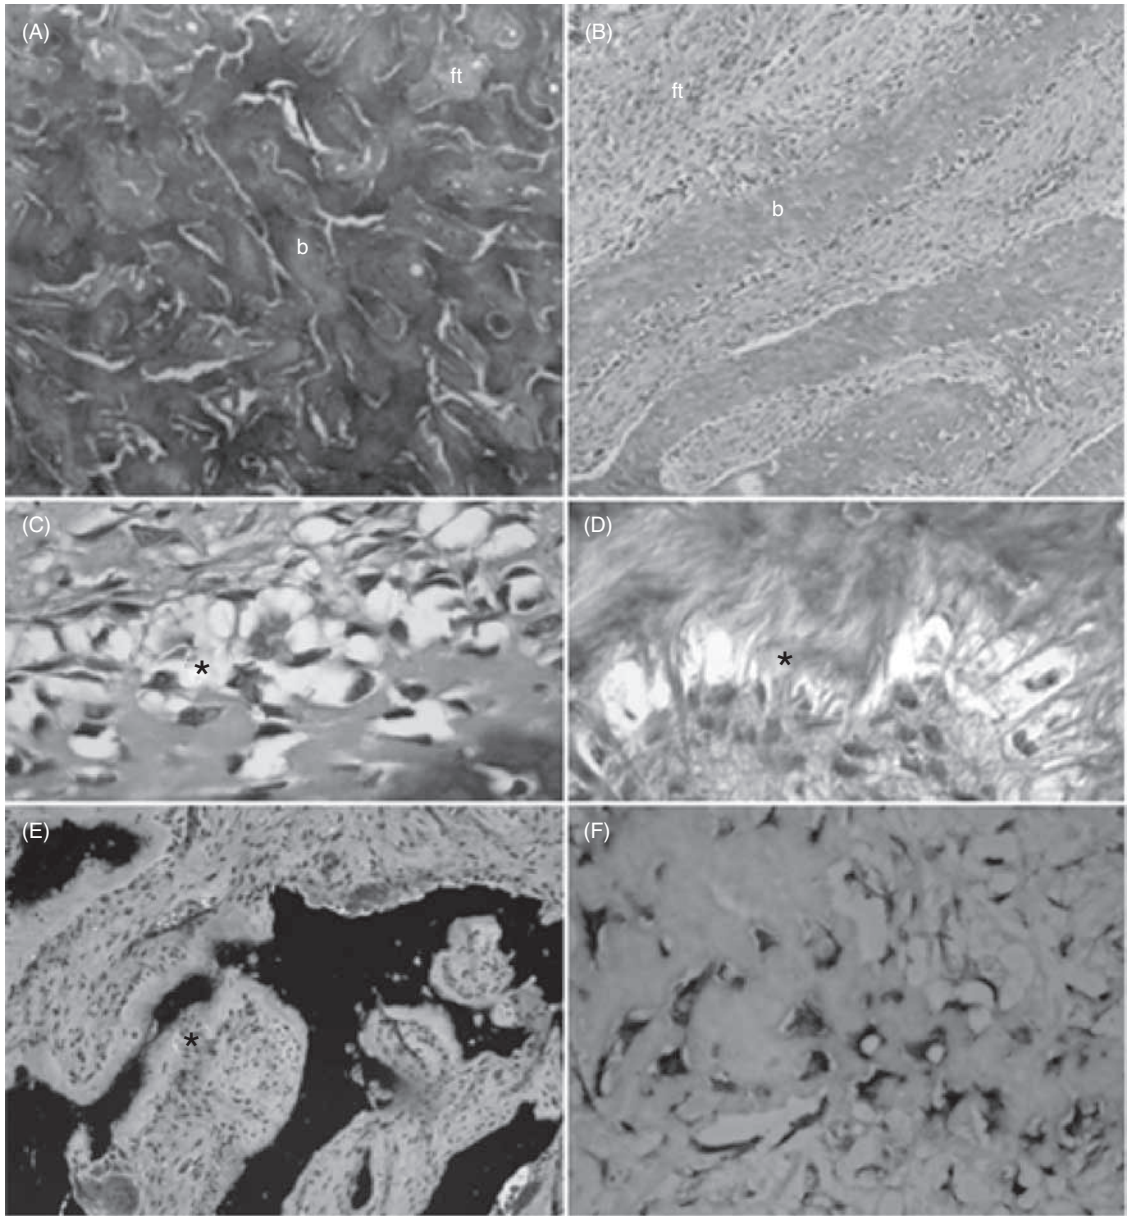

Fig. 94.2. Representative histological images of craniofacial FD. (A) Calvarial FD lesions are characterized by uninterrupted networks of bone trabeculae (b) embedded in the fibrous tissue (ft). (B) In FD, lesions from gnathic bones, newly formed bone trabeculae (b) are deposited within the fibrous tissue (ft) in a typical discontinuous and parallel pattern. (C)–(D) Recurrent histological features of FD. (C) Morphologically abnormal osteoblasts on bone surfaces (asterisk). (D) Collagen fibers perpendicularly oriented to forming bone surfaces (Sharpey fibers, asterisk). (E)–(F) Osteomalacic changes and FGF23 production in FD. (E) Excess osteoid (asterisk) and severe undermineralization of the fibrous dysplastic bone. (F) FGF23 is produced by activated FD osteogenic cells, as shown by *in situ* hybridization.

FD lesions have often been reported to improve clinically over time. Recently it has been shown that this may be dependent on the progressive consumption of mutant clonogenic progenitors followed by regeneration of normal bone and marrow by the remaining wild-type cells [28].

CLINICAL FEATURES

The sites of skeletal involvement (the "map" of affected tissues) are established early in patients with FD. Ninety percent of the craniofacial lesions are established before

the age of 5, and 75% of all sites of FD are evident by the age of 15; the implication is that essentially all clinically significant disease is present very early in life, probably by the age of 5 [3]. Pathological effects of $G_s\alpha$ mutations in osteogenic cells are most pronounced and evident during the phase of rapid bone growth, and account for the fact that childhood and adolescence are the periods during which the disease most commonly presents, is the most symptomatic, and is the period of peak rate of fractures [29, 30]. Presentation in infancy is rare, and usually heralds severe, widespread disease with multiorgan involvement. The most common presenting features are a limp, pain, or a fracture. While in general children are less likely to have pain and/or complain of pain *per se*, their manifestation of pain may be to report being "tired" [31]. In adults, the complaint of pain is common and may be severe. Sites commonly affected are the ribs, long bones, and craniofacial bones, while lesions in the spine and pelvis are typically less painful [31]. Pathological fractures of weight-bearing limb bones are a major cause of morbidity. Deformity of limb bones, which is a common finding, is caused by expansion and abnormal compliance of lesional FD, fracture treatment failure, and occasionally local complications such as cyst formation [18]. Deformity of craniofacial bones is solely the result of the overgrowth of lesional bone.

Although any bone may be affected, the proximal metaphysis of the femora and the skull base are the two sites most commonly involved [31]. Femoral disease usually presents in childhood with limp, pain, fracture, and deformity that ranges from coxa vara to the classical shepherd's crook deformity [Fig. 94.3(A)]. Radiographically, the lesion may be limited to the metaphysis or extend along the diaphysis for a variable length [32]. The picture most commonly observed in children and adolescents consists of an expansile, deforming lesion that arises in the medullary space, with cortical thinning and with a "ground glass" appearance on radiograph [Fig. 94.3(A)]. The radiographic picture is significantly affected by the evolution of the lesion over time, with lesions tending to become more "sclerotic" and less homogenous with time and aging [Fig. 94.3(B)]. Sclerosis in FD lesions of the femur and other limb bones reflects less active disease.

In the skull, the skull base and the facial bones are commonly involved. The typical presentation is in childhood with facial asymmetry or a "bump" that persists, but symmetric expansion of the malar prominences and/or frontal bosses may also be seen. The disease can progress into adulthood and result in disfiguration and, as can be seen on imaging studies, encroachment on the cranial nerves and/or the otic capsule. However, vision and/or clinically significant hearing loss are uncommon but more likely to occur when FD is accompanied by GH excess in the context of MAS [33–35]. Vision loss can also occur uncommonly (fewer than 5% of the patients) in setting of a posthemorrhagic cyst, sometimes referred to as an aneurysmal bone cyst, which may arise in the highly vascular FD bone [36].

Radiographically, craniofacial FD typically has a homogenous "ground glass" appearance in children [Fig. 94.3(C)], but with age the radiographic appearance is mixed with both solid and cystic areas [Fig. 94.3(D)]. Lesions in the spine, ribs, and pelvis are common, but more difficult to appreciate on plain radiographs. These are more readily detected by bone scintigraphy, which is a more sensitive imaging technique for the detection of FD lesions [Fig. 94.3(E)–(G)]. Disease in the spine is common, frequently associated with scoliosis, may require surgery, and can be progressive into adulthood [37]. Because FD in the spine is common and can progress to a degree that can be lethal if untreated, it is important to monitor for the presence of a curve and its relative stability or progression.

Malignancy in FD is rare (less than 1%) [38]. While there is an association between the development of cancer and prior treatment with high dose external beam radiation [39, 40], it may also occur independently of prior exposure to ionizing radiation. Rapid lesion expansion and disruption of the cortex on radiographs should alert the clinician to the possibility of sarcomatous change. Osteogenic sarcoma is the most common but is not the only type of bone tumor that may complicate FD. The clinical course is usually aggressive, and surgery is the primary treatment; chemotherapeutic regimens do not appear to improve prognosis significantly.

MANAGEMENT AND TREATMENT

Diagnosis of FD must be established based on expert assessment of clinical, radiographic, and histopathological features. Markers of bone turnover are usually elevated [8]. The extent of the skeletal disease is best determined with total body bone scintigraphy, which can be used to assess the skeletal disease burden and predict functional outcome [41]. The metabolic derangements associated with FD, especially hypophosphatemia and growth hormone excess, are associated with a significantly worse clinical outcome, and therefore must be screened for and treated [24, 30, 33, 35].

Mutation analysis may be helpful in distinguishing FD from unrelated fibro-osseous lesions of the skeleton, which may mimic FD both clinically and radiographically (osteofibrous dysplasia, ossifying fibromas of jawbones; reviewed in Ref. 18). Isolated lesions of the proximal femur in adults may be improperly diagnosed and classified as distinct fibro-osseous lesions. For example, all cases of so-called liposclerosing myxofibrous tumor, in which *GNAS* mutations were sought, were found to represent monostotic fibrous dysplasia [42]. Multiple non-ossifying fibromas, skeletal angiomatosis, and Ollier's disease may sometimes enter the differential diagnosis. Distinction from these entities relies on histology and mutation analysis.

Disease of the proximal femur, in which there is fracture or impending fracture, is often best treated by

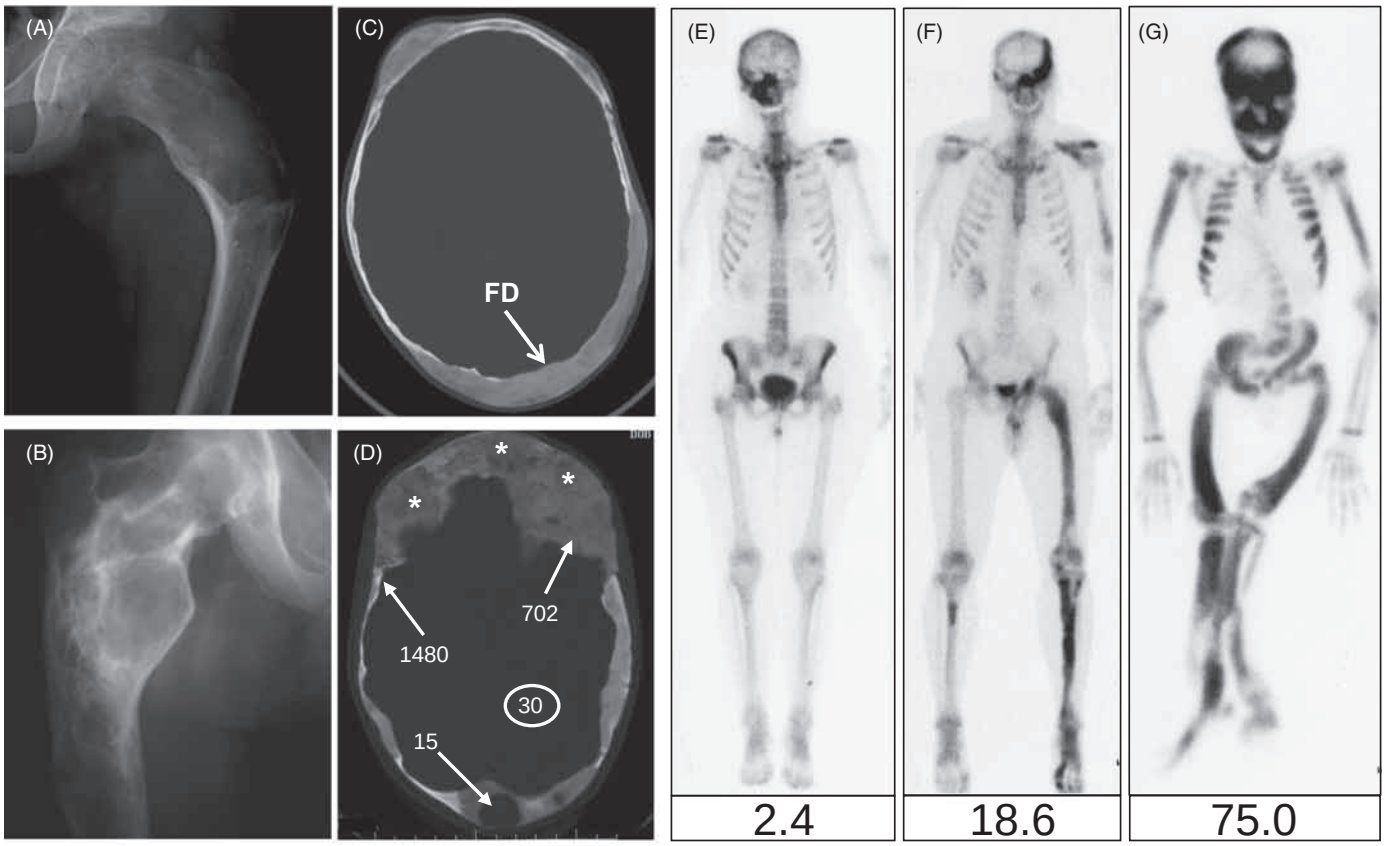

Fig. 94.3. Radiographic appearance of fibrous dysplasia. (A) A proximal femur with typical ground glass appearance and shepherd's crook deformity in a 10-year-old child is shown. (B) The appearance of FD in the femur of an untreated 40-year-old man demonstrates the tendency for FD to appear more sclerotic with time. (C) A CT image of a 10-year-old child with FD is shown. The white arrow indicates an area of FD with typical ground glass appearance that is the predominant radiographic appearance of FD in children. (D) A CT image of a 40-year-old woman demonstrates the typical appearance of craniofacial FD in an older person. Note that compared to that of the 10-year-old in (C), the FD in the frontal bone (asterisks) demonstrates a more heterogeneous pattern that is common in adults of mixed solid and "cystic" lesions. The numbers indicate the Hounsfield Unit (HU) measurements in various types of tissue/lesions that can be seen in FD. The number 1480 indicates the density of the rim of normal bone seen laterally, 702 indicates the HU of typical FD, 30 is the HU density of normal brain tissue, and 15 is the HU density of a fluid-filled lesion (true cyst) that can be rarely observed in FD. (E)–(G) Bone scintigraphy in FD. Representative ^{99}Tc-MDP bone scans that demonstrate the spectrum of disease severity and show tracer uptake at skeletal sites affected with FD. Below each image is the calculated skeletal disease burden score (see Ref. 41). (E) A 50-year-old woman with monostotic FD confined to a single focus involving contiguous bones in the craniofacial region. (F) A 42-year-old man with polyostotic FD shows the tendency for FD to be predominantly (but not exclusively) unilateral, and to involve the skull base and proximal femur. (G) A 16-year-old boy with McCune-Albright syndrome and involvement of virtually all skeletal sites is shown (panostotic FD).

insertion of intramedullary nails, in an effort to prevent serious deformity and limb length discrepancy [32, 43, 44]. In children, this may require specially designed nails or the modification of devices intended for one anatomical site for another, e.g., adult humeral rods for the femur [32, 43]. Indications for surgery of the craniofacial bones may include cosmesis, or documented vision or hearing loss. In all cases, operations should be undertaken with caution and only by experienced surgeons. Contouring or "shaving" procedures for cosmesis often invoke a rapid regrowth, especially in children, and operations for vision loss are frequently not successful at restoring vision [34, 45]. Prophylactic surgery to prevent vision loss is not advocated [34, 35]. Treatment with bisphosphonates (pamidronate, etc.) has been advocated based on observational studies with claims of reduced pain, decreased serum and urine markers of bone metabolism, and improvement in the radiographic appearance of the disease [46, 47]. However, an open label, prospective study with appropriate histological, radiographic, and clinical end points, which also demonstrated pain relief, showed no benefit radiographically or histologically [48]. Ongoing placebo controlled studies in the U.S. and Europe may help to better define the role of bisphosphonates in treating FD.

Two additional drugs that are currently approved for the treatment of other conditions, and which may prove

beneficial in the treatment of FD, are tocilizumab and denosumab. Tocilizumab is an antagonist of the IL-6 receptor that is approved for the treatment of rheumatoid arthritis [49]. Based on *in vitro* data indicating a role for IL-6 excess in the pathophysiology of FD [26], treatment with tocilizumab is rational. As RANKL has also been shown to play a role in the pathophysiology of FD *in vitro* [23], treatment with the anti-RANKL antibody, denosumab, which is approved for the treatment of osteoporosis and cancer-related bone metastases [50, 51], also makes sense.

FUTURE TREATMENT

Currently available medical and surgical therapies are not satisfactory. Current efforts are directed at elucidating the effects of silencing the disease-causing gene in skeletal stem cells in *in vitro* and *in vivo* models of gene therapy [23], on devising strategies for using stem cells as either a tool or a target of therapies [23], and on identifying novel drugs that specifically target the constitutively active $G_s\alpha$ or its functional effects. As part of these approaches, it will be important to elucidate additional molecular mediators of the disease phenotype, downstream of the mutated $G_s\alpha$. Crucial to the overall goal of finding effective methods for therapy and, hopefully, curing FD, is the development of suitable animal models of the disease.

INTRODUCTION

Genetic disorders of the skeleton are a clinically and genetically heterogeneous group of disorders of bone and/or cartilage characterized by abnormalities in growth, development, and/or homeostasis of the human skeleton [1]. They include the osteochondrodysplasias (primarily affecting bone and/or cartilage), the dysostoses (affecting a single bone or group of bones), the brachydactylies (primarily involving the hands and feet) and the lysosomal storage diseases. Although relatively rare individually, the skeletal dysplasias have an estimated birth prevalence of nearly 1/5,000 [2]. The generalized and progressive abnormalities lead to changes in the size and shape of the limbs, trunk, and/or skull, frequently resulting in disproportionate short stature [3]. In the past, most disproportionate dwarfs were referred to as having either achondroplasia [MIM #100800] (i.e., those with short limbs), or Morquio disease [MIM #253010] (i.e., those with short trunks). It is now apparent that there are over 450 distinct genetic disorders of skeleton that must be distinguished one from the other for specific genetic counseling, prognosis, and treatment. A need to develop a uniform and consistent nomenclature and classification system for these conditions led to the International Nomenclatures of Constitutional Diseases of Bone. These were initially formulated in 1972 in Paris and have since been regularly revised. The initial categorizations were purely descriptive and consisted of a mixture of the key clinical, radiographic, and pathologic features of each condition. The concept of "families" of disorders then evolved, where conditions with similar genetic backgrounds or apparent pathogenetic mechanisms were grouped together [4].

In the latest 2010 revision of the Nosology and Classification of Genetic Skeletal Disorders, there was an increase from 372 to 456 disorders in the 4 years since the classification was last revised in 2007 [5, 6]. Of these conditions, 316 are associated with one or more of 226 different genes. This increase reflects the continuing delineation of unique phenotypes among short stature conditions, which in aggregate represent about 5% of children with birth defects [7]. Some of the increase has also been driven by technological improvements in our ability to define the molecular genetic basis of these conditions, which is now known for 316 of the disorders (215 in the prior revision), with defects in 226 (140 previously) different genes. Most of the molecules and pathways recognized to be essential for normal skeletal development have been identified by characterizing the genetic basis of the skeletal dysplasias. These studies have revealed that many different mechanisms can be disrupted, leading to the short stature and deformity that characterize this group of disorders. Defects in structural molecules of the extracellular matrix, which were the first skeletal dysplasias in which the molecular basis was identified [8, 9], continue to be important in the molecular pathogenesis of these disorders [10, 11], as do defects in their post-translational modification and processing [12–15]. However, abnormalities in transcription factors, signal transduction, nucleic acid metabolism, proteoly-

sis, peroxisome function, osteoclast resorption, cytoskeletal structure, and cilia function, among others, have also been identified in skeletal dysplasias.

In this latest 2010 revision of the Nosology and Classification of Genetic Skeletal Disorders, 456 different conditions are listed in 40 groups (Table 95.1): Groups 1–8 are based on a common gene or pathway (collagen II group, aggrecan group). Groups 9–17 reflect radiographic changes in a specific bone structure (vertebrae, epiphyses, metaphyses, diaphysis, or combinations) or involved segment (rhizo, meso, or acro). Groups 18–20 define macroscopic criteria in addition to clinical features (bent bones, slender bones, multiple dislocations). Groups 21–25 and 28 are mineralization defects. Groups 26 and 27 include hypophosphatemic rickets and the large group of lysosomal disorders with skeletal involvement, respectively. Group 29 involves disorganization of skeletal components (enchondromas, exostoses, etc.). Group 30 (overgrowth syndromes with significant skeletal involvement) and Group 31 (genetic inflammatory/rheumatoid-like osteoarthropathies) have been added, underlining the frequent diagnostic overlap between these disorders and primary skeletal disorders. Finally, Groups 32–40 are dedicated to various dysostoses [6].

It is apparent that no single classification of these disorders will be adequate. However, using the Nosology is of benefit to the clinician, providing a list of disorders along with possible differential diagnoses.

MULTIDISCIPLINARY APPROACH

The evaluation of patients with skeletal dysplasias mandates a multidisciplinary approach involving clinical geneticists, radiologists, molecular biologists, and biochemical geneticists for diagnosis and a host of surgical specialists for management of their many complications [16]. A careful clinical examination and detailed radiographic evaluation of the skeleton are the first steps toward an accurate diagnosis. A detailed history (length at birth, growth curves, etc.) and pedigree analysis, followed by anthropometric measurements with special emphasis on body proportions are important. Serial radiographic evaluations are often necessary as some skeletal abnormalities may become evident at a later age [4, 17] (Fig. 95.1). In an adult patient, the availability of a prepubertal skeletal survey, allowing the evaluation of the epiphyses and metaphyses before epiphyseal closure, can be essential for diagnostic purposes. Comparison to normal radiographs at the particular age can be a key for diagnosis. Ossified epiphyses, which are small and/or irregular for age, suggest an epiphyseal dysplasia. Widened, flared, and/or irregular metaphyses suggest a metaphyseal dysplasia, while a diaphyseal abnormality (widening, cortical thickening or marrow space expansion) suggests an osteodysplasia. (Fig. 95.1). A combination of the aforementioned findings with platyspondyly or vertebral irregularities is helpful in recognizing chondrodysplasias coined "spondyloepiphyseal dysplasia (SED), spondyloepimetaphyseal dysplasia (SEMD), etc. [17]. Recognition of other well-known, often pathognomonic skeletal changes in the skeletal survey is helpful in narrowing the list of entities considered in the differential diagnosis [2, 17].

Morphologic examination of cartilage and bone should also be a part of the diagnostic work-up when possible [3]. Patients undergoing surgery should be considered for bone and cartilage specimen collection. Details on the collection and analysis of such specimens can be found at the International Skeletal Dysplasia Registry (www.csmc.edu/skeletaldysplasia).

FUTURE REFLECTIONS OF CURRENT RESEARCH

In the past decade, enormous progress has been made in our knowledge concerning the biochemistry and molecular genetic basis of these disorders [18, 19]. In the 1980s, elucidation of defects in the type I collagen genes in osteogenesis imperfecta paved the way to further assessment of matrix protein defects in the skeletal dysplasias [20]. A large number of matrix protein defects have now been described in the chondrodysplasias, including types I, II, IX, X, and XI collagen; matrillin 3; COMP; perlecan; and aggrecan. In addition to these defects in extracellular (matrix) structural proteins, the chondrodysplasias can also be pathogenetically grouped into disorders with defects in metabolic pathways (including enzymes, ion channels and transporters); defects in folding, processing, transport, and degradation of macromolecules; defects in hormones, growth factors, receptors and signal transduction; defects in nuclear proteins (transcription factors, homeobox genes); defects in RNA processing and metabolism; and defects in cytoskeletal proteins [21, 22].

As the underlying molecular pathogenesis of phenotypically grouped entities are unraveled, the entities are reclassified according to gene or molecular pathway. Two newly formed groups (the TRPV4 group and the aggrecan group) in the latest Nosology are perfect examples (see Table 95.1). The TRPV4 group includes disorders previously classified under different groups and provides a new prototypic spectrum ranging from mild to lethal (from autosomal dominant brachyolmia to metaphyseal dysplasia Kozlowski type to metatropic dysplasia) [19]. Identification of the molecular basis of many skeletal dysplasias has demonstrated that mutations in the same gene can produce quite distinct phenotypes, such as achondrogenesis II [MIM #200610] and Stickler syndrome [MIM #108300] with mutations in *COL2A1* [21]. In contrast, similar phenotypes can be produced by mutations in different genes acting through a similar pathway. For example, Noggin and GDF5 cause multiple synostosis. As the underlying molecular basis of phenotypically grouped entities are unraveled, they are reclassified according to gene or molecular pathway (see Table 95.1).

Table 95.1. Osteochondrodysplasias (Nosology and Classification of Genetic Skeletal Disorders: 2010 Revision)

Name of Disorder	Inheritance	MIM No.	Locus	Gene	Protein

Fig. 95.1. Chondrodysplasias. Classification based on radiographic involvement of long bones and vertebrae (from Ref. 3).

The technology today warrants rapid identification of novel disease-causing genes with new sequencing tools. It is now apparent that no single classification of these disorders will be adequate, necessitating the development of a multidimensional electronic classification tool, incorporating clinical, radiographic, morphologic, biochemical, molecular, and pathway data. The transformation of the Nosology into a database is therefore likely.

Accumulating knowledge on the biology of bone and cartilage and the molecular and pathogenetic defects in each of these disorders provides hope for possible therapeutic approaches in the near future for affected individuals. Finally, research in this group of monogenic disorders continues to provide genetic models for more common multifactorial complex diseases of the bones and joints, such as osteoarthritis, osteoporosis, scoliosis, and disc herniation.

ISCHEMIC BONE DISEASE (OSTEONECROSIS)

Introduction

Regional interruption of blood flow to the skeleton can cause ischemic (aseptic or avascular) necrosis. Ischemia, if sufficiently severe and prolonged, will kill osteoblasts and chondrocytes. Clinical problems will arise if subsequent resorption of necrotic tissue during skeletal repair compromises the bone strength sufficiently to cause fracture with subsequent deformity of bone and secondary damage to cartilage.

Epidemiology

There are little accurate data on the incidence of osteonecrosis, although it is estimated there are approximately 15,000 new cases per year in the U.S. [1]. The disease appears to occur more frequently in males than in females, with the overall male to female ratio being 8:1. The age of onset is variable, although in the majority of cases, the patient is less than 50 years of age. The average age of female cases is on average 10 years older than male cases.

Pathogenesis

Osteonecrosis is often seen in association with a number of different conditions (Table 96.1). Trauma with fracture of the femoral neck interrupts the major part of the blood supply to the head and may lead to osteonecrosis. Glucocorticoids and alcoholism are two of the main iatrogenic factors known to predispose to osteonecrosis.

An increasing number of reports have appeared in the medical literature that suggest that the use of bisphosphonates, especially intravenous bisphosphonates, is associated with osteonecrosis of the jaw (ONJ) [2]. There is no universally accepted definition of ONJ, and it may represent a distinct form of osteonecrosis, different from the other forms. Clinically, it typically appears as an area of exposed alveolar bone that can occur in the mandible or the maxilla. The majority of these reports are in patients with multiple myeloma, breast cancer, or other malignancies. In connection with these malignancies, the patients were receiving or did receive intravenous nitrogen-containing bisphosphonates in much higher doses than those used for osteoporosis and Paget's disease. The condition has also been seen in those receiving treatment with denosumab, a monoclonal antibody against receptor activator of nuclear factor-κB ligand (RANKL) [3].

A mechanical interruption to the bone's blood supply is common to most of the conditions associated with osteonecrosis. For many types of nontraumatic ischemic necrosis, the predisposed sites seem to reflect the physiological conversion of red marrow to fatty marrow with aging [4]. This process occurs from distal to proximal in the appendicular skeleton. As the transition occurs, marrow blood flow decreases. Accordingly, disorders that increase the size and/or number of adipocytes within critical areas of medullary space (e.g., alcohol abuse,

Cushing's syndrome) may ultimately compress sinusoids, thereby leading to infarction of bone. Other factors potentially involved in the pathogenesis of osteonecrosis include fat embolization, hemorrhage, and abnormalities in the quality of susceptible bone tissue. Infection and dental trauma appear important factors in the etiology of ONJ.

A genetic basis to idiopathic osteonecrosis of the femoral head is suggested by the occurrence of disease in twins and a clustering of cases in families [5, 6]. Increased incidence of osteonecrosis in specific animal models also provides further evidence of the existence of susceptibility genes [7]. In sporadic cases of osteonecrosis of the femoral neck, a number of genetic association studies have been conducted, linking specific genes to the pathogenesis of disease. The majority of the studies have, to date, focused on gene polymorphisms affecting the coagulation and fibrinolytic system.

The factor V Leiden mutation (G1691A, Arg506Gln) is a common risk factor for thrombophilia. Three out of four studies investigating the role of the mutation in osteonecrosis have reported a positive correlation of factor V Leiden with primary osteonecrosis [8–11]. Plasminogen-activating inhibitor-1 (PAI-1) was also studied in patients with osteonecrosis. Homozygosity for the 4G allele (4G/4G) has been reported to significantly increase the plasma PAI-1 level, and in two studies by the same group of investigators, the 4G/4G allele was found to be a risk factor of osteonecrosis [11, 12]. Some studies have also investigated the role of 5,10-methylenetetrahydrofolate reductase (MTHFR) gene polymorphism. The MTHFR C677T variant was overrepresented in some groups of primary studies of osteonecrosis, but not in all [11–13]. In another study, the first that did not focus on the coagulation system, the role of endothelial nitric oxide synthase (eNOS) was investigated [14]. Nitric oxide (NO) synthesized by eNOS has vasodilatory effects on vascular tone, inhibits platelet aggregation, and modulates smooth muscle proliferation. Allele 4a of a variable number tandem repeat (VNTR) polymorphism in intron 4 of the eNOS gene was found to be a risk factor for idiopathic osteonecrosis at the hip.

Genetic mutations have been identified in three families with osteonecrosis and dominant inheritance. Mutations in the type II collagen (COL2A2) gene (mapped on chromosome 12q13) proved to be the genetic cause of the disease. Type II collagen is the major structural protein in the extracellular matrix of cartilage [15].

Clinical features

The clinical presentation will be dependent on many factors, including the age of the patient, anatomical site of involvement, and the extent and severity of this involvement. The femoral head is the most common location for the development of osteonecrosis, although it may also occur at other sites including distal femur, humeral head, wrist, and foot. Patients may develop pain that can persist for weeks to months before radiographs show any change, although patients can be asymptomatic. Avascular necrosis at the hip classically will present with pain in the groin, although this can be referred to the buttock, thigh, or knee. The pain is exacerbated by weight bearing but can also be present at rest. Gait may be affected, and patients can present with a limp. Once the femoral head has begun to collapse, range of hip movement will be reduced, and leg shortening may develop.

In osteonecrosis of the hip, involvement of the contralateral hip is present in 30–70% of cases at the time of first examination. Within 3 years of diagnosis, more than 50% of cases will have progressed in the contralateral hip to such a stage where surgical intervention is required [16, 17].

Radiological features

In the earliest stages of the disease, plain radiographs will be normal. Magnetic resonance imaging (MRI) is useful to detect early pathological changes. The most characteristic image is a margin of low signal on T1- and

Table 96.2. Staging of Osteoenecrosis

Stage	Findings	Techniques
0	All techniques normal or nondiagnostic Necrosis on biopsy	Biopsy and histology
1	Radiographs and CT normal Positive result from at least one of the additional investigations listed opposite	Radionucleotide scan MRI Biopsy and histology
2	Radiographic abnormalities without collapse (sclerosis, cysts, osteopenia)	Radionucleotide scan MRI Biopsy and histology
3	Crescent sign	Radiographs CT
4	Flattening or evident collapse	Radiographs CT
5	As for stage 4, with narrowing of joint space	Radiographs
6	As for stage 5, with destruction of joint	Radiographs

T2-weighted images, and is observed in 60–80% of cases. Radionucleotide isotope bone scans and computed tomography (CT) can also be used in cases where MRI is either contraindicated or has been inconclusive. Osteonecrosis can be staged according to the sequence of the radiological changes. These are detailed in Table 96.2.

Laboratory findings

In idiopathic osteonecrosis, laboratory investigations will generally be normal. Investigations may reveal potential contributory factors such as connective tissue disease, diabetes, hyperlipidaemia, coagulopathies, and gout.

Histopathological examination of tissue from affected bone is consistent with the pathogenesis that is suggested from the radiographic examinations. It shows that these various processes of skeletal death and repair are focal and may be occurring simultaneously [18].

Differential diagnosis

In stages 3 and 4 of the disease, the radiological features of the disease are specific. In the later stages 5 and 6, a differential diagnosis is not necessary as by this stage the bone and joint have been irreversibly damaged, and the only treatment option would be joint replacement. In the earlier stages of the disease (1 and 2), other diseases of bone, cartilage, and synovial tissue should be considered in the differential diagnosis.

Treatment

Medical treatment includes non-weight-bearing for osteonecrosis affecting load-bearing bones. This may be for between 4 and 8 weeks. Vasoactive drugs such as prostacyclin may play a role in early stages of osteonecrosis [19]. Bisphosphonates have also been shown to be effective in the treatment of osteonecrosis. Data have been observed for alendronate [20] and zoledronate [21].

Surgical treatment for osteonecrosis involves core decompression. This reduces the intramedullary pressure within the ischemic bone and has been postulated to improve circulation. The outcome from core decompression at the femoral head, with regard to resolution of radiographic changes and improvement in symptoms, varies from between 34% and 95% in the early stages of the disease [22]. These results appear better than continuing with conservative measures such as non-weight-bearing.

INFILTRATIVE DISORDERS

Systemic mastocytosis

In systemic mastocytosis (OMIM 154800) there is widespread infiltation of tissues with mast cells. These cells can be widely disributed in nearly every organ, and originate from bone marrow progenitor cells. An activating mutation in the C-KIT gene coding for c-kit (the receptor for stem cell factor) that controls mast cell development has been identified [23]. The relationship, however, between these mutations and the clinical phenotype is not fully clarified.

The clinical features of mastocytosis are produced by liberation of mast cell products. Urticaria pigmentosa has been described in between 14% and 100% of patients with systemic mastocytosis. Radiographic appearances can be variable, and the diagosis is often confirmed on bone biopsy and histological examination. The diagnosis can also be made by the measurement of urinary excretion of mast cell mediators such as N-methyl histamine.

Treatment of systemic mastocytosis must be "tailored" in individual patients [24, 25]. Severe bone pain from advanced bone disease has been reported to respond to radiotherapy [26]. In early trials, bisphosphonates have controlled pain and improved bone density [27].

Histiocytosis-X

"Histiocytosis-X" is the term used to unify what had been regarded as three distinct entities: Letterer-Siwe disease (OMIM 246400), Hand-Schüller-Christian disease (OMIM 267700), and eosinophilic granuloma [28, 29]. An immature, clonal Langerhans cell is considered the pathognomonic and linking feature, and the condition is now called Langerhans cell histiocytosis (OMIM 604856).

Many tissues and organs can be involved, including brain, lung, oropharynx, gastrointestinal tract, skin, and bone marrow. Prognosis is age-related; infants and the elderly have poorer outcomes. The signs and symptoms of the three principal clinical forms also differ.

Letterer-Siwe disease presents between several weeks and 2 years of age with hepatosplenomegaly, lymphadenopathy, anemia, hemorrhagic tendency, fever, failure to grow, and skeletal lesions. Hand-Schüller-Christian disease is a chronic condition that begins in early childhood, although symptoms may not manifest until the third decade. The classic triad of findings consists of exophthalmos, diabetes insipidus, and bony lesions, although this is only seen in 10% of cases. Eosinophilic granuloma occurs most frequently in children between 3 and 10 years of age, and it is rare after the age of 15 years. A solitary and painful lesion in a flat bone is the most common finding.

Histiocytosis-X tends to be benign and self-limiting when there is no systemic involvement. Treatment for severe disease includes chemotherapy, radiation therapy, and immunotherapy [30].

Tumoral Calcinosis—Dermatomyositis

Nicholas Shaw

Tumoral Calcinosis 810
Dermatomyositis in Children 812
References 813

TUMORAL CALCINOSIS

Tumoral calcinosis is a rare metabolic disorder characterized by the progressive deposition of calcium phosphate crystals in periarticular spaces and soft tissues. The biochemical hallmark of this condition is hyperphosphataemia due to increased renal tubular reabsorption of phosphate. This form, which is referred to as hyperphosphataemic familial tumoral calcinosis (HFTC) is an autosomal recessive disorder (OMIM #211900). However, tumoral calcinosis is also described in the absence of elevated phosphate, which is referred to as normophosphataemic familial tumoral calcinosis (NFTC) (OMIM #610455). Although the first description of this condition was in 1898, the term "tumoral calcinosis" was not used until 1943 [1].

Clinical features

Mineral deposition manifests as soft tissue masses around major joints. In one report, the order of frequency for the site of first lesions is hips, elbows, shoulders, and scapulae [2]. Onset of the lesions can vary from 22 months to adulthood, with the majority manifesting by 20 years of age. Many cases described in the Anglo-American literature have been of black ancestry with a large number of cases reported from Africa. In many reports, familial cases are described with what appears to be either an autosomal recessive or dominant pattern of inheritance. The soft tissue masses are usually painless and can progressively grow in size to that of an orange or grapefruit. Although they occur around joints they do not usually impair range of movement as they are extracapsular. They can compress adjacent neural structures such as the sciatic nerve and may also cause ulceration of overlying skin, causing a sinus tract that leaks a chalky fluid and may become infected. Some affected subjects have been reported to have features of pseudoxanthoma elasticum, i.e., skin changes, vascular calcification, and angioid streaks of the retina. A specific dental abnormality may be seen with hypoplastic teeth containing short bulbous roots and almost complete obliteration of pulp cavities with pulp stones. A related condition, which is termed "hyperostosis-hyperphosphatemia syndrome" is characterized by recurrent attacks of bone pain and swelling particularly affecting the long bones associated with an elevated level of plasma phosphate. There is now evidence that the two conditions represent a continuous spectrum of the same disease.

Radiographic findings

On plain X-ray, early and small lesions are located in regions known to be occupied by bursae and are often distributed in a para-articular fashion along the extensor surfaces of large joints [3]. These soft tissue lesions comprise multiple globular amorphous calcific components separated by radiolucent fibrous septae. Occasionally fluid levels can be seen indicating a cystic component (Fig. 97.1). An inflammatory process "diaphysitis" may also be seen on plain X-ray, computed tomography (CT),

Fig. 97.1. An area of tumoral calcinosis overlying the right hip in a young child.

or magnetic resonance imaging (MRI) in some cases usually occurring in the middle third of long bones. Vascular calcification has also been reported on plain X-ray or CT. An isotope bone scan is the most reliable and simplest method for detection, localization, and assessment of extension of the calcific masses. Periarticular masses that are radiologically indistinguishable from those described in tumoral calcinosis may be seen in patients with chronic renal failure. Individuals with hyperostosis–hyperphosphatemia syndrome show radiographic changes of periosteal reaction and cortical hyperostosis.

Biochemical findings

Many subjects with tumoral calcinosis have been shown to have elevated levels of plasma phosphate and levels of serum 1,25 dihydroxyvitamin D_3 that are either elevated or inappropriately normal [4]. The tubular maximum of tubular phosphate reabsorption in relation to the glomerular filtration rate (GFR) ($TmPO_4$/GFR) is elevated, but renal function is otherwise normal. However, the condition is also described with normal levels of plasma phosphate. Plasma calcium, alkaline phosphatise, and serum parathyroid hormone are usually normal. Metabolic balance studies have demonstrated positive calcium and phosphorous balances due to increased gastrointestinal absorption and reduced renal excretion.

Histopathology

It is suggested that the early lesions are triggered by bleeding followed by aggregation of foamy histiocytes that then become transformed into cystic cavities lined by osteoclast-like giant cells and histiocytes. Movement and friction due to the periarticular location of the lesions appear to be key to the transformation. In a review of 111 cases from Zaire collected over a 30-year period histology identified exuberant cellular proliferative changes adjacent to the classical cystic form [5]. These consisted either of ill-defined reactive-like perivascular solid cell nests admixed with mononuclear and iron-loaded macrophages or well-organized fibrohistiocytic nodules of variable size embedded in a dense collagenous stroma. Mature lesions are filled with calcareous material in a viscous milky fluid.

Etiology and pathogenesis

The first identification of a genetic basis for tumoral calcinosis was in 2004 when, in a study of large Druze and African-American kindreds, the gene was mapped to 2q24-q31 with identification of biallelic mutations in the *GALNT3* gene in affected individuals [6]. The *GALNT3* gene encodes a glycosyltransferase enzyme responsible for initiating mucin-type O-glycosylation. Haplotype analysis in families with normophosphatemic familial tumoral calcinosis has excluded linkage to 2q24-q31. In a family previously felt to have autosomal dominant inheritance, individuals expressing the full phenotype were shown to have biallelic mutations in *GALNT3* while those who were heterozygous for the mutations showed incomplete expression of the condition, with increased plasma phosphate or 1,25 dihydroxyvitamin D_3 levels but no calcified deposits [7]. Thus, autosomal recessive inheritance of the condition was confirmed. Subsequently, mutations in the gene for *FGF23* were identified in affected individuals who were negative for mutations in *GALNT3* [8, 9]. In addition, elevated plasma levels of C-terminal fibroblast growth factor 23 (FGF23) have been shown in these individuals with low plasma levels of intact FGF23, suggesting failure of secretion of the intact protein from cells.

GALNT3 is now known to produce an enzyme that selectively o-glycosylates a furin-like convertase recognition sequence in FGF23 thus preventing proteolytic processing of FGF23 and allowing secretion of intact FGF23. Thus, mutations in *GALNT3* result in defective secretion of intact FGF23 resulting in hyperphosphatemia and increased synthesis of 1,25 dihydroxyvitamin D_3. Recently, a mutation in the *KLOTHO* gene was reported in a 13-year-old girl with tumoral calcinosis, who in addition to elevated plasma phosphate and 1,25 dihydroxyvitamin D_3 levels also had hypercalcemia and a high serum parathyroid hormone [10]. She had evidence of elevated levels of both C-terminal and intact FGF23 but reduced FGF23 bioactivity. KLOTHO is a cofactor required by FGF23 to enable it to bind and signal through its FGF receptors [11]. Thus, mutations in three genes, *GALNT3*, *FGF23*, and *KLOTHO* have been shown to cause the clinical and biochemical features of tumoral calcinosis. Individuals with the related condition hyperostosis-hyperphosphatemia syndrome have now been shown to

have homozygous or compound heterozygous mutations in the *GALNT3* gene [12, 13] thus confirming that the two conditions represent different aspects of the continuous spectrum of the same disease. There is now evidence that normophosphatemic familiar tumoral calcinosis can be caused by mutations in the gene encoding the sterile alpha motif domain-containing-9 protein (*SAMD9*) [14].

Treatment

Surgical removal of the calcified masses may be required if they are painful, affect function, or for cosmetic reasons. Several different medical approaches to treatment have been reported, although they are usually individual case reports. Aluminium hydroxide in combination with dietary phosphate and calcium restriction has been reported to be successful [15]. Calcitonin has been used to induce phosphaturia [16], and the combination of acetazolamide with aluminium hydroxide used for a 14-year period in one patient was reported to be effective in improving the lesions [17]. Bisphosphonate therapy with alendronate was reported to alleviate symptoms within 12 weeks in one patient [18]. Another potential treatment option is the use of the phosphate binding agent sevelamer, which is primarily used in patients with end stage renal failure. It was used in conjunction with acetazolamide and a low phosphate diet in a 3-year-old girl with a large periarticular mass at the left elbow due to a homozygous mutation in the FGF23 gene [19]. This resulted in a reduction in the plasma phosphate with a significant reduction in the size of the mass.

The identification of the role of FGF23 in phosphate metabolism and tumoral calcinosis may hopefully lead to new medical approaches to treatment.

DERMATOMYOSITIS IN CHILDREN

Juvenile dermatomyositis is an idiopathic inflammatory disorder of the skin and muscle. It is characterized by progressive weakness predominantly of the proximal muscles and a rash that particularly affects the face and the extremities. It differs from adult onset dermatomyositis in that it is frequently associated with small vessel vasculitis in the skin, muscle, and gastrointestinal tract, and there is no association with malignancy. Dystrophic soft tissue calcification or "calcinosis" occurs in damaged or devitalized tissues in the presence of normal calcium/phosphorous metabolism (Fig. 97.2).

Clinical presentation

It is a rare disorder with an estimated incidence of 1.9–2.5 per million children aged under 16 years and is more common in girls than boys, with a ratio of around 2:1. In a U.K. survey, the median age of onset was 6.8 years with two peak ages of onset in the girls of 6 and 11 years [20]. Eighty-eight percent of the reported cases were Caucasian. Calcinosis is not a feature at initial presentation and is usually noted 1 to 3 years after the disease onset and is reported to occur in 20–40% of affected individuals [21]. The duration of untreated dermatomyositis is associated with pathological calcifications thus demonstrating a clear link with chronic inflammation [22]. The dystrophic calcification can cause pain, skin ulceration, limited joint mobility, contractures, and a predisposition to abscess formation. The calcification once present typically remains stable, but some spontaneous resolution is reported infrequently. The clinical course of dermatomy-

Fig. 97.2. Subcutaneous calcification in a child with dermatomyositis.

ositis in children is variable with some having long-term relapsing or persistent disease whereas others recover.

Biochemical and histological features

Levels of plasma calcium, phosphate, and alkaline phosphatase are usually normal. Urinary levels of γ-carboxyglutamic acid have been reported to be elevated particularly if there is calcinosis. The mineral present in the calcified deposits has been shown to be a poorly crystallized hydroxyapatite [21]or carbonate apatite [23]. They contain relatively more mineral than matrix with a composition more similar to enamel than bone. Bone matrix proteins such as osteopontin, sialoprotein, and osteonectin are present within the calcifications with more osteonectin than is found in human bone.

Radiographic features

Four types of dystrophic calcification can occur:

1. Superficial masses within the skin
2. Deep, discrete, subcutaneous nodular masses near joints that can impair movement (calcinosis circumscripta)
3. Deep, linear, sheet-like deposits within intramuscular fascial planes (calcinosis universalis)
4. Lacy, reticular subcutaneous deposits that encase the trunk to form a generalized "exoskeleton"

"Milk of calcium" fluid collections are a rare complication of calcinosis [24]. Although established calcification can be readily seen on plain X-rays, MRI appears to be a sensitive method for detection and localization of muscle inflammation and edema. It is also an excellent modality for monitoring progression or remission of the disease [25].

Treatment

High-dose corticosteroids soon after the onset of symptoms remains the mainstay of current treatment, reducing the potential risk of calcinosis by suppression of the inflammatory process. Additional agents that are used include methotrexate and infliximab. Several different therapies including bisphosphonates, diltiazem, and surgical extirpation have been utilized to treat the calcinosis, with individual case reports suggesting benefit [26, 27]. However, a review of the published literature over a 32-year period concluded that no treatment has convincingly prevented or reduced calcinosis with a lack of systematic study and clinical therapeutic trials [28].

Progressive Osseous Heteroplasia 817
References 818

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA

Fibrodysplasia ossificans progressiva (FOP: MIM #135100) is a rare heritable disorder of connective tissue characterized by congenital malformations of the great toes and progressive heterotopic endochondral ossification (HEO) in characteristic anatomic patterns [1, 2]. HEO may also occur sporadically following joint replacement, central nervous system trauma, athletic injury, war wounds, atherosclerosis, and valvular heart disease [3, 4].

FOP, first described in 1692, has more than 800 cases reported and is among the rarest of human afflictions, with an estimated incidence of 1 per 2,000,000 individuals [1, 2]. All races are affected [2]. Autosomal dominant transmission with variable expression and complete penetrance is established [5]; however, reproductive fitness is low and most cases are sporadic. Gonadal mosaicism has also been described [6].

Clinical presentation

Malformations of the great toes are present at birth in all classically affected individuals (Fig. 98.1). Typically, episodes of soft-tissue swelling (flare-ups) leading to HEO begin during the first decade of life (Fig. 98.1) [7, 8]. FOP is usually diagnosed when radiographic evidence of heterotopic ossification is noted; however, misdiagnosis is common and leads to unnecessary biopsies and invasive procedures that result in permanent harm [1, 2, 9].

The severity of FOP differs greatly among patients [5, 10]. Most individuals become immobilized and confined to a wheelchair by the third decade of life [1, 2, 7]. Wide variability in the rate of disease progression, even among identical twins, attests to the important postnatal influence of environmental factors [11].

Flare-ups appear spontaneously or may be precipitated by muscle fatigue, minor trauma, intramuscular injections or influenza-like viral illnesses [2, 12, 13]. Swellings develop rapidly during the course of several hours. Aponeuroses, fascia, tendons, ligaments, and connective tissue of voluntary muscles may be affected. Although some lesions may regress spontaneously, most mature by an endochondral pathway to form heterotopic bone with marrow elements [14]. Flare-ups are episodic and recur with unpredictable frequency. Once ossification develops, it is permanent. Disability is cumulative [7, 8].

Bony masses immobilize joints and cause contractures and deformity. Ossification around the hips, typically present by the third decade of life, often prevents ambulation [7]. Involvement of the muscles of mastication (frequently following injection of local anesthetic or overstretching of the jaw during dental procedures) leads to permanent ankylosis of the jaw, impairs nutrition, and affects quality of life [15, 16]. Ankylosis of the spine and ribs as well as chin-on-chest deformity further restrict mobility and may imperil cardiopulmonary function (Fig. 98.1) [1, 2, 7, 17, 18]. Scoliosis is common and associated with malformation of the ribs and costovertebral joints or with heterotopic bone that asymmetrically connects the ribs to the pelvis [19]. Restrictive disease of the chest wall may lead to early mortality [20, 21]. Vocal muscles,

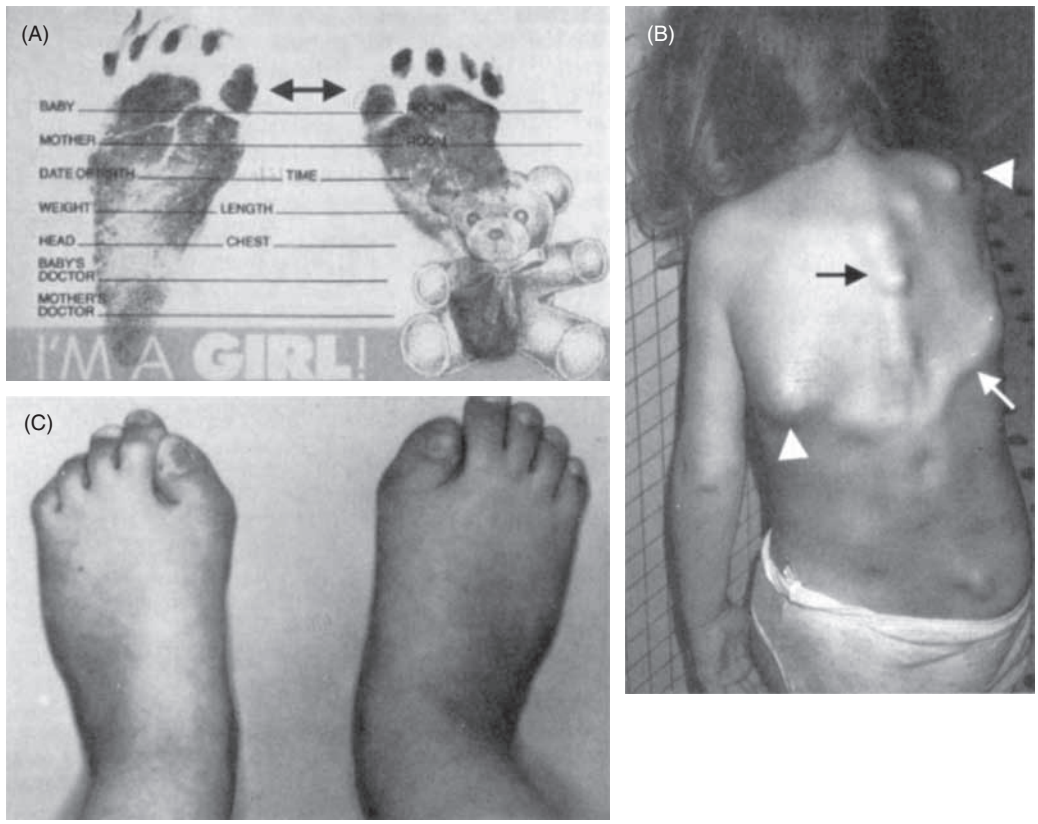

Fig. 98.1. Fibrodysplasia ossificans progressiva. Characteristic features of FOP are seen in early childhood. The presence of short malformed great toes at birth (A, arrows) heralds the later spontaneous appearance of the preosseous soft tissue lesions on the neck and back (B, arrow heads) and should provoke suspicion of FOP even before the transformation to heterotopic bone (B, arrows). An inspection of the toes (C) and/or genetic DNA sequence analysis of ACVR1 will confirm the diagnosis and may alleviate the need for a lesional biopsy (trauma) that could exacerbate the condition [from Kaplan FS and Smith RM. 1997. Clinical vignette—Fibrodysplasia ossificans progressiva (FOP). *J Bone Miner Res* 12: 855. Reproduced with permission of the American Society for Bone and Mineral Research].

smooth muscles, diaphragm, and heart are spared [1]. Hearing impairment is common [22].

Radiologic features

Skeletal anomalies and soft-tissue ossification are characteristic radiologic features of FOP [23]. Skeletal malformations involve the great toe, although other skeletal anomalies commonly occur. In some cases, the thumbs are strikingly short [1, 2]. Osteochondromas are frequent [14, 24, 25]. Progressive fusion of cervical vertebrae may be confused with Klippel-Feil syndrome [1, 26]. Malformation of the temporomandibular joints and fusion of costovertebral joints is common [15, 21]. The femoral necks may be broad and short [2, 25]. Early degenerative arthritis is common [27].

Radiographs and bone scans suggest normal modeling and remodeling of heterotopic bone [28]. Fractures are not increased and repair through normal processes in either the heterotopic or normotopic skeleton [29].

Bone scans detect abnormalities in soft tissue before heterotopic ossification can be demonstrated by conventional radiographs [28]. Computed tomographic and magnetic resonance imaging of early lesions have been described [30].

Laboratory findings

Routine biochemical studies are usually normal, although serum prostanoids, urinary basic fibroblast growth factor, and alkaline phosphatase levels may be increased during the inflammatory, fibroproliferative, and osteogenic phases of disease flare-ups, respectively [1, 2, 31–33]. Elevated numbers of circulating osteoprogenitor cells have been noted during early flare-ups [34].

Histopathology

Early preosseous FOP lesions consist of an intense aggregation of mononuclear inflammatory cells including lymphocytes, macrophages, and mast cells in the perivascular spaces of edematous muscle [35–37]. Following the catabolic phase of muscle cell death, a highly anabolic fibroproliferative phase (often mistaken for *aggressive juvenile fibromatosis*) appears and consists, in part, of mesenchymal-like stem cells that are dedifferentiated from Tie2+ cells that differentiate through an endochondral pathway into mature heterotopic bone [35, 38–41].

Etiology and pathogenesis

Similarities between FOP and the effects of the *Drosophila* decapentaplegic gene (*BMP4* homologue) mutations suggested involvement of the bone morphogenetic protein (BMP) signaling pathway in the pathogenesis of FOP [42]. The BMP signaling pathway is highly dysregulated in FOP cells [43–48]. FOP cells overexpress BMP4 and are unable to appropriately upregulate the expression of multiple BMP antagonists in response to a BMP challenge [43, 45, 46]. They exhibit a defect in BMP receptor internalization and increased activation of downstream targets, suggesting that altered BMP receptor signaling participates in ectopic bone formation in this disease [47, 48]. BMP4 transgenic mice develop an FOP-like phenotype [49].

Genome-wide linkage analysis identified linkage of FOP to 2q23-24, a locus that includes the activin A type I receptor/activin-like kinase 2 (ACVR1/ALK2) gene encoding a BMP type I receptor [50]. A recurrent heterozygous missense mutation (c.617G > A; R206H) in the glycine-serine (GS) activation domain of ACVR1/ALK2 was identified in all affected individuals with classic features of either sporadic or inherited FOP, making early molecular confirmation possible [50, 51]. Protein modeling predicted destabilization of the GS domain, consistent with dysregulated activation of ACVR1/ALK2 as the underlying cause of the ectopic chondrogenesis, osteogenesis, and joint fusions seen in FOP [50]. The GS domain is a specific binding site for FKBP1A (also known as FKBP12), a highly conserved inhibitory protein that prevents leaky activation of type I receptors in the absence of ligand. Experimental data support that the ACVR1/ALK2 (R206H) protein has reduced interaction with FKBP1A in the absence of BMP and suggests that this impaired FKBP1A-ACVR1/ALK2 interaction contributes in part to BMP-independent pathway signaling [52, 53]. Individuals with rare variants and atypical forms of FOP have been described, and all have activating mutations of ACVR1/ALK2 that, like the canonical R206H mutation, cause loss of autoinhibition of the receptor (25). Activation of the mutant receptor by a putative pH-sensitive salt bridge has been suggested [54]. Basal and ligand-stimulated dysregulation of BMP signaling are found in connective tissues progenitor cells from FOP patients, and *in vitro* and *in vivo* disease models [52, 55–60].

Treatment

There is no established medical treatment for FOP [1, 2, 61]. Medical management is currently supportive [61–62]. High-dose glucocorticoids have limited use in the management of the early inflammatory phase of flare-ups. The disorder's rarity, variability, and fluctuating clinical course pose substantial uncertainties when evaluating experimental therapies. Bone marrow transplantation is ineffective, as even a normal immune system may trigger FOP flare-ups in a genetically susceptible chimeric host [33]. Focused research based on targeted inhibition of BMP signaling [63–66], and/or inhibition of the preosseous chondrogenic anlagen of HEO offers hope for the future [67–70].

Removal of FOP lesions is often followed by significant recurrence. Surgical release of joint contractures is unsuccessful and risks new, trauma-induced HEO [1, 2]. Spinal bracing is ineffective and surgical intervention is associated with numerous complications [19]. Dental therapy should preclude mandibular blocks and stretching of the jaw [1, 2, 15, 16]. Dental techniques for focused administration of anesthetic are available. Guidelines for general anesthesia have been reported [15]. While physical therapy to maintain joint mobility may be harmful by provoking or exacerbating lesions, occupational therapy evaluations are often helpful [71]. Intramuscular injections should be avoided [12]. Prevention of falls, influenza, recurrent pulmonary infections, and complications of restrictive chest wall disease is important [20, 72].

Prognosis

Despite widespread heterotopic ossification and severe disability, some patients live productive lives into their seventh decade. Most, however, die earlier from cardiopulmonary complications of severe restrictive chest wall involvement [1, 2, 17, 21].

PROGRESSIVE OSSEOUS HETEROPLASIA

Research on FOP led to the discovery of progressive osseous heteroplasia (POH: MIM #166350), a distinct developmental disorder of heterotopic ossification [73–75]. As with FOP, POH is an autosomal dominant genetic disorder of heterotopic ossification. However, unlike in FOP, heterotopic ossification in POH commonly begins in the dermis and progresses to deeper tissues by an intramembranous, rather than an endochondral pathway [60, 75]. Identification of two patients with POH-like features who also had Albright hereditary osteodystrophy

suggested the possibility of a genetic link between the two conditions [75, 76], which was confirmed in a third patient with pure POH [77]. These discoveries led to the rapid identification of paternally inherited inactivating mutations of the *GNAS* gene as the cause of POH [78], although the molecular and cellular basis for the mosaic distribution of lesions in affected individuals is unknown. There are no specific phenotype–genotype correlations that distinguish POH from the more benign forms of limited dermal ossification [79]. Reduced expression of Gs-alpha, one of several proteins encoded by *GNAS*, can induce an osteoblast-like phenotype in human mesenchymal stem cells [80]. *GNAS*-encoded G-proteins and downstream cyclic adenosine monophosphate (cAMP) signaling appear to regulate cell fate lineage decisions at an early cell commitment stage and appear to regulate osteogenesis, at least in part, through interactions with the BMP signaling pathway [81]. Heterozygous inactivation of *Gnas* by disruption of the Gs-alpha-specific exon 1 alters osteoblast differentiation in *Gnas* (+/–) mice and manifests as subcutaneous heterotopic ossification by an intramembranous process [82]. Treatment is presently supportive [75].

INTRODUCTION

Osteogenesis imperfecta (OI), also known as brittle bone disease, is a genetic disorder of connective tissue characterized by fragile bones and a susceptibility to fracture from mild trauma and even acts of daily living [1–3]. The clinical range of this condition is extremely broad, ranging from cases that are lethal in the perinatal period to cases that may be difficult to detect and can present as early osteoporosis. Individuals with OI may have varying combinations of growth deficiency, defective tooth formation (dentinogenesis imperfecta), hearing loss, macrocephaly, blue coloration of sclerae, scoliosis, barrel chest, and ligamentous laxity. Classical OI is an autosomal dominant condition caused by defects in type I collagen, the major structural component of the extracellular matrix of bone, skin, and tendon. Classical OI is generally described using the Sillence classification [4], a nomenclature based on clinical and radiographic features, which was first proposed in 1979. Subsequent biochemical and molecular studies have shown that the mild Sillence type I OI is caused by quantitative defects in type I collagen,[5] whereas the moderate and severe types are caused by structural defects in either of the two chains that form the type I collagen heterotrimer [1]. Recurrence of classical OI types in the children of unaffected parents is caused by parental mosaicism [6]. Recent exciting developments have identified the genetic causes of multiple forms of recessive OI, a relatively rare condition in which the clinical range overlaps predominantly with the lethal and severe Sillence types, although moderate forms have also been described [7]. Some cases of recessive OI are caused by defects in any of the three components of the prolyl 3-hydroxylation complex, cartilage-associated protein (CRTAP) [8–10], prolyl 3-hydroxylase 1 (P3H1) [11–13], and cyclophilin B (CyPB) [14–16]; this complex modifies the α1(I) chain of collagen in the endoplasmic reticulum [17]. Other cases are caused by deficiency of chaperones involved in collagen folding and intracellular transport, HSP47 [18] and FKBP10 [19–22], or a multifunctional pigment epithelium-derived factor (PEDF) which is a potent antiangiogenic factor [23, 24]. The autosomal dominant type V OI is caused by a mutation in *IFITM5*, which encodes the transmembrane protein Bril [25]. The genetic etiology of less than 5% of OI remains unknown.

CLINICAL PRESENTATION

Because the currently delineated 11 types of OI vary widely in symptoms and in the timing of their onset, the diagnosis and its differential varies with the age of the individual in question. A positive family history is usually not present, because most mutations occur *de novo*. Prenatally, severe types II, III, VII, VIII, IX, or X OI may be difficult to distinguish from thanatophoric dys-

plasia, campomelic dysplasia, and achondrogenesis type I [26]. Neonatally, types III or VIII OI and infantile hypophosphatasia may have an overlapping presentation, but infantile hypophosphatasia has the radiographic distinction of spurs extending from the sides of knee and elbow joints, in addition to the biochemical distinction of a low serum alkaline phosphatase level. In childhood diagnoses of the milder forms of OI, the major distinctions are with juvenile and idiopathic osteoporosis and child abuse.

The key diagnostic element for OI is the generalized nature of the connective tissue defect, with facial features (flat midface, frontal bossing, triangular shape, bluish sclerae, yellowish or opalescent teeth), relative macrocephaly, thoracic configuration (barrel chest or pectus excavatum), joint laxity, vertebral compressions, and growth deficiency present in variable combinations in each case. The recessive forms of OI caused by defects in the collagen 3-hydroxylation complex overlap clinically with types II and III OI [8, 11], while the recessive forms caused by defects in *SERPINH1*, *SERPINF1*, and *FKBP10* overlap clinically with types II, III, and IV [18–21, 23, 24]. All recessive forms have white sclerae, while dominant forms may have blue or sometimes white sclerae. When a diagnosis is still in doubt, collagen biochemical studies, DNA sequencing of type I collagen, and determination of expression levels of the recessive genes provide helpful information on the presence of a mutation.

CLINICAL TYPES

The classification proposed by Sillence in 1979 (Table 99.1) is based on clinical and radiographic criteria that distinguished four types [4]. Although both clinical and laboratory practice have subsequently evolved, the classification has continued to be useful and is still in general use in a modified form. The Sillence types have autosomal dominant inheritance; recurrence of a collagen mutation in the children of unaffected parents is almost always caused by parental mosaicism. More recently, the types of OI have been extended to include V through XI, although they are defined by different criteria than types I–IV (OMIM 166200, 166210, 259420, 66220). Type V OI (OMIM 610967) is defined by bone histology and clinical/radiographic signs [25]. Type VI OI (OMIM 610968), with autosomal recessive inheritance and a distinctive bone histology suggesting a mineralization defect, is defined both genetically, as defects in *SERPINF1*, and biochemically, as low to absent PEDF in serum [24]. Types VII (OMIM 610682), VIII (OMIM 610915), and IX OI (OMIM 259440) have autosomal recessive inheritance and white sclerae. Type VII was first described histologically and clinically; it was later shown to be caused by mutations in *CRTAP* [8, 9, 27]. Type VIII was first defined biochemically and molecularly as deficiency of P3H1 [11]. Types IX and X (OMIM 613848) were identified by consideration of *PPIB* and *SERPINH1* as logical candidate genes. Types XI and VI were identified by homozygosity mapping in OI pedigrees without defects in the known OI genes [19, 23].

Type I OI is the mildest form of the disorder. There is postnatal onset of fractures, usually after ambulation is attained, and even beginning in early middle age when type I OI can present as early onset osteoporosis. Fractures decrease markedly after puberty. Individuals with type I OI usually have blue sclerae and often have easy bruising. They may have hearing loss (onset as early as late childhood, but usually in the 20s) or joint hyperextensibility. Growth deficiency and long bone deformity are generally mild. Type I has been divided into A and B subtypes, based on the absence or presence of dentinogenesis imperfecta.

Type II OI is usually lethal in the perinatal period, although survival for months is not uncommon, and survival to a year or more has been noted. These individuals are often born prematurely and are small for gestational

Table 99.1. Osteogenesis Imperfecta Nosology

	OI Type	Inheritance	Phenotype	Gene Defect
Classical Sillence Types	I	AD	Mild	Null *COL1A1* allele
	II	AD	Lethal	*COL1A1/COL1A2*
	III	AD	Progressive deforming	*COL1A1/COL1A2*
	IV	AD	Moderate	*COL1A1/COL1A2*
Overactive calcification	V	AD	Distinctive histology	*IFITM5* (Bril)
Mineralization Defect	VI	AR	Mineralization defect	*SERPINF1*(PEDF)
3-Hydroxylation Defects	VII	AR	Severe (hypomorphic) Severe to lethal (null)	*CRTAP*
	VIII	AR	Severe to lethal	*LEPRE1* (P3H1)
	IX	AR	Moderate to lethal	*PPIB* (CyPB)
Chaperone Defects	X	AR	Severe to lethal	*SERPINH1* (HSP47)
	XI	AR	Progressive deforming, Bruck syndrome	*FKBP10* (FKBP65)

age. Legs are usually held in the frog leg position with hips abducted and knees flexed. Radiographically, long bones are extremely osteoporotic, with *in utero* fractures and abnormal modeling (often a crumpled cylindrical shape). The skull is severely undermineralized with wide-open anterior and posterior fontanels. Scleral hue is blue-gray. The bones of these infants are composed predominantly of woven bone without haversian canals or organized lamellae. Demise is generally of pulmonary origin, especially respiratory insufficiency and pneumonias.

Type III OI is known as the progressive deforming type. Most individuals with type III OI survive childhood with severe bone dysplasia. The presentation at birth may be similar to the mild end of the type II OI spectrum. They have extremely fragile bones and, over a lifetime, will have dozens to hundreds of fractures. The long bones are soft and deform from normal muscle tension and subsequently to fractures. These individuals have extreme growth deficiency; final stature is in the range of a prepubertal child. Almost all type III cases develop scoliosis. Radiographically, metaphyseal flaring and "popcorn" formation at growth plates are seen in addition to osteoporosis. They require intensive physical rehabilitation and orthopedic care to attain assisted ambulation in childhood; many will require wheelchairs for mobility. This form is compatible with a full lifespan, although many individuals have respiratory insufficiency and *cor pulmonale* in middle age; some die in infancy and childhood from respiratory causes.

Type IV is the moderately severe Sillence form. The diagnosis may be made at birth or delayed until the toddler or school ages. Scleral hue is variable. These children often have several fractures a year and bowing of their long bones. Fractures decrease after puberty. Essentially all type IV individuals have short final stature, often in the range of pubertal children; many of these children are responsive to growth hormone for significant additional height and improved bone histology [28]. Radiographically, they have osteoporosis and mild modeling abnormalities. They may have platybasia. Many develop vertebral compressions and scoliosis. With consistent rehabilitation intervention and orthopedic management, these individuals should be able to attain independent mobility. This form is compatible with a full lifespan.

OI/EDS is a discrete subgroup of patients who have an overlap of the skeletal symptoms of OI (type IV, usually, or III) and the joint laxity of Ehlers-Danlos syndrome (EDS). Hip dysplasia occurs in some patients and early progressive scoliosis in others. Tissue is friable, requiring extra intervention for spinal fixation. These individuals have a mutation in the amino terminal region of the type I collagen chains that interferes with collagen N-propeptide processing [29].

Recently, types V–XI OI have been classified. Although these types have continued the Sillence numeration, they are based on different criteria than the Sillence types. Types V and VI were defined using bone histology distinctions and generally have a phenotype that would be included in Sillence types IV and III, respectively [25, 30]. These individuals do not have defects in type I collagen. Types VII, VIII, and IX are recessive forms, whose phenotypes overlap with Sillence types II and III [8, 11, 12, 14–16]. These forms have a deficiency of components of a collagen modification complex in the endoplasmic reticulum. Types X and XI OI have defects in collagen chaperones and overlap phenotypically with lethal and moderate/severe OI, respectively [18–21].

Type V OI is associated with a triad of findings: a radiodense metaphyseal band, hypertrophic callus at fractures or surgical sites, and calcification of the forearm interosseous membrane [25]. They have normal teeth and variable sclerae. On histology, the bone lamellae are mesh-like. Recently, a unique mutation in *IFITM5*, which adds 5 residues to the 5′ end of Bril, has been identified as causing all cases of type V OI.

Type VI OI also has distinctive bone histology [30]. The lamellae have a "fish-scale"-like appearance under the microscope, and histomorphometry suggestive of a mineralization defect. These individuals have moderate to severe skeletal disease, with normal teeth and sclerae. Alkaline phosphatase is slightly elevated. Recently, defects in *SERPINF1* have been identified as the cause of type VI OI [24].

Type VII OI is an autosomal recessive form caused by defects in *CRTAP*, cartilage-associated protein [8, 9]. The index pedigree occurs in an isolated First Nations community in northern Quebec [27]. These individuals have rhizomelia and moderate bone disease, associated with a hypomorphic mutation in *CRTAP*. Null mutations in *CRTAP* have been shown to cause a lethal form of OI, with white sclerae, rhizomelia, and a small to normal cranium [8].

Type VIII OI is an autosomal recessive form caused by defects in prolyl 3-hydroxylase 1 (P3H1, encoded by *LEPRE1*). P3H1 forms a complex in the endoplasmic reticulum (ER) with CRTAP, and there is considerable overlap in the phenotypes of OI VII and VIII. Null mutations in *LEPRE1* result in a phenotype that overlaps types II and III OI but has distinct features, including white sclerae, extreme growth deficiency, and undermineralization [11]. For example, a 15-year-old child is the length of a 3-year-old, and a 3-year-old is the length of a 3-month-old. There is a recurring *LEPRE1* mutation that occurs in contemporary West Africans and African-Americans of West African descent that is lethal in homozygous individuals [11].

Type IX OI is caused by defects in the third component of the collagen 3-hydroxylation complex, peptidyl-prolyl *cis-trans* isomerase (*PPIB*) [14–16]. Among the few cases reported, mutations causing premature stop codons or misfolded protein lead to severe lethal OI resembling types VII and VIII in collagen biochemistry and phenotype, except without rhizomelia [15, 16]. A mutation that alters the *PPIB* start codon has a moderate phenotype and normal collagen biochemistry [14].

Type X OI, a recessive form caused by defects in the ER-localized collagen chaperone HSP47, has been identi-

fied in only one infant [18]. The phenotype was severe/lethal, with dentinogenesis imperfecta and with features atypical for OI, including skin bullae and pyloric stenosis. Dermal collagen had normal post-translational modification.

Type XI OI, a recessive form caused by abnormalities in the collagen chaperone FKBP10, causes progressive deforming OI, with fractures of long bones, platyspondyly, and scoliosis, but normal sclerae and teeth [19–22]. The phenotypic spectrum of *FKBP10* mutations encompasses Bruck syndrome 1 (OI plus congenital contractures) and a predominantly congenital contracture disorder (Kuskokwim syndrome). The variability of contracture manifestations from *FKBP10* mutations was initially interpreted incorrectly as separate syndromes.

RADIOGRAPHIC AND DUAL ENERGY X-RAY ABSORPTIOMETRY FEATURES

The skeletal survey in classical OI shows generalized osteopenia. Long bones have thin cortices and a gracile appearance. In moderately to severely affected patients, long bones have bowing and modeling deformities, including a cylindrical configuration from an apparent lack of modeling, metaphyseal flaring, and "popcorn" appearance at the metaphyses [31]. Long bones of the upper extremity often seem milder than those of the lower extremity, even without weight bearing. Vertebrae often have central compressions even in mild type I OI; these often appear first at the T_{12}-L_1 level, consistent with weight-bearing stress. In moderate to severe OI, vertebrae will have central and anterior compressions and may appear compressed throughout. The compressions are generally consistent with the patient's L_1-L_4 dual energy X-ray absorptiometry (DXA) Z-score but do not correlate in a straightforward manner with scoliosis. In the lateral plane film of the spine, it is not easy to assess the asymmetry of vertebral collapse, which, along with paraspinal ligamentous laxity, is generally the cause of OI scoliosis. The skull of OI patients with a wide phenotypic range of severity has wormian bones, although this is not unique to OI. Patients with types III and IV OI may also have platybasia, which should be followed with periodic computed tomography (CT) studies for basilar impression and invagination [32].

In type V OI, radiographic features are crucial elements of the diagnostic triad of dense metaphyseal bands, ossification of the interosseus membrane of the forearm, and hypertrophic callus. The dense metaphyseal bands evolve from a rachitic appearance in the perinatal period [33]. In type VI OI, intrauterine fractures were not reported; rather, radiographic features of severe OI developed progressively but were not distinctive from those of severe OI type IV or type III OI, including vertebral compressions, long bone bowing and disorganization, protrusio acetabuli, and bulbous metaphyses [30].

The skeletal radiographs of only a few infants and children with types VII, VIII, and IX OI have been described [8, 9, 11, 14, 27]. Types VII and VIII OI have extreme osteoporosis and abnormal long bone modeling, leading to a cylindrical appearance. The bone material appears cystic and disorganized. In surviving children with type VIII, there is flaring of the metaphyses. These children also have gracile hands that appear relatively long but have shortened metacarpals.

Radiographs in the one infant reported with a mutation affecting HSP47 (OI type X) show progression over the first year of life [18]. At birth, there were multiple intrauterine fractures associated with severe undermineralization, thin ribs, bowing of long bones, and platyspondyly. By 1 year of age, the cranium was enlarged and undermineralized, the ribs were broad, and the long bones were undertubulated. Rhizomelia was apparent at birth and persisted. There have been multiple reports of radiographs in type XI OI (*FKBP10* mutations) [19–22]. These show severe osteopenia and bowing deformities of long bones, with regional lucencies but without cylindrical modeling defects. Kyphosis/scoliosis develops in childhood.

Bone densitometry by DXA (L1-L4) is useful over a wide age and severity range of OI. It aids diagnosis in milder cases and facilitates longitudinal follow-up in moderate to severe forms. There is a general correlation of Z-score and severity of OI. Type I individuals are generally in the -1 to -2 range, type IV Z-scores cluster in the -2 to -4 range, whereas type III spans -3 to -6. Children with type VIII OI have -6 to -7 Z-scores. It is important to remember that the Z-score compares the mineral quantity of the bone being studied to bone with a normal matrix structure and crystal alignment. In OI, many mutations result in irregular crystal alignment on the abnormal matrix, in addition to reduced mineral quantity. DXA does not measure bone quality, which includes bone geometry, histomorphometry, and mechanical properties.

LABORATORY FINDINGS

Serum chemistries related to bone and mineral metabolism are generally normal. Alkaline phosphatase may be elevated after a fracture and is slightly elevated in type VI [30]. PEDF has been reported to be low to absent in type VI, which may provide a useful screening test [24]. Acid phosphatase is elevated in type VIII OI and can logically be expected to be elevated in type VII. Hormones of the growth axis have normal levels [34]. Bone histomorphometry shows defects in bone modeling and in the production and thickening of trabeculae [35]. Cortical width and cancellous bone volume are decreased in all types; trabecular number and width are also decreased. Bone remodeling is increased, as are osteoblast and osteoclast surfaces. When viewed under polarized light, the lamellae of OI bone are thinner and less smooth than in controls. Mineral apposition rate is normal; crystal disorganization may contribute to bone weakness.

ETIOLOGY AND PATHOGENESIS

About 85–90% of patients who have clinical OI have abnormalities of type I collagen, the major structural protein of the bone extracellular matrix. The recessive types of OI either have a defect in a component of a complex that interacts with collagen post-translationally and 3-hydroxylates αl(I)Pro986 in the endoplasmic reticulum, and/or are deficient in a chaperone protein that assists collagen folding [7]. PEDF defects likely have a distinct mechanism, possibly related to disruption of its direct binding to collagen near the carboxyl end of the α1(I) chain, or to its antiangiogenic function [36, 37]. These recessive forms together can be estimated to make up 5–7% of OI cases. Autosomal dominant type V OI is about 5% of cases; patients share a unique mutation in *IFITM5*, which adds 5 residues to the extracellular 5′-end of the transmembrane protein Bril [25]. A small group of OI patients have unknown mutations.

The pathophysiology of OI encompasses multiple levels of dysfunction, ranging from abnormal function of bone cells and matrix, mineralization, and whole tissue. The overlapping features of dominant and recessive OI are providing important indicators of crucial pathways. Murine studies have implicated bone cell dysfunction (osteoblast ER stress, with increased expression of CHOP and GRP78, and impaired matrix production, as well as increased osteoclast numbers and activity), matrix heterogeneity resulting from heterozygosity for the mutant allele, abnormal levels of non-collagenous proteins in matrix, abnormal cell–matrix interactions, and hypermineralization of whole bone tissue demonstrated by Fourier transform infrared spectroscopy (FTIR) and bone mineral density distribution (BMDD) [38].

Cultured dermal fibroblasts are convenient cells in which to examine the collagen biochemistry of probands using gel electrophoresis. Probands with type I OI, which synthesize a reduced amount of structurally normal type I collagen because of a null *COL1A1* allele, display a relative increase in the COL3/COLl ratio [5]. Probands with the clinically significant types II, III, and IV OI synthesize a mixture of normal collagen and collagen with a structural defect. With rare exceptions, the structural defects are either substitutions for one of the glycine residues that occur at every third position along the chain and are essential for proper helix folding (80%) or alternative splicing of an exon (20%), resulting more frequently in out-of-frame than in-frame alternative transcripts. Structural abnormalities delay helix folding, expose the constituent chains to modifying enzymes for a longer time, and result in overmodification that is detectable as slower electrophoretic migration. The biochemical test does not accurately detect abnormalities in the amino one third of the α1(I) or the amino half of the α2(I) chain [39]. Cultured fibroblasts from patients with types VII and VIII OI, and some with type IX OI, also produce collagen with overmodification of the helical regions of the chains, suggesting that deficiency of the collagen 3-hydroxylation complex delays helix folding [8, 10, 11, 15, 16].

Mutation detection by direct sequencing is more sensitive than the biochemical test, although it does not provide functional information. Collagen sequencing is available either as exon-by-exon sequencing of DNA or transcript sequencing of cDNA. Each technique will miss a small percent of unusual mutations, such as large deletions or rearrangements or low percentage splicing defects.

Genotype-phenotype modeling of the more than 800 mutations currently available has yielded different patterns for the two chains, supporting distinct roles in maintaining matrix integrity [40]. About one-third of the substitutions in α1(I) are lethal, especially those to residues with a branched or charged side chain. Two exclusively lethal regions coincide with the proposed major ligand-binding regions for the collagen monomer with integrins, matrix metalloproteinases (MMPs), fibronectin, and cartilage oligomeric matrix protein (COMP). For the α2(I) chain, only one-fifth of substitutions are lethal; these substitutions are clustered in eight regularly spaced regions along the chain, coinciding with the proteoglycan binding regions on the collagen fibril.

TREATMENT

Early and consistent rehabilitation intervention is the basis for maximizing the physical potential of individuals with OI [41, 42]. Physical therapy should begin in infancy for the severest types, promoting muscle strengthening, aerobic conditioning, and if possible, protected ambulation. Programs to ensure that children have muscle strength to lift a limb against gravity should continue between orthopedic interventions using isotonic and aerobic conditioning. Swimming should be encouraged.

Orthopedic care should be in the hands of a surgeon with experience in OI. Fractures should not be allowed to heal without reduction to prevent loss of function. The goals of orthopedic surgery are to correct the deformity for ambulation and to interrupt a cycle of fracture and refracture. The classic osteotomy procedure requires fixation with an intramedullary rod. The hardware currently in use includes telescoping rods (Bailey-Dubow [43] or Fassier-Duval [44] rods) and non-elongating rods (Rush rods). Important considerations include selection of a rod with the smallest diameter suited to the situation to avoid cortical atrophy. Children who are anticipated to have significant growth may require fewer rod revisions with either of the extensible rods. The secondary features of OI, including abnormal pulmonary functions, hearing loss, and basilar invagination, are best managed in a specialized coordinated care program. The severe growth deficiency of OI is responsive to exogenous growth hormone administration in about one-half of cases of type IV OI [28] and most type I OI [45]; some treated children can attain heights within the normal growth curves. Responders to recombinant growth hormone (rGH) also experience increased L1-L4 DXA,

bone volume per total volume (BV/TV), and bone formation rate (BFR). Growth hormone remains under study for its effects on OI skeletal integrity. Four controlled trials have shown the benefits and limitations of bisphosphonate treatment for classical OI [46–49]. The trabecular bone of vertebral bodies has the most positive response. Bone mineral density (BMD) is increased, although the functional meaning of this measurement is difficult to assess because it also includes retained mineralized cartilage; the increase in Z-scores tapers after 1 to 2 years of treatment. More importantly, the vertebral ability to resist compressive forces is shown as increased vertebral area and decreased central vertebral compressions. The effect of bisphosphonate treatment on predominantly cortical long bone is more equivocal. There is a combination of increased stiffness and load bearing that is balanced by weakened bone quality [50]. There is, at best, a trend toward reduced fracture incidence or a reduced relative risk rather than a clear statistical benefit. The functional changes in ambulation, muscle strength, and bone pain reported in the uncontrolled trials have been shown to be placebo effects. The prolonged half-life and recirculation of pamidronate in children up to 8 years after treatment cessation may pose pediatric specific skeletal and reproductive risks [51]. Prolonged or high-dose administration to children can induce defective bone remodeling [52] and may lead to accumulation of bone microdamage. Delayed osteotomy healing was noted at conventional doses [53]. Our current management of bisphosphonates for classical OI is to treat for 2–3 years and then discontinue the drug but continue to follow the patient.

There is some experience in the pharmacological treatment of rare dominant and recessive types of OI. Type V OI is reported to have a response to pamidronate similar to classical OI patients [54]. Ten children with type VI OI and four children with VII OI had improved lumbar vertebral shape and BMD with pamidronate treatment, but changes in fracture rates or mobility scores were limited [55, 56].

INTRODUCTION

Marfan syndrome (MFS; OMIM 1547000) is a dominantly inherited disorder of the connective tissue with an estimated incidence of approximately 1 per 5,000 live births and cardinal manifestations in the cardiovascular, ocular and musculoskeletal systems [1]. MFS is caused by mutations that perturb the structure or expression of the gene coding for fibrillin-1 (*FBN1*), the major structural component of extracellular microfibrils [1, 2]. Fibrillin microfibrils confer structural integrity to different tissues as components of the elastic fibers or as elastin-free assemblies; additionally, they instruct cell behavior by interacting with integrin receptors and transforming growth factor-β (TGFβ) and bone morphogenetic protein (BMP) complexes [2, 3]. MFS is considered to be part of a larger group of connective tissue disorders that similarly display morphogenetic and/or functional anomalies in different organ systems (Table 100.1); strict diagnostic criteria differentiate MFS from these phenotypically related conditions (Table 100.2) [4–6]. Some of these MFS-related disorders are occasionally associated with mutations in *FBN1*, while others are caused by dysfunctions of proteins that interact with fibrillin-1 and/or regulate TGFβ signaling [7–15]. The present chapter reviews the skeletal phenotypes of MFS and related disorders.

FIBRILLINOPATHIES

Marfan syndrome

Many of the skeletal abnormalities in MFS are either commonly found in the general population or present in related connective tissue disorders (Table 100.3). Malformations of the appendicular skeleton, such as disproportionate long limbs (dolichostenomelia) and fingers (arachnodactyly), are often the most evident manifestations in MFS. Arachnodactyly and joint hypermobility gives rise to the characteristic wrist sign (overlap of the thumb covering the entire fingernail of the fifth finger when wrapped around the contralateral wrist) and thumb sign (projection of the entire distal phalanx of the thumb beyond the ulnar border of the hand when it is folded across the palm). Hindfoot valgus with forefoot abduction and lowering of the midfoot (pes planus), medial protrusion of the femoral head (protusio acetabuli), and reduced elbow extension are additional findings in the appendicular skeleton. Craniofacial anomalies are the least specific traits of MFS and include high-arched palate, long narrow skull (dolicocephaly), recessed lower mandible (retrognathia), malar hypoplasia, sunken eye (enophthalmos) and downward-slanting palpebral fissures.

Loeys-Dietz syndrome 2B (LDS2B)	AD	610380	3p22	*TGFBR23*

AD: autosomal dominant; AR: autosomal recessive; NA: not available.

In the axial skeleton, longitudinal rib overgrowth causes anterior or posterior displacement of the sternum (pectus carinatum or pectus excavatum, respectively) [5]; surgical repair of severe pectus excavatum is recommended to ameliorate cardiac and pulmonary function [16–19]. Spine deformities in MFS include thoracolumbar kyphosis and vertebral displacement (spondylolisthesis), and more commonly thoracic lordosis and progressive scoliosis more than 20° (generally thoracic and convex to the right). Scoliosis with a greater-than-30° curve worsens in MFS patients at a higher rate than in individuals afflicted with idiopathic scoliosis [20]. In contrast to idiopathic scoliosis, spinal bracing in MFS is usually inadequate to manage severely progressive scoliosis, and surgical repair carries a greater risk of complications [21–23]. Enlargement of the outer layer of the meningeal sac in the lumbosacral spine (dural ectasia) is another common axial skeleton manifestation. Dural ectasia (usually at the L5-S2 level) is a common manifestation that affects 63–92% of adults and 40% of children with MFS [24–30]. The abnormality is often associated with herniation of the nerve root and promotion of secondary changes in the osseous structures leading to thinner pedicles and laminae, in addition to increased risk of dural tear and failure of corrective surgery [24–30]. Moderate to severe low back pain, headache, and proximal leg pain, as well as weakness and numbness are additional symptoms associated with dural ectasia [31, 32].

Osteopenia is a controversial finding in MFS, especially in pediatric patients [33–39]. Whereas some dual X-ray absorptiometry (DXA) studies have identified reduced bone mineral density (BMD) in pre- and postmenopausal women and adolescents with MFS, other studies have been more equivocal mostly due to the inherent problem of interpreting DXA scans of significantly longer bones [33–39]. As a result, the etiology and significance of low BMD in relationship to increased long-term risk for fractures remain uncertain, and application of current therapies of bone mineral replacement in MFS patients is generally viewed as premature.

Congenital contractural arachnodactyly

Congenital contractural arachnodactyly (CCA; also known as Beals syndrome) is a rare dominantly inherited condition characterized by multiple joint contractures, arachnodactyly, dolichostenomelia, scoliosis, and osteopenia (Table 100.3); additionally, CCA displays the distinguishing feature of crumpled ears [40]. Although generally milder than MFS, severe and neonatal lethal forms of CCA have also been described [41–43]. Elbow, knee, and finger contractures are found at birth in all CCA patients and generally improve with time. Kyphoscoliosis is often present at birth or early in childhood and contributes to morbidity later in life. Differential diagnosis between MFS and CCA is sometimes difficult due to the presence of overlapping features. Cases in point are the cardiovascular abnormalities and ocular complications that have been reported in severely affected CCA patients, and the crumpled ears and finger contractures (campodactyly) that have been observed in individuals with neonatal lethal MFS [40–42, 44]. Mutations in CCA cluster within a region of fibrillin-2 that corresponds to the fibrillin-1 segment where neonatal lethal MFS mutations map [45]. The functional significance of this observation remains obscure.

Table 100.2. Revised Diagnostic Criteria of Marfan Syndrome (Ref. 5)

In the absence of family history (FH)
1. Ao ($Z \geq 2$) *and* EL: MFS*
2. Ao ($Z \geq 2$) *and* *FBN1*: MFS
3. Ao ($Z \geq 2$) *and* systemic score (≥7 points): MFS*
4. EL *and* *FBN1* with known Ao: MFS
   - EL with *or* without systemic score *and* no *FBN1* *or* with Ao *and* *FBN1* unknown: Ectopia lentis syndrome
   - Ao ($Z < 2$) *and* systemic score (≥5) with at least one skeletal feature without EL: MASS
   - MVP *and* Ao ($Z < 2$) *and* systemic score (>5) without EL: MVPS

In the presence of family history (FH)**
5. EL *and* FH of MFS: MFS
6. Systemic score (≥7 points) *and* FH of MFS: MFS*
7. Ao ($Z \geq 2$ above 20 years of age or ≥3 below 20 years of age) *and* FH of MFS = MFS*

Systemic score (Score ≥7 indicates systemic involvement; maximum = 20 points)
- Wrist *and* thumb sign: **3**; wrist *or* thumb sign: **1**
- Pectus carinatum deformity: **2**; pectus excavatum or chest asymmetry: **1**
- Hindfoot deformity: **2**; plain pes planus: **1**
- Pneumothorax: **2**
- Dural ectasia: **2**
- Protrusio acetabuli: **2**
- Reduced US/LS *and* increased arm/height *and* no severe scoliosis: **1**
- Scoliosis or thoracolumbar kyphosis: **1**
- Reduced elbow extension: **1**
- Facial features (3/5): **1** (dolichocephaly, enophtalmos, downslanting palpebral fissures, malar hyoplasia, retrognathia)
- Skin striae: **1**
- Myopia >3 diopters: **1**
- Mitral valve prolapse (all types): **1**

Ao: aortic diameter at the sinuses of Valsalva; **EL**: ectopia lentis; ***FBN1***: fibrillin-1 mutation **MASS**: **m**yopia, mitral valve prolapse, **a**ortic root dilation, **s**keletal findings, **s**triae syndrome **MVPS**: **m**itral **v**alve **p**rolapse **s**yndrome; **US/LS**: upper segment/lower segment ratio; **Z**: Z-score.
*If discriminating features of SGS, LDS, or vascular EDS are present, then *TGFBR1/2* testing, collagen biochemistry, and *COL3A1* testing are indicated.
**When a family member was independently diagnosed using the above criteria.

PATHOGENESIS

Studies of *Fbn1* mutant mice have correlated elevated TGFβ activity with the onset and progression of cardiovascular, muscular, and lung abnormalities [46–49]. These findings have translated into a new therapeutic strategy for aortic disease progression in MFS that blunts promiscuous TGFβ signaling through the action of the AT1 receptor blocker (ARB) losartan [50]. Mice deficient for fibrillin-1 and/or fibrillin-2 have also correlated discrete perturbations of local TGFβ and BMP signaling with distinct organ-specific manifestations, such as those affecting bone growth and homeostasis [2, 3].

Fibrillin gene expression in the forming skeleton begins well before mesenchyme cell differentiation, and thereafter fibrillin proteins accumulate at several skeletal sites where they form macroaggregates whose distinct morphologies are believed to reflect the discrete mechanical properties of cartilaginous and bony matrices [51–54]. As in other organ systems, fibrillin-2 is produced in significantly lower amounts than fibrillin-1 during the formation and remodeling/repair of skeletal tissues [51]. Even though fibrillins are structural components of the same extracellular elements and bind TGFβ and BMP complexes with equal affinity, mutations in *Fbn1* or *Fbn2* give rise to distinct skeletal phenotypes due to discrete perturbations of TGFβ and/or BMP signaling. Whereas dural attenuation associated with increased TGFβ activity is solely observed in mice that underexpress fibrillin-1 ($Fbn1^{mgR/mgR}$ mice), impaired BMP-driven digit formation is exclusively seen in mice that lack fibrillin-2 ($Fbn2^{-/-}$ mice) [55, 56]. Characterization of reduced BMD in $Fbn1^{mgR/mgR}$ and $Fbn2^{-/-}$ mice has further underscored the notion that fibrillin proteins play different roles in modulating the local bioavailability of local TGFβ and BMP signals. Osteopenia in $Fbn2^{-/-}$ mice is impaired because enhanced latent TGFβ activation inhibits osteoblast maturation while concomitantly stimulating osteoblast-dependent osteoclastogenesis via receptor activator for nuclear factor-κB ligand (RANKL) upregulation [57, 58]. Reduced BMD in $Fbn1^{mgR/mgR}$ mice is instead associated with elevation of both TGFβ and BMP signaling, which leads to accelerated osteoblast differentiation and RANKL-dependent augmentation of osteoblast-driven osteoclastogenesis [58, 59]. These perturbations of TGFβ and BMP signaling are thought to translate into discrete material and mechanical properties of $Fbn1^{mgR/mgR}$ and $Fbn2^{-/-}$ long bones, as genetic evidence has excluded a prominent role of microfibrils in providing the structural framework for mineral deposition [57, 60]. However, inhibition of promiscuous TGFβ signaling through ARB treatment of $Fbn1^{mgR/mgR}$ mice failed to improve reduced BMD even though it ameliorated aneurysm progression [59]. These findings strongly argue for a multifaceted treatment therapy in MFS that takes into account the distinct physiological roles of microfibril-controlled TGFβ and BMP bioavailability in various tissues, at different stages of organ formation and growth, and during matrix remodeling and repair.

MARFAN SYNDROME-RELATED DISORDERS

In rare instances, *FBN1* mutations can also cause the skeletal abnormalities that characterize Shprintzen-

Goldberg syndrome (SGS) or Weill-Marchesani syndrome (WMS) [8, 9, 61, 62]. The former condition is a rare autosomal dominant disorder in which cranial malformations and neurodevelopmental deficits are present together with MFS manifestations in other organ systems; additionally, there is also significant clinical overlap between SGS and Loeys-Dietz syndrome (LDS) (Table 100.3). Heterozygous *FBN1* mutations have been identified in two unrelated SGS patients, and neither of them maps to a region of the protein devoid of MFS-causing defects [8, 61, 62]. WMS is a clinically homogeneous but genetically heterogeneous disorder that exhibits MFS antithetic skeletal manifestations, such as short stature, short and stubby hands and feet (brachydactyly), and joint stiffness (Table 100.3). An in-frame FBN1 deletion has been identified in a patient with autosomal dominant WMS, whereas nonsense and frame-shift mutations in the ADAMTS10 protease have been reported in two individuals with autosomal recessive WMS [9, 63, 64]. Interestingly, *in vitro* evidence suggests a role for ADAMTS10 in promoting the biogenesis rather than the turnover of fibrillin microfibrils [65]. Short stature, stiff joints, and skin thickening characterize geleophysic dysplasia (GD) and acromelic dysplasia (AD), and which in some cases are also associated with domain-specific *FBN1* mutations [15]. These ADs differ from each other in the mode of inheritance and facial features, as well as for the presence of unique cardiac valvular (GD) or skeletal (AD) manifestations (Table 100.3). Homozygous nonsense and missense mutations leading to misfolding and reduced secretion of ADAMTSL2 have been identified in other GD patients [66]. Additional evidence suggests that interaction between ADAMTSL2 and fibrillin-1 is important for both microfibril biogenesis and the regulation of TGFβ bioavailability [15, 66]. It is, however, unknown how dysregulated processes of microfibril assembly and

TGFβ signaling can lead to opposite skeletal phenotypes in MFS and GD/AD.

LDSs display both MFS traits and unique features and are caused by heterozygous mutations in either the *TGFBR1* (LDSs 1A and 2A) or the *TGFBR2* (LDSs 1B and 2B) gene [14, 67]. Whereas there are no phenotypic differences between LDSs 1A and B and between LDSs 2A and B, the spectrum of craniofacial anomalies distinguishes LDSs 1A and 1B from LDSs 2A and 2B (Table 100.3). Additionally, LDSs 2A and 2B overlap substantially with the vascular form of Ehlers-Danlos syndrome (EDS; OMIM 130050), a condition typically caused by mutations in type III collagen (*COL3A1*). LDS craniofacial and skeletal manifestations include hypertelorism, uvula malformations, malar hypoplasia, arched palate, retrognathia, pectus deformity, scoliosis, joint laxity, and dural ectasia; craniosynostosis, cleft palate, and clubfoot deformity can also be present, whereas overgrowth of long bones is mild or absent (Table 100.3). Even though *TGFBR* mutations in LDS are predicted to impair receptor function, experimental findings indicate that they are paradoxically associated with increased TGFβ signaling [14, 67]. Thus, it has been argued that loss-of-function *TGFBR* mutations in LDS either activate an unproductive compensatory response or have gain-of-function properties [5]. Similar mechanisms may explain the apparent paradox that increased bone mass is associated with decreased TGFβ signaling in a rare selective tooth agenesis syndrome (STHAG), but with increased TGFβ activity in a progressive diaphyseal dysplasia (CED) [12, 68, 69]. Hence, the current view of MFS and related disorders is that phenotypic outcomes reflect the spatiotemporal responses of resident cells to dysregulated TGFβ and/or BMP bioavailability rather than simply the impact of the mutations on TGFβ and/or BMP signaling.

ACKNOWLEDGMENTS

We thank Ms. Karen Johnson for organizing the manuscript. Studies from the authors' laboratory that are described in this review were supported by grants from the National Institutes of Health (AR-42044, AR-049698) and the National Marfan Foundation.

INTRODUCTION

Inborn errors of metabolism from enzyme deficiencies can importantly affect the skeleton. Five types are reviewed here.

HYPOPHOSPHATASIA

Hypophosphatasia (HPP) is the rare heritable rickets or osteomalacia (OMIM 146300, 241500, 241510) [1] characterized biochemically by subnormal activity of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP) [2, 3]. Although TNSALP is normally present in all tissues, HPP disturbs predominantly the skeleton and teeth. Muscle weakness is often an important finding. Approximately 350 cases have been reported, showing a remarkable range of severity with four overlapping clinical forms described according to patient age when skeletal disease is discovered: perinatal, infantile, childhood, and adult. Odonto-HPP features dental manifestations only [4]. Generally, the earlier the skeletal problems the more severe the clinical course [2, 3].

Perinatal HPP manifests *in utero* [5]. At birth, extreme skeletal hypomineralization causes caput membraneceum and short deformed limbs [3]. Such newborns usually live briefly while suffering increasing respiratory compromise. Prolonged survival is very rare. The radiographic features are pathognomonic [2]. Sometimes, the skeleton is so poorly calcified that only the skull base is seen [3]. Alternatively, the calvarium can be ossified only centrally, segments of the spinal column may appear missing, and severe rachitic changes manifest in the limbs [3].

Infantile HPP presents before 6 months of age [3, 6]. Development appears normal until poor feeding, inadequate weight gain, hypotonia, and wide fontanels are noted. Rachitic deformities are then recognized. Vitamin B_6-dependent seizures may appear [7]. Hypercalcemia and hypercalciuria can cause recurrent vomiting, nephrocalcinosis, and sometimes renal compromise [6, 8]. Functional craniosynostosis may occur with the illusion of widely open fontanels (hypomineralized calvarium). A flail chest predisposes to pneumonia [6]. There can be spontaneous improvement or progressive skeletal deterioration [3, 6] with an estimated 50% of patients dying in infancy [2, 3, 7]. Radiographic changes are characteristic but less striking than in perinatal HPP [2]. Abrupt transition from relatively normal appearing diaphyses to hypomineralized metaphyses can suggest sudden metabolic deterioration. Progressive skeletal demineralization with fractures and thoracic deformity herald a lethal outcome [6].

Childhood HPP causes premature loss of deciduous teeth (at younger than 5 years of age), without root resorption, from hypoplasia of dental cementum [4]. Lower incisors are typically shed first, but the entire dentition can be lost. Permanent teeth fare better. Delayed walking

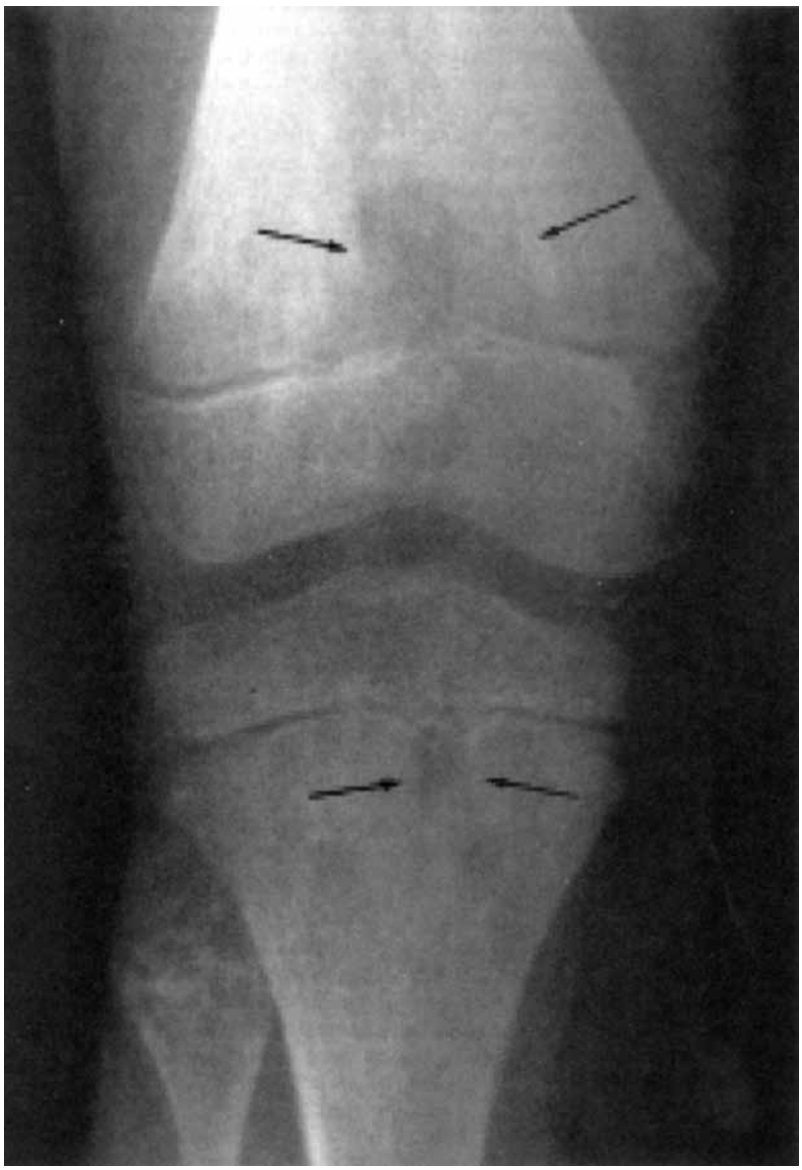

Fig. 101.1. The metaphyses at the knees of this 10-year-old boy with childhood hypophosphatasia show characteristic "tongues" of radiolucency (arrows). Note, however, that his mineralization defect (rickets) does not manifest with uniform widening of the growth plates.

with a waddling gait, short stature, and dolichocephaly are common [3]. Static myopathy is a poorly understood complication [2]. After puberty, patients seem improved, but skeletal symptoms can recur in middle age [2, 3, 9]. Radiographs show characteristic "tongues" of lucency projecting from growth plates into metaphyses (Fig. 101.1) [2]. True premature fusion of cranial sutures with craniosynostosis can cause a "beaten-copper" appearance of the skull [2].

Adult HPP usually presents during middle age, often with poorly healing, recurrent, metatarsal stress fractures [9]. Discomfort localized in the thighs or hips can reflect femoral pseudofractures [9–11]. Patients may recall rickets and/or premature loss of deciduous teeth during childhood [9]. Chondrocalcinosis, pseudogout, and pyrophosphate arthropathy from calcium pyrophosphate dihydrate crystal deposition may occur [2]. Radiographs can show osteopenia, metatarsal stress fractures, chondrocalcinosis, and subtrochanteric femoral pseudofractures [2, 9–11].

HPP rickets/osteomalacia is remarkable because serum levels of calcium and inorganic phosphate (Pi) are not reduced, and ALP activity is low, not high [3]. In fact, hypercalcemia occurs frequently in infantile HPP,[6, 8] apparently from dyssynergy between gut absorption of calcium and the defective skeletal growth and mineralization [2, 3]. In childhood and adult HPP, approximately 50% of patients are hyperphosphatemic because of enhanced renal reclamation of Pi (increased TmP/GFR) [2, 3]. Serum parathyroid hormone (PTH) and $1,25(OH)_2D$ concentrations are suppressed if there is hypercalcemia. Nondecalcified sections of HPP bone show rickets or

osteomalacia without secondary hyperparathyroidism [12].

Three phosphocompounds accumulate endogenously in HPP [2, 3]: phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP). PPi assay is a research technique. If vitamin B_6 is not supplemented, elevated plasma PLP is an especially good marker for HPP [2, 3]. The worse the hypophosphatasemia (low serum ALP activity), the greater the plasma PLP, and the more severe the clinical manifestations [2, 3].

Perinatal and infantile HPP are autosomal recessive diseases [2, 5, 6]; carrier parents and siblings often have low or low normal serum ALP activity, and sometimes mildly elevated plasma PLP levels. Pyridoxine given orally causes exaggerated increments in plasma PLP levels in all patients and in some carriers [2, 3]. Milder forms of HPP (odonto-HPP, childhood HPP, and adult HPP) represent either autosomal dominant or autosoma1 recessive disorders [13, 14].

HPP is diagnosed from a consistent clinical history and physical findings, radiographic or histopathological evidence of rickets or osteomalacia, and hypophosphatasemia together with TNSALP substrate accumulation [2, 3]. Mutation analysis of *TNSALP* is available commercially. Approximately 280 mutations (approximately 80% missense) have been identified [14].

Disturbances in vitamin B_6 metabolism in HPP indicate that TNSALP functions as a cell surface enzyme [2, 3]. Extracellular accumulation of PPi, an inhibitor of hydroxyapatite crystal growth, impairs skeletal mineralization [2, 3, 15]. *TNSALP* knockout mice manifest infantile HPP [16] and have helped elucidate the role of *TNSALP* [15].

There is no established treatment for HPP. Marrow cell transplantation seemed to rescue two severely affected infants [6]. Teriparatide appeared to stimulate TNSALP biosynthesis by osteoblasts and heal fractures in a woman with HPP [10]. Bone-targeted enzyme-replacement therapy using a recombinant form of TNSALP is currently experimental and showed excellent promise in severely affected infants and young children [17]. Preliminary reports are also favorable for childhood HPP. In childhood HPP, dietary restriction and binders to correct hyperphosphatemia (to thereby reduce inhibition of TNSALP by Pi) could merit study [10].

Unless deficiencies are documented, avoiding traditional treatments for rickets or osteomalacia seems best in HPP, because circulating levels of calcium, Pi, and 25(OH)D are usually not reduced [2, 3]. In fact, supplementation could provoke or exacerbate hypercalcemia or hypercalciuria [6]. Hypercalcemia in perinatal or infantile HPP responds to restriction of dietary calcium and perhaps to salmon calcitonin and/or glucocorticoid therapy [6, 8]. Fractures can mend spontaneously, but healing may be delayed, including after osteotomy. Load-sharing intramedullary rods, rather than load-sparing plates, seem best for fractures and pseudofractures in adults [11]. Expert dental care is important. Soft foods and dentures may be necessary, even for pediatric patients.

Sonography and radiographs of fetuses have detected HPP in the second trimester [5]. Early diagnosis requires *TNSALP* mutation identification [18]. Importantly, patients with "benign prenatal" HPP manifest bowing *in utero* that corrects postnatally and resembles infantile, childhood, or odonto-HPP [5].

MUCOPOLYSACCHARIDOSES

Mucopolysaccharidoses (e.g., Hunter, Hurler, Morquio disease) are a family of disorders caused by diminished activity of the lysosomal enzymes that degrade glycosaminoglycans (acid mucopolysaccharidoses) [19, 20]. Accumulation of these complex carbohydrates within marrow cells somehow alters the skeleton in a pattern referred to by radiologists as "dysostosis multiplex," [20–22] featuring macrocephaly, dyscephaly, a J-shaped sella turcica, osteoporosis with coarsened trabeculae, oar-shaped ribs, widened clavicles, oval or hook-shaped vertebral bodies, dysplasia of the capital femoral epiphyses, coxa valga, epiphyseal and metaphyseal dysplasia, and proximal tapering of the second and fifth metacarpals. Joint contractures are also common [19, 20]. It may be that bone morphogenetic protein (BMP) signaling is disrupted [23]. However, the severity and precise manifestations vary according to the specific enzymopathy and the underlying gene mutations [24]. Each disorder manifests with a broad range of severity [19, 20]. Enzyme assays or genetic testing is available [1, 19, 20].

Mucopolysaccharidoses are increasingly treated by marrow cell transplantation or enzyme-replacement therapy [25, 26].

HOMOCYSTINURIA

Homocystinuria in its classic form is a rare (1:60,000–300,000) autosomal recessive disorder (OMIM 236200) caused by cystathionine β-synthase deficiency [27]. Consequently, homocystine, an intermediate in methionine metabolism, accumulates endogenously, predisposing to thrombosis and embolism and modification of connective tissue proteins including fibrillin within periosteum and perichondrium. Total homocystine is increased in plasma. Major clinical problems involve the eyes, central nervous system (CNS), vasculature, and skeleton [27]. Dislocation of the ocular lens can be the initial manifestation. Mental subnormality and thrombotic events are important complications. Patient appearance suggests Marfan syndrome; however, joint mobility is limited. Bones are elongated and overtubulated [21, 22].

There may be pectus excavatum or carinatum, arachnodactyly, and genu valgum [27]. Generalized osteoporosis occurs with "codfish" vertebrae and kyphoscoliosis [21, 22]. Mild manifestations are said to predict responsiveness (including skeletal disease) to pyridoxine

(vitamin B_6) therapy, but this is controversial [27, 28]. Treatment may instead include a low methionine-cysteine diet and betaine [27].

There are other causes of hyperhomocysteinemia being studied in relationship to common forms of osteoporosis [28–31].

ALKAPTONURIA

Alkaptonuria is a rare (less than 1 in 250,000) autosomal recessive disorder (OMIM 203500) [1] caused by a deficiency of homogentisic acid oxidase from loss-of-function mutations within the *AKU* gene [32]. Consequently, phenylalanine and tyrosine degradation is blocked, leading to tissue accumulation and urine excretion of homogentisic acid. Oxidation and polymerization of homogentisic acid explains the characteristic black appearance of urine exposed to air and discoloration of connective tissues [32]. "Ochronosis" refers to the pigmentation in the sclera, skin, teeth, nails, bucchal mucosa, endocardium, intima of large vessels, hyaline cartilage of major joints, and intervertebra1 disks [32]. In elderly patients, pigmentation is also striking in costal, laryngeal, and tracheal cartilage, and in fibrocartilage, tendons, and ligaments. Although its pathogenesis is not well understood, severe degenerative disease from tissue fragility occurs in the spinal column where disks calcify and vertebrae fuse, and in major peripheral joints, especially the hips and knees [33]. Perhaps homogentisic acid inhibits collagen synthesis by inhibiting lysyl hydroxylase [32]. Radiographic changes in the spine are nearly pathognomonic, showing dense calcification of the remaining disk material. Calcification of ear cartilage can also occur. The shoulders and hips are most likely to develop osteoarthritis.

There is no established medical treatment, but a low-protein or other special diets seem worthwhile. Ascorbic acid may block homogentisic acid polymerization [32].

DISORDERS OF COPPER TRANSPORT

Wilson disease (OMIM 277900) and Menkes disease (OMIM 309400) [1] are genetic disorders of copper (Cu^{2+}) caused by deficiencies of $Cu2^+$-transporting ATPases in the trans-Golgi of different tissues [34].

Wilson disease affects approximately 1 in 55,000 individuals in the United States, causes impaired biliary excretion of Cu^{2+}, and leads to hepatic injury and Cu^{2+} storage in additional tissues with marked variability in the severity of clinical sequelae. Kayser-Fleischer rings in the eyes, hepatitis and cirrhosis, renal tubular dysfunction and calculi, neurological disease, and hypoparathyroidism are potential complications [34]. Skeletal disease includes osteoporosis, osteomalacia, and chondrocalcinosis with osteoarthritis and joint hypermobility. There can be hyperphosphaturia and hypercalciuria. Loss-of-function mutation disrupts the ATPase, $Cu2^+$ transporting, beta-polypeptide gene, *ATP7B* [1]. $Cu2^+$ chelation using penicillamine is effective for most cases [34].

In Menkes disease, inherited as an X-linked recessive trait [1], boys develop $Cu2^+$ deficiency that leads to kinky, sparse hair, and CNS disease including mental retardation, seizures, and intracranial hemorrhage [34]. The skeletal sequelae include short stature, microcephaly, brachycephaly, wormian bones, metaphyseal dysplasia featuring widening and spurs, osteoporosis, and joint laxity [21, 22]. Death usually occurs by the age of 3 years. A mild form is called "occipital horn syndrome" [34]. Serum $Cu2^+$ and ceruloplasmin levels are low because of mutation within the ATPase, $Cu2^+$ transporting, alpha-polypeptide gene, *ATP7A*. [1]

INTRODUCTION

The kidneys are primarily responsible for control of extracellular calcium balance. Renal calcium absorption occurs by a series of sequential events as the urine passes through the nephron. Most of the filtered calcium is recovered by proximal tubules, with progressively smaller fractions retrieved as the insipient urine passes through consecutive tubule segments. The bulk of calcium absorption is not hormonally regulated. Hormonal and pharmacological, regulation of calcium absorption is achieved by adjusting the magnitude of calcium recovery in distal segments.

PROXIMAL TUBULE

Approximately 60% of filtered calcium is reabsorbed by proximal tubules [1, 2]. Absorption is mostly passive, driven by the favorable electrochemical gradient generated by the primary absorption of chloride and water [3–5] and proceeding through the lateral intercellular spaces that form the paracellular pathway [Fig. 102.1(A)]. A small fraction of active calcium absorption is present in rats under conditions where passive calcium movement was eliminated [6]. Although minor by comparison with the magnitude of passive paracellular calcium transport, active cellular absorption by proximal tubules amounts to some 20μmol/min [6], or approximately twice that of the distal nephron, where calcium absorption is entirely cellular. Thus, though slight by comparison with passive proximal calcium absorption, active calcium absorption is substantial compared to that occurring in more distal nephron segments.

HENLE'S LOOP

Thin descending and ascending limbs of Henle's loop exhibit low calcium permeability [7, 8] and do not contribute meaningfully to calcium economy.

Thick ascending limbs of Henle's loop, in contrast, are major sites of calcium absorption. Approximately 20–25% of the filtered calcium is absorbed by thick ascending limbs. Calcium is recovered by both medullary and cortical portions of thick ascending limbs. Unlike proximal tubules, where calcium absorption is mostly passive and proceeds through the paracellular pathway, calcium movement in thick ascending limbs is characterized by parallel movement mediated by active transcellular movement and passive paracellular calcium transport [Fig. 102.1(B)]. Passive calcium absorption is driven by the lumen-positive transepithelial voltage, which provides the driving force for movement through calcium-permeable tight junctions. In this setting, the

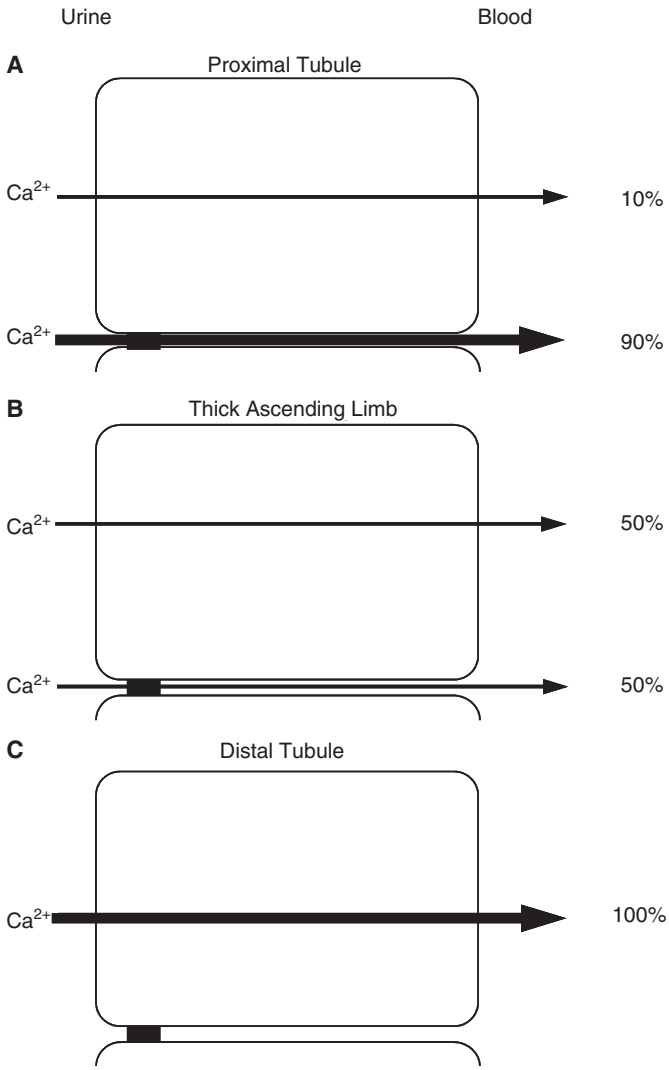

Fig. 102.1. Relative magnitude of cellular and paracellular calcium absorption in proximal tubules, thick ascending limbs, and distal tubules. In thick ascending limbs, transcellular calcium absorption stimulated by PTH approximates the extent of paracellular calcium transport. Notably, in distal tubules calcium absorption proceeds entirely through a cellular pathway.

rate and magnitude of calcium transport are parallel and proportional to those of sodium. Physiological actions or pharmacological or pathological events that enhance sodium absorption increase the voltage and thereby augment calcium absorption. Conversely, maneuvers that decrease sodium absorption reduce calcium absorption. Such interventions commonly involve diuretics such as furosemide or bumetanide that inhibit sodium absorption by thick ascending limbs and increase calcium excretion. Less commonly, mutations of the Na–K–2Cl cotransporter (*Slc12a1*), ROMK apical K^+ channel (*KCNJ1*), or basolateral ClC–K2 basolateral Cl^- channel (*CLCNKB*) associated with the different forms of Bartter's syndrome, are accompanied by hypercalciuria, underscoring the parallel nature of sodium and calcium absorption by thick ascending limbs [9].

Active, transcellular calcium transport by medullary and cortical thick ascending limbs also contributes to net absorption by thick ascending limbs [7, 10].

DISTAL TUBULE

Distal convoluted tubules reabsorb 5–10% of the filtered calcium. Here, calcium absorption is entirely transcellular, proceeding against a steep electrochemical gradient [Fig. 1(C)] [11–13]. Transcellular calcium movement is a two-step process, wherein calcium enters the cell across apical membranes and following diffusion across the cell is extruded across basolateral membranes. Calcium entry is mediated by calcium ion channels [14–17], and extrusion is accomplished by the plasma membrane Ca^{2+}-ATPase and Na^+/Ca^{2+} exchange [14, 15, 18]. Calcium entry is generally believed to be mediated by TrpV5 (ECaC1, CAT2) [19–21]. TrpV5-null mice exhibit appreciable renal calcium wasting, thus establishing its participation in some aspects of calcium homeostasis in rodents [50]. TrpV5 is a homotetramer that is constitutively active, which is difficult to reconcile with a regulated, negative feedback process [51]. Recent studies show that by stimulating protein kinase A, parathyroid hormone (PTH) phosphorylates and activates TrpV5 [52].

Notably, calcium and sodium transport are inversely related in distal convoluted tubules and this is a hallmark of calcium absorption by this nephron segment. Evidence for the inverse relationship comes from the pharmacological effects of thiazide diuretics, which increase sodium excretion while decreasing that of calcium. Independent evidence comes from patients with Gitelman's syndrome. This inherited disorder is due to inactivating mutations of the Na–Cl cotransporter (NCC; *Slc12a3*) that mediates sodium absorption by distal convoluted tubules. Patients [53, 54] and experimental animals [55] with Na–Cl cotransporter mutations exhibit characteristic hypocalciuria. Gordon syndrome, which results from mutations in the lysine deficient protein kinase WNK4 causes constitutive activation of NCC. As expected, this not only increases Na absorption but also promotes hypercalciuria, underscoring the reciprocal nature of distal tubule Na and Ca movement.

It has been proposed recently that α-klotho modulates renal calcium homeostasis by acting on distal tubules [56]. Homologous recombination of α-klotho results in a phenotype that includes osteoporosis and renal calcium wasting [57, 58]. The proposed mechanism for this effect involves enhanced Ca^{2+} entry secondary to augmentation of the Na^+ gradient following recruitment by α-klotho of the Na^+,K^+-ATPase to basolateral cell membranes. It was suggested that this action, in cooperation with TRPV5, $calbindin_{28k}$, and the NCX1 Na^+/Ca^{2+} calcium exchanger,

enhances calcium absorption. Although there is little doubt that α-klotho participates in renal calcium balance, we believe it unlikely that the mechanism proposed by Imura accounts for this action because it would result in parallel increases of Ca^{2+} and Na^{+} transport, whereas the signature of distal tubule calcium absorption is the well-established inverse relation between Ca^{2+} and Na^{+} flux. Alternatively, the finding that α-klotho activates TRPV5 by hydrolyzing extracellular sugar residues provides a more compelling mechanism [59]. α-Klotho effects on PTH-dependent renal calcium absorption in intact animals, may involve indirect actions on PTH secretion [56] in combination with rather than direct effects on distal nephron calcium movement. A comprehensive picture of the mechanism of PTH action on renal calcium homeostasis requires further examination.

The contribution of cortical collecting tubules to renal calcium conservation is modest at best and uncertain. A small absorptive flux of calcium has been noted as has an equally small secretory transport [13, 60–62]. Net calcium transport in isolated perfused rabbit cortical collecting ducts varied with the magnitude and direction of the transepithelial voltage [60]. A small net secretory calcium flux was observed under ambient conditions. The Ca^{2+} permeability was very low compared with that of thick ascending limbs and proximal tubules. It is conceivable that secretory calcium transport could play a role in regulating calcium excretion when long-term changes of transepithelial voltage occur, for instance, as an adaptive response to changes in mineralocorticoid status [63].

EFFECT OF DIURETICS

Thiazide diuretics and functionally related agents such as metolazone have the unique ability to decrease renal calcium excretion, especially upon chronic administration, while simultaneously increasing sodium excretion. Thiazide diuretics are widely used in the therapeutic management of hypertension, congestive heart failure, and idiopathic hypercalciuria.

Dissociation of sodium and calcium excretion by thiazide diuretics arises primarily from increased calcium reabsorption by distal tubules, but secondarily because of a compensatory elevation of calcium recovery by proximal tubules. The anticalciuric action of thiazide diuretics makes them uniquely useful in treating hypercalciuria. This calcium-sparing effect, which may not be evident upon initial administration of the drug, is particularly beneficial in individuals who are prone to calcium stone formation. Diuretics such as furosemide and bumetanide that act on the loop of Henle's loop cause profound increases in calcium and magnesium excretion. At one time they were used in treating hypercalcemia. However, better alternatives are now available that avoid the likely distortions of extracellular electrolyte balance that accompany treatment with loop diuretics.

LESSONS FROM THE GENETIC HYPERCALCIURIC STONE-FORMING RATS

The primary end point for successful treatment of patients with calcium-containing kidney stones is a decrease in the rate of stone recurrence [64–68]. While decreasing stone formation is an important goal, what should concern clinicians equally is maintaining and improving the patient's bone mineral density (BMD) and bone quality [69]. Stone formers have both a reduction in BMD [66, 69–81] and an increase in fracture rate compared to non-stone formers [70, 71]. While acute stone episodes often are resolved quickly, patients may live the remainder of their lives in pain and with reduced function due to the osseous complications related to fractures [82].

The majority of human kidney stone formers with calcium-containing kidney stones are hypercalciuric when compared to non-stone formers [64–68]. Patients with idiopathic hypercalciuria often excrete more calcium than they absorb, indicating a net loss of total body calcium [64, 66, 78, 83–90]. The source of this additional urine (U) calcium is almost certainly the skeleton, the largest repository of body calcium [79, 91, 92]. Idiopathic hypercalciuria has been associated with markers of increased bone turnover [81, 93, 94]. Urinary hydroxyproline is increased in unselected patients with idiopathic hypercalciuria [93], and serum osteocalcin levels are elevated in stone formers who have a defect in renal tubule calcium reabsorption but not in those with only excessive intestinal calcium absorption [94]. Studies with ^{47}Ca demonstrate increased bone formation and resorption, with the latter predominating [95]. Cytokines known to increase bone resorption have also been shown to be elevated in patients with idiopathic hypercalciuria [75, 96–98].

BMD is correlated inversely with UCa excretion in both men [99] and women [100]. This relationship was confirmed in stone formers but not in non-stone formers [92]. A number of studies demonstrate that patients with nephrolithiasis have a reduction in BMD compared to matched controls [66, 69, 71–81]. After adjusting for a large number of variables, an analysis of the Third National Health and Nutrition Examination Survey (NHANES III) demonstrated that men with a history of kidney stones have a lower femoral neck BMD than those without a history of stones [70]. Analysis of almost 6,000 older men again demonstrated an association of kidney stones with decreased BMD [101]. Stone formers have an increased risk of fractures [70, 71]. In NHANES III there was an increased risk of wrist and spine fractures in stone formers [70], and, in a retrospective analysis, stone formers had an increased incidence of vertebral fractures, but not fractures at other sites [71].

To help understand the mechanism of idiopathic hypercalciuria in humans, we developed an animal model of this disorder [22–49]. Through over 90 generations of successive inbreeding of the most hypercalciuric progeny

	Hypercalciuric Stone-Forming (IH) Humans	Genetic Hypercalciuric Stone-Forming (GHS) Rats
Urine Ca Excretion	Increased (by definition)	Increased (Refs. 22–41, 46, 67, 106)
Intestinal Ca Absorption	Increased in most patients (Refs. 64, 66, 78, 83, 85, 89, 90, 95, 107–124)	Increased (Refs. 22–41)
Renal Tubular Ca Reabsorption	Decreased in many patients (Refs. 125–127)	Decreased (Ref. 30)
Bone Resorption	Increased in most patients—as evidenced by markers of bone resorption (Refs. 75, 81, 93, 94, 96–98)	Increased (Refs. 29, 33)
Bone Mineral Density	Decreased in most patients (Refs. 66, 72–80, 128, 129)	Decreased (Ref. 46)
Serum PTH	Normal to reduced (Refs. 80, 112, 130–132) or elevated (Refs. 130, 131)	Reduced (Refs. 106)
Serum $1,25(OH)_2D_3$	Normal to elevated (Refs. 79, 80, 89, 91, 111, 112, 133–136)	Normal to elevated (Refs. 28, 36, 37, 42, 103)
Vitamin D Receptor	Increased number (Ref. 104) or no increase (Ref. 137) Gene polymorphisms (Ref. 138–151)	Increased number (Ref. 28, 33, 36, 103, 152)
Ca Receptor	Changes in number not reported Activating and inactivating mutations associated with hyper- and hypocalciuria, respectively (Refs. 153, 154) Gene polymorphisms (Refs. 155, 156)	Increased number (42) Treatment with cinacalcet activates the receptor – associated with increased UCa in SD but not GHS rats (Ref. 106)
Stone formation	Consequence of hypercalciuria (Refs. 64, 66, 83, 85, 87–90, 157–162)	Present (Refs. 22–24, 29, 31, 32, 34)

of the most hypercalciuric Sprague-Dawley (SD) rats, we established a strain of rats that now consistently excrete approximately 8–10 times as much urinary calcium as SD controls (Table 102.1, Fig. 102.2). Compared to SD rats, the genetic hypercalciuric rats have a normal serum calcium and absorb far more dietary calcium [38, 44], similar to observations in man [64, 66]. The increase in intestinal calcium absorption is due to a significant increase in the mucosal-to-serosal (absorptive) calcium flux with no change in the serosal to mucosal (secretory) flux [38]. When the hypercalciuric rats are fed a diet essentially devoid of calcium, UCa excretion remains significantly elevated compared with that of similarly fed SD rats, indicating a defect in renal tubule calcium reabsorption or an increase in bone resorption, or both [37], again similar to observations in humans [79, 102]. Cultured bone from the hypercalciuric rats released more calcium than the bone of SD rats when exposed to increasing amounts of calcitriol [33], and the BMD of the hypercalciuric rats is lower than that of the SD rats [46]. Administration of a bisphosphonate, which significantly inhibits bone resorption, to hypercalciuric rats fed a low-calcium diet significantly reduces urinary calcium excretion [29]. Utilizing clearance studies, a primary defect in renal calcium reabsorption is observed [30]. Thus, these hypercalciuric rats have a systemic abnormality in calcium homeostasis: they absorb more intestinal calcium, they resorb more bone, and they do not adequately reabsorb filtered calcium (Fig. 102.3). We have found that the bone, kidney and intestine of our inbred strain of hypercalciuric rats have an increased number of vitamin D receptors (VDRs) and calcium-sensing receptors (CaSR) [33, 36, 42, 45, 103]. We have recently found that the elevated levels of VDRs are regulated by a decreased level of the transcription factor Snail [48], suggesting potential underlying mechanism(s) for the hypercalciuria. In a human study, circulating monocytes from patients with idiopathic hypercalciuria were shown to have an increased number of VDRs [104]; however, we do not know if hypercalciuric humans have altered levels of Snail.

After eating standard rat chow (1.2% Ca) for 18 weeks, virtually all of these hypercalciuric rats form kidney stones while there is no evidence for stone formation in SD rats [34]. The stones contain only calcium and phosphate (P), without oxalate (Ox), and by X-ray diffraction the stones are exclusively poorly crystalline apatite [23, 24, 31, 34]. When fed additional hydroxyproline, an amino acid that is metabolized to oxalate [105], these rats formed CaOx kidney stones [22, 26], the most common kidney stones formed by man [22, 26]. As each of the hypercalciuric rats forms renal stones, they have been termed genetic hypercalciuric stone-forming (GHS) rats [22–24, 26, 29, 31, 32, 34, 44]. The pathophysiology responsible for the hypercalciuria parallels that found in hypercalciuric humans and is thus an excellent model of hypercalciuria (Table 102.1).

We have recently demonstrated that GHS rats have a reduction in BMD and bone strength even when fed a diet with ample calcium [46] (Fig. 102.4). GHS rats had

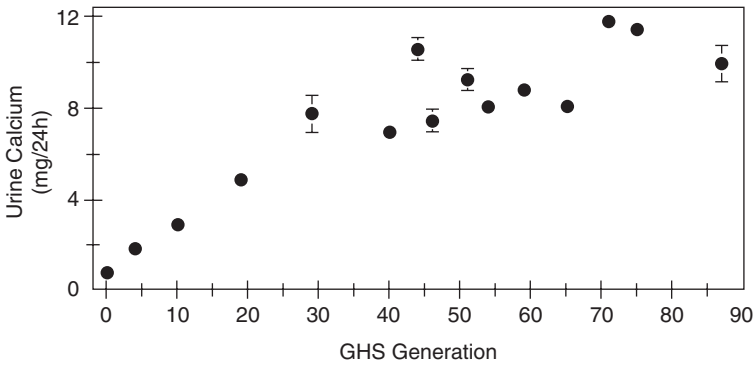

Fig. 102.2. Through successive inbreeding of the most hypercalciuric progeny of SD rats we have established a strain of genetic hypercalciuric stone-forming (GHS) rats that all excrete ~8–10 times as much urinary Ca as the parental strain. All data from published studies (Refs. 22–49).

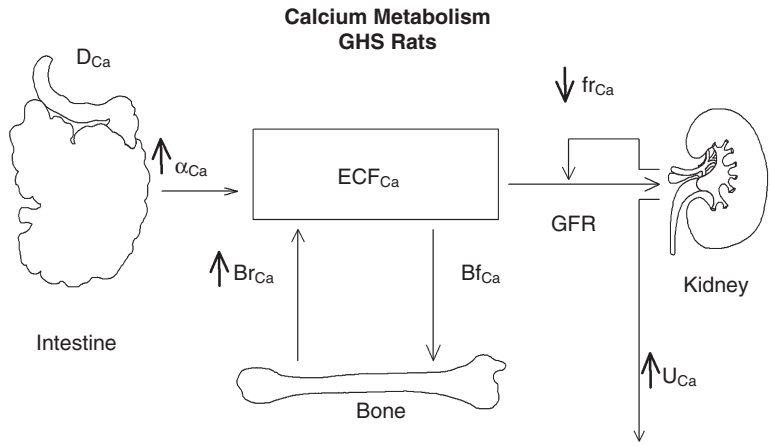

Fig. 102.3. Systemic abnormality in Ca homeostasis in GHS rats: increased intestinal Ca absorption, increased bone resorption, and decreased Ca reabsorption.

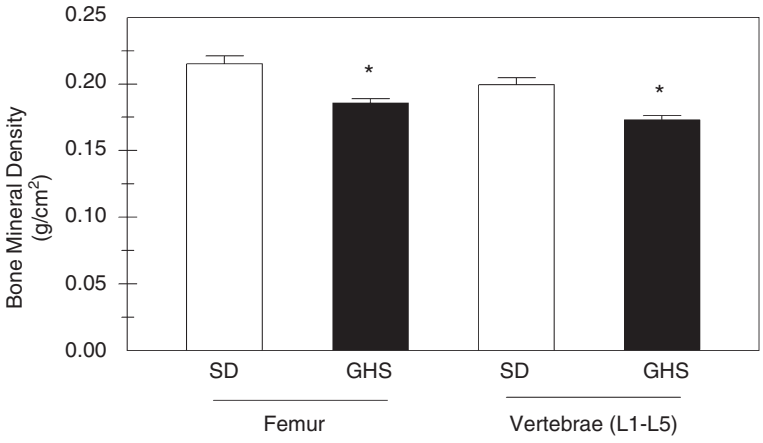

Fig. 102.4. GHS rats have a reduction in BMD in femur and vertebrae even when fed a normal Ca diet (Ref. 63).

reduced cortical (humerus) and trabecular (L1-L5 vertebrae) BMD and had a decrease in trabecular volume and thickness. GHS rats had no change in vertebral strength (failure stress), ductibility (failure strain), stiffness (modulus), or toughness, whereas in the humerus, there was reduced ductibility and toughness and an increase in modulus, indicating that the defect in mechanical properties is mainly manifested in cortical, rather than trabecular, bone. In the GHS rat, the cortical bone is more mineralized than the trabecular bone. Thus, the GHS rats, fed an ample calcium diet, have reduced BMD with reduced trabecular volume, mineralized volume, and thickness, and their bones are more brittle and fracture prone, indicating that GHS rats have an underlying defect of bone not related to a deficiency in dietary calcium.

Thiazide diuretic agents such as chlorthalidone (CTD) reduce UCa excretion in normal [163] patients with hypercalciuria [164] and rats [43, 165]. These drugs act by

stimulating calcium reabsorption in the distal convoluted tubule [163] and by producing extracellular fluid volume depletion [166]. Thiazide diuretics are used to treat CaOx stone disease [65, 66]; a meta-analysis revealed that in studies of more than 2 years' duration, there was a significant reduction in stone recurrence rate [167]. A number of studies have shown that when thiazides are used to treat hypertension [168] there is a reduction of osteoporotic fractures [169, 170] and often an increase in BMD [171, 172].

We used GHS rats to test the hypothesis that CTD would have a favorable effect on BMD and bone quality. GHS rats were fed an ample calcium diet and half were also fed CTD [49]. As expected, CTD reduced UCa in GHS rats [43, 165, 173]. In the axial and appendicular skeletons, an increase in trabecular mineralization was observed with CTD compared to controls [49]. CTD also improved the architecture of trabecular bone. Using microcomputed tomography (μCT), trabecular bone volume (BV/TV), trabecular thickness and trabecular number were increased with CTD. A significant increase in trabecular thickness with CTD was confirmed by static histomorphometry. CTD also improved the connectivity of trabecular bone. Significant improvements in vertebral strength and stiffness were measured by vertebral compression. Conversely, a slight loss of bending strength was detected in the femoral diaphysis with CTD. These results obtained in hypercalciuric rats suggest that CTD can favorably influence vertebral fracture risk.

Epidemiology of Nephrolithiasis

Murray J. Favus

Introduction 856
Geographic Distribution of Prevalence and Incidence 856
Nutrition and Lifestyle 857
Genetics 858
Other Disorders 858
References 858

INTRODUCTION

Nephrolithiasis is a frequent disease that affects about 10% of people in Western countries and is a common cause of emergency room visits, hospitalizations, and surgical procedures. Population studies indicate that the prevalence of calcium oxalate stones has been constantly increasing during the past 50 years in industrialized countries. As the composition of stones varies depending on gender and age of patients, dietary patterns, and associated disorders, a review of the epidemiology of kidney stones provides insight into potential causes and contributing factors.

GEOGRAPHIC DISTRIBUTION OF PREVALENCE AND INCIDENCE

Prevalence (patients with a history of kidney stones) and incidence (rate of new kidney stones in the population) of kidney stones reveal its global distribution and the increasing frequency throughout the Western world. In the United States, the prevalence of kidney stones among men and women has been tracked from the periodic National Health and Nutrition Examination Surveys (NHANES)[1]. From the 2003 report, the prevalence of kidney stones increased from the years 1976 to 1980 (3.8%) to the years 1988 to 1994 (5.2%) and then stabilized (Table 103.1). Incidence data reported by the Mayo Clinic [3] show a decrease in men between 1970 and 2000 from 155 to 105 per 10,000 population. At the same time, incidence in women rose from 43.2 to 68.4 per 10,000 population.

In Germany, Hesse et al. [4] reported increased prevalence in the population between 1979 and 2001 from 4.0% to 4.7% and a greater increase in the incidence rates among those 14-years-old and above. A summary of population changes shows the stone prevalence rates and incidence per 100,000 affected subjects (Table 103.1) also increased in the population of other European countries.

In several countries in Asia, the prevalence of kidney stones is higher than in the United States. Reports from China [5] show the prevalence in men is 8.0% and 5.1% in women. In Korea [6], men and women have a kidney stone prevalence of 6.0% and 1.8%, respectively. The highest reported prevalence in Asia is from Taiwan [7] with an overall frequency of 9.6%, including 14.5% among men and 4.3% among women.

It remains unknown as to whether the increased prevalence and incidence are due to the increase in calcium oxalate and/or calcium phosphate stones, or to the less common stones composed of uric acid, struvite (infection), or cysteine. The widespread increases in prevalence may be a real increase in stones or may be due to the discovery of stones in otherwise asymptomatic subjects because of the use of sensitive techniques such as ultrasound and computed tomography (CT). Nevertheless, the global distribution of stones by gender has consistently

favored men to women by ratios of 5:1 to 2:1. In the past 30 years, a trend for increased stones among women may be related to the concomitant rapid increased prevalence of obesity in women compared to men [8].

NUTRITION AND LIFESTYLE

Nutritional risk factors for stone disease are well known. They include excessive consumption of animal proteins, sodium chloride, and the rapidly absorbed monosaccharides, and insufficient dietary intake of fruits and potassium-rich vegetables. As a consequence, an excessive production of hydrogen ions may induce several changes in urine chemistries including low urine pH, high urine calcium and uric acid excretion, and low urine citrate excretion. Excess in caloric intake, high chocolate consumption inducing hyperoxaluria, and low water intake are other factors that favor excessive urine concentration of solutes. Restoring dietary balance is the first advice to prevent stone recurrence. However, the striking increase in the common calcium oxalate stones suggests that steps be taken to prevent stone formation.

Fluid intake, climate, and occupation

Observation studies [3, 8] suggest high fluid intake reduces the risk for calcium oxalate kidney stones, and the results of one randomized controlled trial of high fluid intake resulted in fewer kidney stones [9].

Water hardness is due to increased calcium concentration, and drinking hard water has been associated with increased urine calcium excretion [10] but not an increase in kidney stones.

Stone prevalence may vary by region, suggesting a contribution of climate; however, separation of climate from other regional variables such as genetic factors and dietary preferences has been difficult. In general, within a country, warmer regions have higher kidney stone prevalence. In the hot and humid climate of the southeast region of the United States, the local climate is thought to be a major influence in the high prevalence of kidney stones [1]. There is little comparable information on the relationship of climate and stone formation in other countries.

Certain workplace conditions such as being hot (steel mills) or largely outdoors (lifeguards) have long been recognized as associated with increased stone risk. Shared clinical experience suggests that occupations that limit regular fluid intake such as long-distance truck drivers, teachers, and executives confined to day-long meetings may be at increased risk for kidney stone formation.

Calcium intake

The long-standing treatment of calcium oxalate kidney stones by reducing dietary calcium intake has given way to a substantial body of evidence from both epidemiologic data [11–14] and intervention trials that show reduced calcium intake does not lower kidney stone risk. Indeed, higher calcium intake reduces stone formation rates [15–17]. A randomized clinical trial of male hypercalciuric calcium oxalate stone formers showed that those fed a high calcium diet of 1,200 mg per day with restricted salt, oxalate, and protein had a 51% lower risk of new stone formation compared to those ingesting a diet low in calcium of 400 mg per day and low in oxalate [15]. In contrast to the effects of dietary calcium, calcium supplements appear not to reduce the incidence of kidney stones. A large randomized clinical trial in which postmenopausal women maintained their usual calcium intake and were supplemented with additional 1,000 mg calcium was associated with a 17% increase in the appearance of new kidney stones [16].

Salt

Dietary salt has increased over the past 200 years and its effects include increased urinary calcium excretion [18]. Epidemiologic data suggest a positive correlation between salt ingestion and first-time kidney stone formation in women but not men [11, 12].

Protein

Population studies of the impact of protein intake on kidney stone formation have yielded variable results. Two large follow-up cohort studies concluded that protein intake increased stone formation only in men with normal body mass index (BMI) [19], and that there was no association of animal protein intake and stone incidence in premenopausal women [14]. In idiopathic hypercalciuria [15], lower protein intake was associated with lower stone formation, but the diet associated with lower stone formation was also higher in dietary calcium, which by itself can reduce stone disease (see above). Randomized controlled trials have failed to confirm that low protein intake reduces kidney stone risk. It is possible that the source of protein may differ in the rate of stones, possibly because of differences in sulfate-rich amino acid content, urinary acid excretion, and urine pH [20, 21].

Oxalate

Prospective cohort studies in men and women reveal only a modest effect of dietary oxalate on the risk of kidney stone formation with the difference in risk increasing by about 20% when lowest and highest quartiles of dietary oxalate are compared [17]. The difference in oxalate intake across quartiles was largely due to the amount of spinach ingested. Thus, urinary oxalate excretion is an important contributor to calcium oxalate stone formation; and urinary oxalate excretion is not solely determined by dietary oxalate.

GENETICS

Heritable factors in stone disease are largely from retrospective kindred studies in which 40% of stone formers reported a first-degree relative with a history of kidney stones [22]. In a prospective study, men with a family history of stones had a risk of incident stones double those without such a family history [23]. A twin study showed that a concordance of stones in monozygotic twins approached twice the rate observed in dizygotic twins [24]. Using this data, heritability was estimated to account for 56% of stone prevalence.

OTHER DISORDERS

Obesity and diabetes

Men and women with increased BMI are at increased risk for kidney stone formation [25]. Weight gain in the adult years carries a greater risk compared to those whose weight was stable. The worldwide increase in the prevalence of obesity may be contributing to the increased stone risk among women [26]. Obesity influences the urine composition and therefore the crystal composition of stones. For example, in both men and women, the lower urine pH in obesity is associated with an increase in uric acid stones (uric acid stones accounted for 63% of stones in obese stone formers compared to 11% uric acid stone among in non-obese stone formers) [27]. A greater number of uric acid stone formers were diabetic (27.8%) compared to 6.9% of calcium stone formers [28] and may reflect the high frequency of coexistent diabetes and obesity.

Two large prospective cohort epidemiologic studies concluded that diabetes is also a risk factor for stones [29] with the relative risk of incident stones of 1.3 in diabetic versus nondiabetic older women and 1.6 in younger women. No such association was found for men.

INTRODUCTION

The physician evaluating a patient with nephrolithiasis needs to keep in mind the relative prevalence of various stone types. Calcium salts (oxalate, phosphate, or mixed) are the most common stone types, together accounting for 70–75% of nephrolithiasis; low urinary volume, hypercalciuria, hyperoxaluria, hypocitraturia, and hyperuricosuria are identified risk factors [1]. Struvite stones (magnesium ammonium phosphate) represent approximately 10–15% [1] and form in an alkaline urine with high ammonium concentration that results from infection with urease-producing bacteria [2]. Uric acid stones, accounting for 5–10%, are associated primarily with an acidic urine; hyperuricosuria and low urinary volume are additional risk factors, as is insulin resistance [1, 3]. Cystine stones account for approximately 1%. They are the only clinical consequence of hereditary cystinuria, which is the only cause of cystine stones. Stones composed of crystallized drugs represent less than 1% of all stones worldwide.

BASIC EVALUATION OF THE STONE PATIENT

Essential to every evaluation of renal colic, whether an initial or repeat event, is a detailed history, basic metabolic profile, serum uric acid, urinalysis with urine culture, non-contrast helical computed tomography (CT) of the abdomen (i.e., "stone-protocol CT kidneys"), and, if a stone has been retrieved, stone analysis [4]. The history should include stone burden (both in the past and present), the number and type of stone-related urologic procedures, previous medical therapies aimed at risk reduction, and related medical illnesses that may contribute to stone-forming risk [e.g., malabsorption syndromes, inflammatory bowel disease, bowel resection, sarcoidosis, hyperparathyroidism, gout, renal tubular acidosis (RTA), recurrent urinary tract infections (UTIs), neoplasm, immobilization, renal anomaly]. Stone formers have a higher incidence of obesity, dyslipidemia, hypertension, physical inactivity, and diabetes mellitus [5]. A family history of stone disease is associated with an increased risk of stone occurrence and recurrence [6]. A careful dietary history is useful to identify foods that contain excesses of oxalate (such as nuts, chocolate, legumes, soy, green leafy vegetables, berries, and rhubarb), uric acid (examples include shellfish, organ meats, and yeast), and animal protein. Dietary history must also include total daily sodium and calcium consumption. Finally, it is imperative to get a detailed accounting of type and amount of fluid per day. Daily excretion of large amounts of water (greater than 2 liters per day) reduces stone-forming risk. Coffee and tea have traditionally been considered to have high oxalate content. Alcoholic beverages have been purported to increase the risk of stones, but prospective studies have found that beer and wine decrease risk of stone formation [7], possibly due to inhibition of anti-diuretic hormone (ADH) release.

Grapefruit juice has been associated with an increased risk of stones in epidemiologic studies.

Medications should be reviewed to identify drugs that increase stone-forming risk (acetazolamide, loop diuretics, topiramate, excess vitamin D, and calcium) as well as those that can themselves crystallize and, thus, precipitate to form stones (triamterene, indinavir, nelfinavir, amprenavir, atazanavir, acyclovir, and sulfonamide antibiotics) [8–11].

The basic metabolic profile is useful for clues to the etiology of stone disease. Hypokalemia promotes intracellular acidosis, which increases citrate reabsorption in the proximal tubule; hypocitraturia is a known risk factor for calcium stone formation. Hypobicarbonatemia with a normal anion gap may indicate the presence of a distal RTA, a risk factor for calcium phosphate crystallization. Hypercalcemia should alert one to the possibility of primary hyperparathyroidism, sarcoidosis, other granulomatous diseases, or malignancy as an underlying etiology of calcium stones. Blood urea nitrogen (BUN) and creatinine measurements (and the associated 4-model modification of diet in renal disease (MDRD) glomerular filtration rate (GFR) estimates that now often accompany basic metabolic profiles) mark the level of renal function, with acute changes indicating the need for more urgent medical attention as obstruction to urine flow may be present.

A serum uric acid is useful because hyperuricemia, when the result of overproduction or excessive intake, is associated with hyperuricosuria. The presence of hyperuricosuria has been linked with an increased risk of both uric acid and calcium oxalate stones, although the association with calcium oxalate has been called into question [12].

The urinalysis can provide an abundance of useful information. A high specific gravity indicates a concentrated urine and is useful to follow compliance with fluid intake, as a low urine volume is a risk factor for stones of all types. Dipstick urine pH, while not as accurate as a metered urine pH, is useful if measured on fresh urine. An alkaline pH on a first-morning void is consistent with distal renal tubular acidosis, a risk factor for calcium phosphate stones. A pH of 8 or higher, however, is not consistent with normal physiology and indicates infection with urease-producing bacteria, a risk factor for magnesium ammonium phosphate (struvite) stones, particularly when associated with positive tests for nitrite and leukocyte esterase. Hematuria could indicate current stone disease or, in children, the presence of hypercalciuria [13]. On urine microscopy, crystals, if present, can identify the culprit stone-type (Fig. 104.1).

RADIOGRAPHIC EVALUATION

In a patient with renal colic, radiography is essential in assessing stone burden, stone location(s), and the presence of obstruction. Studies commonly used include the plain abdominal film [kidney-ureter-bladder (KUB) film]; ultrasound; intravenous pyelogram (IVP); and helical, non-contrast CT scanning. Except for ultrasound, care should be taken in ordering these tests given the growing epidemiologic evidence linking the amount of ionizing radiation from imaging procedures and malignancy. Historically, stones were classified as radiopaque or radiolucent based on their appearance on KUB (Fig. 104.2). Struvite, cystine, and calcium-containing stones are radiopaque. Cystine stones are radiodense because of the disulfide bonds. Indinavir stones and pure uric acid stones are radiolucent on KUB; uric acid stones, but not indinavir stones, are visible on helical CT scanning. A KUB, however, has an unfavorable sensitivity and specificity profile (45–59% and 71–77%, respectively) and is not usually the best option in the initial stone evaluation [14]. Ultrasonography has high specificity (97%), provides excellent visualization of hydronephrosis, and avoids exposure to radiation, but has a lower sensitivity than KUB because of difficulty identifying calculi that are small or that are located in the ureter [14] (Fig. 104.3). For this reason, ultrasound is preferred only for patients in whom it is important to limit exposure to ionizing radiation (e.g., pregnancy). IVP, previously the gold standard, has better sensitivity (64–87%) than KUB or ultrasound and excellent specificity similar to that of ultrasonography [14]. It may also play a therapeutic role by promoting an osmotic diuresis. However, compared to non-contrast, helical CT of the kidneys, IVP has a lower sensitivity, it takes more time, and it exposes the patient to iodinated contrast and higher doses of radiation [15]. Indications for IVP include evaluation of a patient in whom indinavir stones or medullary sponge kidney are suspected.

In most circumstances the best option for imaging is non-contrast, helical CT of the kidneys. Sensitivity and specificity for this modality are both at or above 95% [14] (Fig. 104.4). While more expensive than other imaging modalities, the higher cost of helical CT is offset by speed of diagnosis, ease of use, and better sensitivity [16]. It has the added advantage of detecting other causes of abdominal pain that may present with symptoms resembling renal colic [17].

Refinements in CT imaging have led to the development of multidetector computed tomography (MDCT), which tries to determine the chemical composition of urinary tract stones based on individual crystals' Hounsfield characteristics. Because of overlap in these Hounsfield values with this technique, new dual-source CT (DSCT) machines have been developed and are able to distinguish pure uric acid, mixed uric acid, cystine, and calcium stones [18, 19]. This technology, currently offered in only a handful of medical centers, still requires additional study before it can become widely available.

STONE ANALYSIS

Stone analysis should be performed on all patients in whom a specimen is available, as it is the most direct

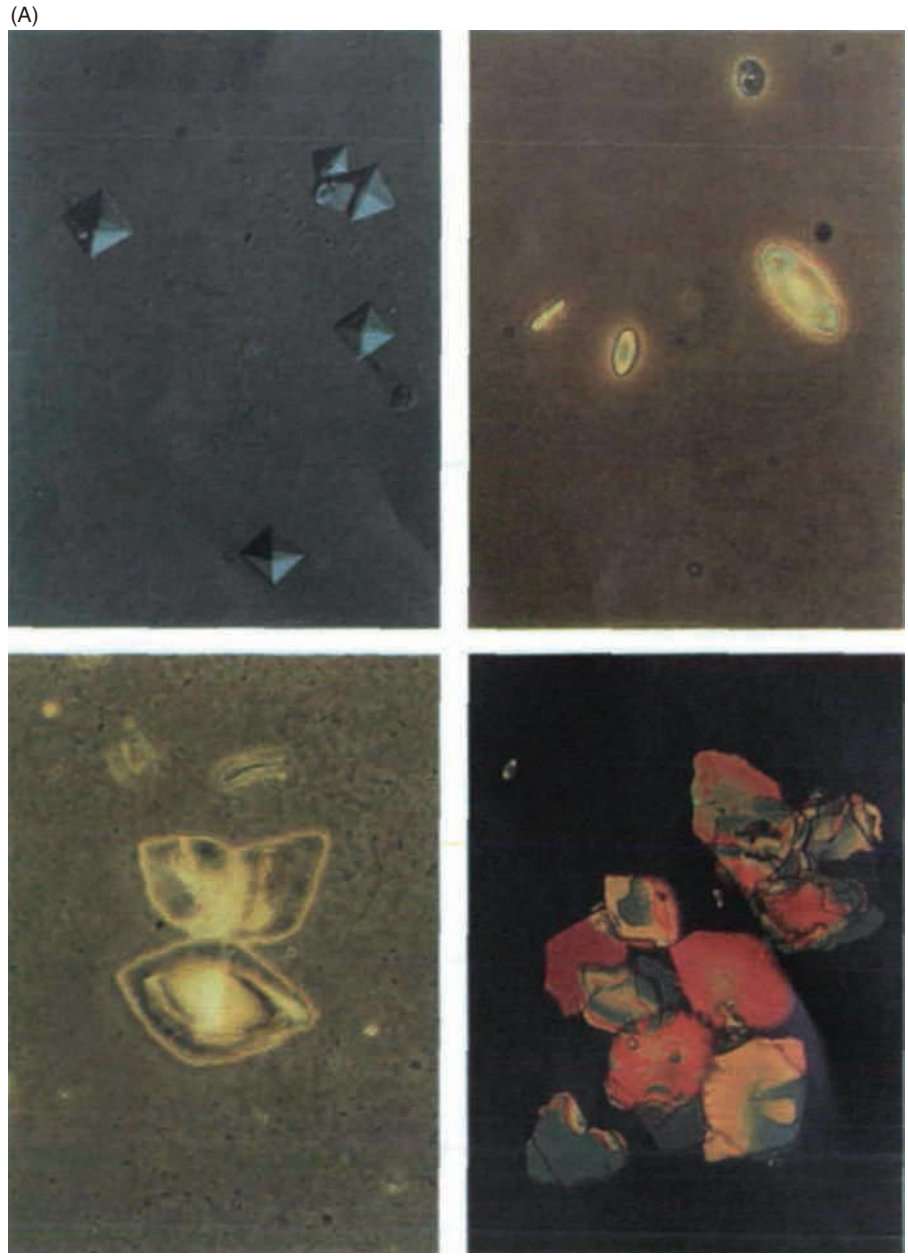

Fig. 104.1. Crystals. (A) Clockwise from top left: Typical bipyramidal calcium oxalate dihydrate crystals (interference-contrast, 640x). way to identify stone type and allows for stone-specific therapy. Currently accepted methods of analysis include polarization microscopy, infrared spectroscopy, and X-ray crystallography/diffractometry [20]. Polarization microscopy, a technique that identifies crystals based on their interaction with polarized light, is inexpensive, quick, and requires very little stone material; the disadvantages include less reliability in identifying calcium phosphate, uric acid, and mixed stones [20]. Infrared spectroscopy is based on the interaction of infrared light and the molecules making up a stone (Fig. 104.5). Its advantages include ease of use, small sample requirement, and ability to identify noncrystalline material (which often makes up 5% of an individual stone) while the major disadvantage is the amount of time required to perform the test [20]. X-ray diffractometry is based on the diffraction of X-rays by the crystalline structure (Fig. 104.6). The advantage of this technique is its ability to identify any crystal type; the main drawback, however, is its inability to identify noncrystalline material [20].

METABOLIC PROFILING

Which patients should have full metabolic profiling?

Beyond this evaluation of patients with acute renal colic, the cost-effectiveness of additional testing is not established for all adult first-time stone formers. It is clear that a child with stones, even on the first event, deserves a thorough metabolic evaluation given the increased likelihood of finding an inherited cause. Furthermore, metabolic evaluation of adults with multiple or recurrent stones has been shown to reduce overall costs [21, 22]. Other patients in whom metabolic evaluation should be considered include patients with noncalcareous stones, reduced renal function, single functioning kidney, a strong family history of kidney stones, calcium oxalate stone formers with an increased risk of enteric oxaluria (those with a history of bariatric surgery, short bowel syndrome, chronic diarrhea, or malabsorption), anatomic urinary tract abnormalities, and recurrent urinary tract

Reprinted with permission from Ref. 39.

infections [4]. The core of this additional testing is 24-hour urine profiling, which should be performed 2 to 4 weeks after an acute episode of renal colic has resolved. The components of a 24-hour urine study include measurements of volume, creatinine, calcium, oxalate, citrate, uric acid, sodium, potassium, chloride, magnesium, phosphorus, ammonium, sulfate, urine urea nitrogen, and pH. Specialized laboratories will use these data to derive the protein catabolic rate and supersaturation measures for calcium oxalate, calcium phosphate, and uric acid. If the stone type is not known and cystine is in the differential diagnosis, qualitative cystine screening should be performed; the screen involves a colorimetric test using cyanide-nitroprusside on a 24-hour urine collection. If this is positive, or if the stone is known to be cystine, quantitative testing should be performed using solid-phase assay [23]. Given the day-to-day variability in urine chemical composition, the initial metabolic evaluation should include two 24-hour urine collections [24]. Adequacy of the urine collection can only be evaluated by reviewing the creatinine excretion, which should be 20–25 mg/kg lean body weight in males and 15–20 mg/kg in females. Additional laboratory studies depend on the results of the 24-hour testing.

Supersaturation

Unique to every salt is a characteristic termed the ion activity product (AP). The solubility product (SP) is defined as the AP below which crystallization does not occur. The formation product (FP) is defined as the AP at which crystallization does occur. Supersaturation is a value obtained by the ratio AP/SP: A value less than 1 indicates that crystallization will not occur, while a value greater than or equal to 1 indicates that crystallization can (but, in contradistinction to FP, does not have to) occur [25]. FP can be classified further into homogeneous or heterogeneous. Homogenous FP is the AP at which crystallization will occur independent of other urine components. Heterogeneous FP, however, is an AP dependent on the promoters and inhibitors present in the urine. The interval between SP and $FP_{homogeneous}$ is termed the "metastable range of supersaturation"; crystallization of a salt with an AP in this range depends on the balance between promoters (e.g., calcium, oxalate, sodium, urine pH, and low urine volume) and inhibitors (e.g., citrate, pyrophosphate, potassium, magnesium, and high urine volume) of stone formation.

In human urine, calcium oxalate AP normally exists in the metastable range of supersaturation [26]. A major goal of stone prevention is to reduce supersaturation, particularly for the salt of the stone type the patient has experienced, if that is known. Increasing urinary volume will reduce the supersaturation of all salts proportionately. Therapeutic measures for altering specific solutes are discussed in Chapter 106.

Hypercalciuria

Hypercalciuria, the most commonly identified metabolic abnormality on 24-hour urine profiling, is defined as excretion of more than 200 mg/day of calcium in females and more than 250 mg/day in males [27]. The differential diagnosis of hypercalciuria is discussed in Chapter 102. If hypercalciuria is documented, laboratory evaluation should include measurement of intact parathyroid hormone (PTH), phosphorus, 1,25-dihydroxy vitamin D_3, magnesium, and thyroid-stimulating hormone (TSH). Given the growing evidence of bone demineralization in patients with hypercalciuria, a dual energy X-ray absorptiometry (DXA) scan to evaluate for osteoporosis may be considered as well [28]. Since dietary calcium restriction below a recommended daily intake of 800–1,000 mg is not of therapeutic value in patients with stones, categorization of patients into subsets of hypercalciuria based on intestinal absorption, bone resorption, or renal reabsorption, is not clinically useful.

Hyperoxaluria

Hyperoxaluria is typically defined as an oxalate excretion of more than 45 mg/day [27]. Most cases of hyperoxaluria are diet-mediated (foods rich in oxalate include dark green leafy vegetables, legumes, berries, nuts, chocolate, soy, and ripe rhubarb). Ethylene glycol (i.e., antifreeze), when ingested, is metabolized to oxalate and can cause stones.

Oxalate levels greater than 80–100 mg/day suggest that enteric oxaluria is likely contributing as well. Enteric oxaluria can result from a malabsorptive process (such as in pancreatic insufficiency, cystic fibrosis, or Crohn's disease, or following gastric bypass or bariatric surgery) in which undigested fatty acids in the colon saponify calcium, allowing more free oxalate to remain in solution and not be complexed with calcium, resulting in enhanced oxalate absorption. Non-absorbed bile salts also increase colonic permeability to oxalate. At levels above 100 mg/day, primary hyperoxaluria, a rare inherited disease that results in enhanced conversion of glyoxylate to oxalate, should be considered as an etiology. This topic is also discussed further in Chapter 102.

Hyperuricosuria

Hyperuricosuria is defined as urinary uric acid excretion exceeding 750 mg/day and 800 mg/day in women and men, respectively [27]. It is a risk factor for both calcium oxalate and uric acid nephrolithiasis (again, the former association has recently been called into question) [3, 12]. A purine-rich diet is often a factor, but it is believed that many patients may have mild metabolic overproduction of uric acid. Other less common causes include gout, leukemia, tumor lysis syndrome, Lesch-Nyhan syndrome, enhanced phosphoribosylpyrophosphate synthetase activity, xanthinuria, and 2,8-dihydroxyadeninuira. Uric acid stones are significantly more common among nephrolithiasis patients with type 2 diabetes, obesity, and/or metabolic syndrome. The principal metabolic feature responsible for this association is an overly acidic urine, which leads to the precipitation of sparingly soluble uric acid crystals in urine and subsequent development of stones [29]. It is hypothesized that insulin resistance impairs ammoniagenesis, thereby reducing the urine pH, resulting in a milieu favorable for uric acid crystallization.

Hypocitraturia

Hypocitraturia is defined as less than 500 mg/day in women and less than 350 mg/day in men [27]. Citrate, by forming a soluble salt with calcium, inhibits calcium stone formation. Acidemia reduces citrate excretion while alkalemia augments it. Most cases are related to the protein or acid content of the diet, but patients with hypocitraturia should be assessed for hypokalemia, diarrhea, infection, distal renal tubular acidosis, and for the use of acetazolamide.

Urine pH

Uric acid and cystine crystallization is favored by acidic urine, while calcium phosphate and struvite stone formation occurs in an alkaline urine. A persistently alkaline urine combined with hypocitraturia is highly suggestive of a distal renal tubular acidosis.

Other factors

Calcium excretion parallels sodium excretion; reducing sodium intake (and, thus, excretion) may reduce calciuria. It has also been suggested that excessive sodium intake is predictive of stone risk independently of its effects in increasing the excretion of calcium, uric acid, and oxalate [8]. Hypokalemia, by causing intracellular acidosis, can result in hypocitraturia, thereby increasing stone risk. Increased potassium excretion, on the other hand, decreases the risk of stone formation [30]. Magnesium in the urine has been shown to inhibit calcium oxalate crystallization, and enteral magnesium may reduce intestinal oxalate absorption [31]. Phosphate measurements are required to evaluate urinary supersaturation and usually are reflective of dietary intake. When evaluated in the context of serum levels of PTH, phosphate, and calcium, urinary phosphate excretion can yield information regarding disorders of the calcium–vitamin D–PTH axis. Ammonium levels are increased in urine that is infected with urease-producing bacteria, promoting struvite formation; ammonium excretion is physiologically increased in acid-loading states [32, 33]. Under conditions of impaired acid excretion (i.e., a distal renal tubular acidosis), ammonium excretion may be low.

Markers of protein excretion, such as urinary sulfate, urine urea nitrogen, and protein catabolic rate, serve as an indirect measure of acid load; the acid, which requires buffering from bone, can result in hypercalciuria [34, 35].

Finally, an initial stone risk profile assessment should include cystine screening. Cystinuria is suspected when urine concentrations are greater than 75 mg/L [36].

Effect of gender on normal ranges of urinary constituents

Women typically excrete less calcium and uric acid, and more citrate, than men, and the distribution curves that define the "normal" ranges in men and women reflect this. The normally higher levels of two important stone constituents, and normally lower levels of citrate, explain much, though not all, of the increased risk of stones in men. However, it should be remembered that the distribution of these solutes is continuous, and that a given level of solute has the same relevance to stone risk in a man or a woman. In this regard, the supersaturation ratios for each stone salt that are provided by specialty laboratories are particularly helpful.

ACKNOWLEDGMENT

The authors thank Dr. Anil Singh for valuable assistance in the preparation of this chapter.

INTRODUCTION

Kidney stone disease, or nephrolithiasis, results from urinary crystal aggregation in a protein matrix within the urinary tract. This condition reflects a deviation from the equipoise in normal human urine between stone promoters and inhibitors, in favor of promoters. In general, higher urinary pH (with the exception of struvite stones, which form in alkaline urine), higher urine volume and dilution, higher urinary citrate, and free flow of urine serve as natural stone inhibitors. Kidney stones occur about one-tenth less frequently in children than in adults, representing from 1in 1,000 to 1 in 7,600 pediatric hospital admissions in previous studies [1]. More recent analysis of the United States Kids' Inpatient Database revealed diagnoses of kidney or ureteral stones in 0.2% of hospital discharges, which would suggest an increasing prevalence in this population. In this study, girls were more likely affected than boys by a 2:1 ratio, and the fraction of those with stones increased markedly with age [2]. This differs from the adult disease, where there is a male preponderance (3:1). Within subtypes of stone disease, however, male children do have a slightly higher incidence of stones related to hypercalciuria and urinary tract abnormalities [3].

Predisposing factors for nephrolithiasis can be determined in the majority of children affected. These include metabolic abnormalities in 48–86%, urinary tract infection in 14–75%, and coexisting structural urinary tract abnormalities in 10–40%.[3–5].The recurrence rate of kidney stones in children has been reported as anywhere from 6.5% to 54% [3, 4, 6–8], and children with metabolic disorders as a cause of their stone are nearly five times more likely to have a recurrence [6]. Calcium oxalate stones are the most common found in children, with a frequency of 45–65%. These are followed by calcium phosphate (14–30%), struvite (13%), cystine(5%), uric acid (4%), and mixed (4%) stones [3, 9].

PREDISPOSING CONDITIONS

Abnormalities of the urinary tract

Anatomic abnormalities of the genitourinary tract may produce urinary stasis, allowing for crystal aggregation by heterotopic nucleation and/or infection. Most stones in North American children are located within the kidney or ureter. When recurrent bladder stones are seen, they are most often in the face of complex urologic abnormalities [10]. However, because most patients with urologic anomalies do not form stones, a full metabolic evaluation should still be performed in such children presenting with nephrolithiasis.

Infection/struvite stones

Urinary tract infections may coexist with kidney stones that arise from a metabolic origin, making it necessary

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

to rule out metabolic etiologies in such cases. Infection-related stones are more common in males, and more than one-half of children with these stones have genitourinary abnormalities [3]. Patients with surgically augmented bladders, particularly those augmented with intestinal segments, are at especially high risk for developing struvite stones in the bladder [11]. Formation of struvite stones ($Mg–NH_4–PO_4$) and calcium phosphate apatite-based stones is favored by an alkaline pH, resulting from NH4 production by urea-splitting bacteria. *Proteus* species are the most common culprit, but *Pseudomonas*, *Klebsiella*, *Steptococcus*, *Serratia*, *Staphyloococcus*, *Candida*, and *Mycoplasma*species can produce urease, too. The stones produced in this setting tend to grow rapidly, often forming staghorn calculi, a term signifying complete filling of the urinary infundibulum with stone.

Metabolic abnormalities

Hypercalciuria

Calcium oxalate and calcium phosphate stones in children are most frequently caused by hypercalciuria, defined as a urinary calcium excretion of more than 4 mg/kg/day. Patients with hypercalciuria may present with microscopic or gross hematuria, dysuria, or urgency, even in the absence of any stones. Such children often have a positive family history of kidney stones and may have up to a 17% chance of subsequently developing urolithiasis [12, 13].

Familial idiopathic hypercalciuria (FIH) is the most common subset of hypercalciuria. Although the genetic basis of this condition is unknown, it seems to be inherited in an autosomal dominant pattern with incomplete penetrance. The pathophysiology of FIH is not yet well defined but may include any combination of the following, to varying degrees: a primary kidney tubular reduction in calcium resorption, increased dietary calcium absorption in the gastrointestinal tract secondary to excessive 1,25-dihydroxy-vitamin D action, and increased bone resorption [14]. The contribution of bone resorption to this disorder has important clinical implications, because restricting calcium intake in these patients may worsen their propensity toward significant osteoporosis [15].

Causes of hypercalciuria are listed in Table 105.1, but this list is not exhaustive. Dent's disease is an X-linked recessive condition of nephrolithiasis and subsequent kidney failure, linked to mutations in the *CLCN5* gene located on chromosome Xp ll.22 [16]. This gene is responsible for the transduction of a voltage-gated chloride channel in the kidney, the lack of which leads to hypercalciuria, low molecular weight proteinuria, nephrolithiasis, nephrocalcinosis, and varying degrees of glycosuria, aminoaciduria, and phosphaturia [17]. Approximately 15% of those with the phenotype of Dent's disease, however, have a separate defect in the *OCRL1* gene. This gene is located on the X chromosome, encodes a phosphatidylinositol 4,5-bisphosphate 5-phosphatase, and is the same gene implicated in Lowe syndrome [18]. Bartter syndrome occurs with one of a series of mutations of genes coding for transporters in the thick ascending limb of the Loop of Henle. These genes include *NKCC2*, which transduces the Na–K–2Cl transporter (type I Bartter syndrome); *ROMK*, which transduces the potassium channel (type II); and *CLCNKB*, which transduces the chloride channel (type III). There is also a type IV Bartter syndrome, or Bartter syndrome with sensorineural deafness, which is caused by a mutation in the gene for barttin, a P-subunit of the chloride channel. Type V has a similar phenotype as type IV but is caused by defects in one or both of the chloride channels that colocalize with barttin: C1C-Ka and C1C-Kb. Distal renal tubular acidosis (dRTA) is a condition of metabolic acidosis, growth retardation, hypercalciuria, and nephrocalcinosis. When associated with a mutation in the *ATP6B1* gene responsible for a vacuolar H^+-ATPase, it is associated with deafness and an autosomal dominant inheritance. Familial hypomagnesemia-hypercalciuria is associated with a mutation in the *PLCN-1*gene for the tight junction protein paracellin-1. Pseudohypoaldosteronism type II is seen with mutations in WNK kinases expressed in the distal nephron and presents with hypertension, hyperkalemia, and metabolic acidosis in addition to hypercalciuria [19].

Other causes of hypercalciuria with normocalcemia include medullary sponge kidney, systemic inflammatory diseases, and iatrogenic, resulting from medications such as loop diuretics and corticosteroids. If hypercalcemia is detected, primary hyperparathyroidism, sarcoidosis, immobilization, thyroid disease, osteolytic

Table 105.1. Causes of Hypercalciuria

Associated with Hypercalcemia	Associated With Normal or Low Serum Calcium
• Primary hyperparathyroidism • Sarcoid • Idiopathic infantile hypercalcemia • Immobilization • Bartter syndrome • Thyrotoxicosis • Bone metastases • Hypervitaminosis D • Williams syndrome	• Familial idiopathic hypercalciuria • Dent's disease • Bartter syndrome • Familial hypomagnesemia-hypercalciuria • Immobilization • Prematurity, often associated with furosemide • Distal renal tubular acidosis • Ketogenic diet • Activating mutation of the extracellular calcium-sensing gene (generally with hypocalcemia) • Medullary sponge disease • Inflammatory diseases (e.g., JRA) • Corticosteroid therapy

metastases, hypervitaminosis D, and Williams syndrome should be considered on the differential [20]. Hypocalcemia with hypercalciuria may occur with activating mutations of the calcium-sensing receptor (CaSR) in the parathyroid gland and kidney, especially when vitamin D and calcium supplementation is employed to raise serum calcium levels, leading to an even further increase in calcium excretion [21].

Hypocitraturia

Hypocitraturia is a contributory cause to nephrolithiasis, because citrate is necessary for the formation of a soluble calcium salt to prevent calcium stone crystallization. Most commonly it is seen in dRTA, but it is also present in a subset of patients with FIH. Hypocitraturia can also occur in concert with other forms of hypercalciuria, hyperuricosuria, or hyperoxaluria. Chronic diarrhea, a high-protein diet, and hypokalemia can also induce low urinary citrate levels and a predisposition to stone formation [22], because citrate absorption in the proximal tubule is stimulated by intracellular acidosis and potassium depletion [23].

Hyperoxaluria

Oxalate is a metabolic product made in the liver and excreted by the kidney, but can also be ingested and absorbed, or be formed, from dietary sources. Type 1 primary hyperoxaluria (PH1) is an autosomal recessive disease in which there is a reduction in, or absence of, alanine glyoxylate aminotransferase-1 (AGT1) activity, leading to increased conversion of glyoxylate to oxalate. Excessive urinary oxalate excretion may lead to crystallization and deposition in the urinary tract and kidney parenchyma. This in turn can result in kidney failure and systemic oxalosis, a clinical situation in which calcium oxalate precipitates in multiple organs and joints. Disease severity in PH1 varies widely. The course may be mild and fully responsive to medical therapy such as vitamin B_6 (pyridoxine) or may present aggressively in infancy with rapid kidney failure and severe systemic manifestations.

Because AGT is predominantly expressed in the liver, diagnosis has in the past relied solely on liver biopsy to assess the presence and activity of AGT. The gene encoding AGT (*AGXT*), located on chromosome 2q37.3, to date has over 100 mutations that have been described that either eliminate, or decrease substantially, enzyme activity [24, 25].The relative ease in modern laboratory medicine at performance of sequence analysis, and the delineation of the molecular basis of many of the mutations behind PH1, has led to the proposal of molecular diagnostic algorithms that may obviate the need for invasive biopsy procedures. Monico et al. [24] have reported comprehensive mutation screening across the entire AGXT coding region in 55 probands with PH1, showing a 96–98% sensitivity in this population. When limited to sequencing of exons 1, 4, and 7, the sensitivity was 77%. Given the relatively small size of the gene, complete molecular analysis should not involve prohibitive expense. An algorithm beginning with limited sequencing of exons 1, 4, and 7, followed by direct sequencing of the entire gene if inconclusive, would make intuitive sense and would eliminate the need for liver biopsy in most patients.

Type 2 primary hyperoxaluria (PH2) results from a deficiency of activity in the enzyme glyoxylatereductase/hydroxypyruvatereductase (GRHPR), which is more widely distributed in the human than AGTl, with a predominance in muscle, liver, and kidney. As a group, patients with PH2 seem to have less morbidity and mortality than those with PHI, with a lower incidence of end-stage kidney disease (ESKD) and an older age at onset of symptoms [26, 27].

A third group of patients has been described who present with calcium oxalate renal stone disease in early childhood and a phenotype similar to PH1 or PH2, but with normal enzymatic activity of AGT and GRHPR, and no signs or symptoms of enteric hyperoxaluria (see below). These patients have been referred to as non-PH1/PH2 patients, and represent about 5% of all cases of PH. In a series of elegant experiments, investigators have recently identified a common genetic locus in affected families and a likely candidate gene, *DHDPSL*, with an expression pattern in liver and kidney cells. Experiments are ongoing to prove the assumption that this gene encodes the enzyme 4-hydroxy-2-oxoglutarate aldolase, activating mutations of which would lead to excessive production ofglyoxolate, and therefore downstream enhanced oxalate as well. It is now proposed that patients with this form of PH caused by this mutation be classified as primary hyperoxaluria type 3 (PH3) [28].

Unfortunately, up to one-third of patients with PH in some case series present at end stage, when uremia develops [29, 30]. For this reason, PH should be considered in patients with recurrent calcium oxalate nephrolithiasis, unexplained nephrocalcinosis, or unexplained ESKD in which the kidneys are echodense with calcium.

Secondary (enteric) hyperoxaluria can result from increased oxalate absorption in the colon caused by small bowel malabsorption of fatty and bile acids. These substances increase colonic permeability to oxalate by binding luminal calcium, freeing unbound oxalate to be absorbed. Epithelial damage in these states also increases colonic absorption, and low dietary calcium intake can exacerbate the condition. There has been more recent interest in enteric hyperoxaluria in the population undergoing bariatric surgery, where nearly 50% of patients may develop hyperoxaluria early in the postoperative period, and stone disease occurs [31]. Depletion of *Oxalobacter formigenes*, an enteric oxalate-degrading bacterium, has also been postulated to contribute to enteric hyperoxaluria, but human data remain inconclusive to date. Other rare secondary causes are pyridoxine deficiency (a cofactor for AGT activity) and excessive intake of oxalate-containing foods(rhubarb gluttony) or oxalate precursors (ascorbic acid, ethyleneglycol).

Hyperuricosuria

Uric acid is the end product of purine metabolism. Hyperuricosuria may occur either in the face of uric acid overproduction or with normal serum uric acid concentrations and can predispose to both uric acid stones and calciumoxalate nephrolithiasis, acting as a heterotopic nucleation factor [32]. Lesch-Nyhan syndrome (complete deficiency of hypoxanthine-guanine phosphoribosyltransferase) and type 1 glycogen storage disease (glucose-6-phosphatase deficiency) are both inborn errors of metabolism that may present with hyperuricemia and hyperuricosuria/urolithiasis [33]. Gout caused by a partial hypoxanthine-guanine phosphoribosyltransferase deficiency can cause uric acid nephrolithiasis in older children. Myeloproliferative disorders and other causes of cell breakdown are other secondary causes of uric acid stones. Ketogenic diets, excessive protein intake, and uricosuric drugs such as high-dose aspirin, probenecid, and ascorbic acid can also cause hyperuricosuria. Normal or low serum uric acid levels may be associated with uricosuria secondary to proximal renal tubular defects. These may be caused by a single defect in the renal urate exchanger URAT1 [34] or disorders of generalized proximal tubule dysfunction. Insulin resistance, as seen in type 2 diabetes mellitus and metabolic syndrome, may also predispose to uric acid stones and an overly acidic urine by decreasing renal ammonia excretion and impairing hydrogen ion buffering [35]. In another perturbation of uric acid metabolism, xanthine stones are formed in an autosoma1 recessive disorder of the gene for xanthine dehydrogenase, whereby uric acid cannot be formed from xanthine precursors.

Cystinuria

Cystinuria is an autosomal recessive disease of disordered dibasic amino acid transport in kidney and may occasionally be diagnosed by the discovery of flat hexagonally shaped cystine crystals in the urine. Children with this condition have elevated urinary cystine, ornithine, arginine, and lysine levels, because all of these amino acids share common dibasic amino acid transporters. Mutations of the *SLC3A1* gene on chromosome 2 and the *SLC7A9* gene on chromosome 19 have been identified [36, 37], and patients may be either homozygous or compound or obligate heterozygotes [38]. Affected homozygous children usually excrete more than 1,000 umol/g creatinine of cystine by the age of 1 year, with a mean excretion of 4,500 umol/g creatinine, exceeding its solubility and leading to lifelong recurrent nephrolithiasis [10].

Melamine poisoning

Melamine is a synthetic chemical used in a variety of commercial products. It has a high non-protein nitrogen content, and when added to milk or animal feed, can falsely elevate their apparent protein content. Melamine nephrotoxicity was brought to international attention in 2008 after reports of nephrolithiasis among Chinese infants who drank milk-based formula contaminated with high levels of melamine, used in an effort to demonstrate a high protein content in the formula without the actual need for milk-based products. The chemical is rapidly excreted in urine and can precipitate in distal tubules. It forms an especially insoluble structure when it complexes with another common commercial chemical, cyanuric acid, in a lower urinary pH. Melamine calculi are radiolucent, best assessed by ultrasound, and may involve the kidney pelvis and /or ureters bilaterally, causing obstruction. Treatment is hydration, urinary alkalinization, pain management, and renal replacement therapy and/or surgical therapy if needed [39]. Screening of asymptomatic, possibly exposed Chinese infants now residing in other areas of the world is not universally recommended, as most stones found in such children have passed easily with hydration [40].

Other causes of kidney stones

Additional clinical situations in which patients are predisposed to forming kidney stones include patients with cystic fibrosis, who may have multiple risk factors, including an absence of the oxalate-degrading bacterium, *O. formigenes*, hyperoxaluria, hypercalciuria, and/or hypocitraturia. Patients taking protease inhibitors for HIV, especially the poorly soluble indinavir, may have urinary excretion of crystallized drug product. Patients on a ketogenic diet for seizure control are predisposed to hypercalciuria and/or hypocitraturia associated with the chronic metabolic acidosis.

CLINICAL EVALUATION

The clinical presentation of urinary tract stones in children may differ from that in adults. Less than 50% of young children with nephrolithiasis will present with abdominal, flank, or pelvic pain as seen in older children, adolescents, and adults with urinary tract stones. Gross or microscopic hematuria (occurring in 33–90% of affected children), dysuria, frequency, emesis, and urinary tract infections are additional common presenting signs in younger patients. A detailed history and physical should guide evaluation of kidney stones. Family history should focus on members with kidney stones (positive in greater than one-third of affected children), gout, arthritis, or chronic kidney disease [3]. The presence of a concomitant urinary tract infection must be sought but should not be accepted as the cause of the stone. Patients should also be advised to submit any passed stones or stone fragments for analysis by polarization microscopy or X-ray diffraction but not by simple chemical analysis.

Useful imaging studies may include plain abdominal radiology, ultrasonography, and helical computed tomog-

raphy (CT). Conventional abdominal radiographs may show only radiopaque but not radiolucent stones, whereas ultrasound of the urinary tract may show both radiolucent and radiopaque stones, in addition to the presence of urinary obstruction or nephrocalcinosis. Ultrasound has largely taken the place of intravenous pyelography (IVP) as an initial study for stone presence, secondary to concerns about radiation and contrast exposure with the latter procedure. Non-contrast helical CT has been found to have high sensitivity and specificity in identifying even small stones without requiring intravenous contrast administration. It may precisely localize stones, detect obstruction and hydronephrosis, and is much more sensitive than the previously mentioned imaging modalities [41].

Because the majority of children with stones may have a metabolic problem that is discoverable and generally amenable to therapy, diagnostic urinary and blood tests for stone evaluation should be obtained while the patient is on their routine activity schedule and diet. At least two 24-hour urine collections should be performed, waiting at least 2 weeks after any acute stone event. This time frame allows for the resumption of the child's normal intake of food and fluids after recovery from pain and/or surgical intervention, which is critical for correct assignment of metabolic disturbances. These collections can assess urinary volume as a reflection of fluid intake and creatinine excretion for completeness of the 24-hour collection (at least 10–15 mg/kg/day in children older than 2 years of age; 6–9 mg/kg/day in children younger than 2 years of age) and measurement of levels of lithogenic substances such as calcium, oxalate, uric acid, and cystine. The collections can evaluate for decreased stone inhibitor levels as well, such as citrate and magnesium. Normal values of these substances are shown in Table 105.2. Serum levels of uric acid, potassium, calcium, phosphorus, creatinine, bicarbonate (total CO), and bio-intact parathyroid hormone (PTH) (if hypercalcemia is present) should be obtained as well at the end of the urinary collections.

Consultation with an expert in pediatric stone disorders is encouraged if questions arise about the results of these diagnostic studies.

Table 105.2. Normative Data for Urinary Solute Excretion*

Substance	Reference Range
Calcium	≤3.5 mg/kg/day
Citrate	>400 mg/g creatinine (spot citrate/Cr ratio >0.51 g/g)
Oxalate	≤0.5 mmol/1.73 m^2/day (<40 mg/1.73 m^2/day)
Uric Acid	Varies with age, up to 815 mg/1.73 m^2/day
Cystine	<60 mg/1.73 m^2/day

*Refs. 14, 63.

SURGICAL MANAGEMENT

The goals of the management of patients with kidney stones are to remove existing stones and prevent stone recurrence, with preservation of kidney function. Pediatric patients usually pass ureteral stones up to 5 mm in size [6]. In the absence of infection or persistent pain, such stones can be safely observed for up to 6 weeks. Larger stones and kidney-located stones, however, require the consideration of surgical intervention, with a goal of achieving and maintaining a stone-free state. The choice of surgical modality depends on stone composition, size, and location along the urinary tract. Shock wave lithotripsy (SWL) uses the generation and focusing of shock wave energy toward the stone. Pulverized fragments are subsequently passed, and multiple treatment sessions are sometimes required. One large pediatric series (n = 344) showed a 92% stone-free rate for renal pelvis stones smaller than 1 cm, a 68% rate for stones 1–2 cm, and a 50% rate for stones larger than 2 cm. Calyceal stone clearance rates were lower [42]. Overall, stone-free rates in children treated using this procedure have ranged from 67% to 99% in various studies [43], with the highest success rates appearing to be in the youngest children [44]. This procedure seems to be safe in young children and infants, with no evidence of long-term changes in glomerular filtration rate or in functional renal parenchymal scarring before and after treatment in the affected kidney [45, 46]. Minor complications such as bruising, renal colic, and hematuria may occur with SWL treatment. Small children may require the use of lung shielding to prevent pulmonary contusion, as well as reduced power settings to avoid injury. Ureteral stenting may also be required for larger stone burdens. In general, large stone burden (greater than 2 cm) and anatomic abnormalities are risk factors for unsuccessful SWL, and alternative urological approaches should be considered in these cases [43]. Struvite, calcium oxalate dehydrate, and uric acid stones are especially amenable to fragmentation with SWL, whereas cystine, brushite, and calcium oxalate monohydrate stones are all resistant to SWL treatment [47].

Percutaneous nephrolithotomy (PNL) is an alternative procedure that may be used alone or in conjunction with SWL in patients with large stone burden, significant renal obstruction, and/or staghorn calculi. It is also commonly used to remove lower pole calculi smaller than 1 cm in size. Percutaneous access to the collecting system of the kidney is achieved, and a wire is advanced to dilate the tract to accommodate a nephroscope.

Stones may be removed or pulverized under direct visualization, making this approach ideal for complex upper tract stones. A nephrostomy tube is often placed postoperatively, although a small series in adults did show a decrease in pain and recovery time, with no increase in complications, with the use of smaller or no nephrostomy tubes [48]. The development of smaller nephroscopes has made PNL available for children, with stone-free rates ranging from 83% to 98% [43].

Table 105.3. Surgical Treatment Options by Stone Size and Location

Location/Size	Shock Wave Lithotripsy	Ureteroscopy	Percutaneous Nephrolithotomy
Renal			
<1 cm	Most common	Optional	Optional
1–2 cm	Most common	Optional	Optional
>2 cm	Optional	Rare	Most common
Lower Pole			
<1 cm	Most common	Optional	Optional
>1 cm	Optional	Optional	Most common
Ureteral			
Proximal	Most common	Optional	Occasional
Distal	Optional	Most Common	Rare

From Durkee CT, Balcom A. 2006. Surgical management of urolithiasis. *Pediatr Clin N Am* 53: 465–477. Used with permission.

Ureteroscopy is most ideally used for the removal and/or fragmentation of distal ureteral stones. Whereas SWL has good efficacy for some smaller ureteral stones, stone-free rates in those with stones larger than 10 mm in size have been found to be markedly higher with ureteroscopy (93%) than with SWL (50%) [49]. Smaller rigid and flexible ureteroscopes have made this procedure an option for pediatric patients and have made the need for concomitant ureteral balloon dilation (and possible risks of stricture and vesicoureteral reflux) less frequent. Once the ureteroscope is passed, laser energy is used to fragment any visualized stones, and flexible wire baskets can be used to remove fragments. Postoperative stenting may be used to facilitate passage of residual fragments or to prevent ureteral obstruction in the face of edema caused by trauma to the ureteral wall. Stenting is not usually done in uncomplicated procedures, with easy passage of the scope [50]. A summary of surgical treatment options by stone size and location is shown in Table 105.3.

MEDICAL MANAGEMENT

Nonspecific management of urolithiasis includes an increase in fluid intake to increase urinary volume, urinary dilution, and inducing stone particle motion through the urinary tract. Other specific measures depend on the underlying predisposing diagnosis.

Hypercalciuria may be treated with a low sodium diet, thiazide diuretics, and adequate potassium intake. Thiazide therapy (e.g., hydrochlorothiazide 1 mg/kg/day, maximum of 25 mg/day) in FIH significantly decreases urinary calcium excretion and rate of stone formation in adults [51]. A decrease in urinary calcium excretion with thiazide treatment in children with FIH has also been shown [52]. In a population with hypercalciuria from immobilization, 18 of 42 children were found to be hypercalciuric, with a higher rate of fractures [53]. A 3-week course of hydrochlorothiazide and amiloride reduced the mean urinary calcium to creatinine ratio by 57.7%. Dietary calcium intake should not be limited. Citrate therapy (e.g., potassium citrate 2 mmol/kg once daily) is also appropriate in cases of documented hypocitraturia.

Another important issue for some patients is that of bone mineral density (BMD) in FIH. One study of 40 girls with FIH and their premenopausal mothers showed that BMD lumbar spine Z-scores were significantly lower in these patients compared with controls [54].Others have shown that thiazide treatment, in addition to decreasing urinary calcium excretion, can also improve BMD scores in children. Average Z-score improved from –1.3 to –0.22 over 1 year of treatment with hydrochlorothiazide and potassium citrate in one study of 18 children [52].

The treatment of struvite stones rests on the eradication of stones, correction of any urinary obstruction, and treatment/ prevention of urinary tract infections. Urinary acidification could theoretically be used to prevent crystallization, but evidence for such an approach is thus far lacking. The urease inhibitor acetohydroxaminic acid (AHA) may have some clinical use [55], but its use is limited by a high incidence of neurologic and gastrointestinal side effects.

Hyperuricosuria may be treated with dietary sodium limitation, oral bicarbonate or citrate supplementation, or addition of allopurinol or newer agents (rasburicase) if increased uric acid production and hyperuricemia are present.

Patients with suspected primary hyperoxaluria should be given a therapeutic course of vitamin B_6 (pyridoxine), and urinary oxalate levels should be used to monitor success or to suggest the need for dose escalation. Orally administered *Oxalobacter formigenes*, an anaerobic bacterium that degrades oxalate, had been found to reduce

urine and plasma oxalate levels in PH patients in a small open-label study [56]. However, a randomized controlled trial of 43 subjects with PH and good kidney function was unable to demonstrate any significant difference in urinary oxalate reduction between subjects who received experimental therapy or a placebo, although the *O. formigenes* treatment was safe and well tolerated [57].

For patients with reduced kidney function, intensive dialysis followed by liver/kidney transplant can be curative, because a new liver replaces the enzymatic defect in PH-l [58, 59]. Pretransplant hemodialysis for five to six times per week, and perhaps with additional nightly peritoneal dialysis, is needed to lessen the systemic oxalate burden and prevent recurrence of disease in the transplant kidney. Prompt referral to a pediatric center with expertise in this disorder is warranted.

Secondary hyperoxaluria that results from enteric hyperoxaluria may be treated with a low-sodium/low-fat diet, high fluid intake, and a dietary calcium intake at the upper end of the daily recommended intake. Limitation of oxalate-containing foods such as chocolate, rhubarb, nuts, and spinach should be advised, as well as possible supplementation with magnesium, phosphorus, and citrate salts.

Cystinuria is treated with fluids (minimum of 3 liters/1.73m2/day) and provision of alkali salts, such as citrate. Low sodium intake can also decrease urinary excretion of cystine. Chelating agents such as D-penicillamine, or more recently, a-mercaptopropionylglycine (tiopronin or Thiola; Mission Pharmacal, San Antonio, TX, USA) may also be prescribed by someone skilled in pediatric stone disease. D-penicillamine may cause a severe serum sickness-like reaction, so its use is not advised, but side effects are less severe with Thiola [22]. Angiotensin-converting enzyme (ACE) inhibition with captopril therapy has been found beneficial in some patients with cystinuria (captopril-cystine complexes are 200 times more soluble than cystine alone) resistant to alkalinization and fluid therapy alone, and perhaps with less bothersome side effects [60]. Captopril, however, is not as effective as thiolcompound therapy.

PROGNOSIS

Estimates of the recurrence rate of urolithiasis in children have ranged from 16% to 67% [3, 33]. Patients with residual fragments after treatment are at risk for symptomatic growth of those fragments [61], and the existence of metabolic disorders is a strong predictor of this growth in children [62]. Additionally, prognosis for nephrolithiasis depends on the type of stones and adherence to therapy. Cystine stones have a high recurrence rate, and obstruction may impair kidney function. Primary hyperoxaluria type I is a progressive disease, often leading to progressive loss of kidney function even with optimal compliance to medical therapy, unless pyridoxine responsiveness is established. Kidney stones from hyperuricosuria may continue to occur with or without symptoms, despite treatment. Therefore, pediatric patients with stone disease should be referred to a subspecialist for appropriate diagnosis, treatment, and long-term nephrology follow-up.

INTRODUCTION

Renal stones form in urine that is supersaturated with respect to the salt of which the stone is composed. Crystallization can be induced at low levels of supersaturation if there are promoters of crystallization in the urine, whereas urinary inhibitors oppose crystallization. Medical treatment of nephrolithiasis works by lowering urine saturation of the stone forming salt, reducing promoters of crystallization, and/or increasing inhibitors of crystallization. Optimal treatment is based on the type of stone and the lithogenic risk factors identified in 24-hour urine chemistries. Treatment may consist of diet, medication, or a combination of both.

Before a discussion of medical therapy, consideration must be given to the goals of treatment. The aim of treatment is to prevent new stone formation and reduce the rate of growth of any existing stones. Radiologic evaluation is a critical component of any treatment regimen. A knowledge of the number and location of all stones at the time treatment is initiated is required to monitor the success of therapy. If a patient develops renal colic and the stone passing is clearly a new stone, then medical therapy has not been successful; the cause of the failure should be studied and the treatment regimen reevaluated. Not only is the knowledge of old versus new stone important for the physician, but also for the patient. Patients who pass a stone despite following the prescribed therapy will become discouraged and stop therapy unless they understand that the stone that passed was present all along. Serial radiologic evaluation (every 1 to 2 years) is also needed to insure that new asymptomatic stones are not forming during treatment.

High fluid intake is the foundation of all medical regimens for renal stone prevention. By keeping urine dilute, urine saturation of all stone forming salts is lowered. Although high fluid intake has long been considered the standard of care, Borghi et al. have performed the only prospective randomized study of high fluid intake for stone prevention [1]. Over the 5 years of follow-up, a 55% reduction of stone recurrence in the group treated with high fluid intake compared to the control group was observed. The high fluid group had an average 24-hour urine volume of 2.5 liters, which provides a reasonable therapeutic goal for patients.

CALCIUM STONES

There are four abnormalities of urine chemistries known to cause calcium oxalate kidney stones: hypercalciuria, hyperoxaluria, hypocitraturia and hyperuricosuria. Therapy is directed against whichever abnormality the patient has.

Hypercalciuria

In the past, low-calcium diets had often been prescribed for calcium stone formers. Although dietary calcium

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

restriction clearly lowers urine calcium, it has never been shown to reduce stone formation in a prospective controlled trial. In addition, the long-term safety of a low-calcium diet has been questioned because hypercalciuria has been associated with reduced bone mineral density (BMD) and increased risk of fractures [2, 3]. However, other dietary interventions can be used to lower urine calcium. Both high-sodium and high-protein diets increase urine calcium excretion, so restriction of these dietary components seems a reasonable intervention. Borghi et al. tested the efficacy of a normal calcium (1,200 mg/day), low-sodium, low-protein intake diet compared with the classic low-calcium diet (400 mg/day) in 120 men with recurrent kidney stones [4]. Stone recurrence was reduced by 48% in the group treated with the low-sodium, low-protein diet compared with the low-calcium diet. Although this study does not answer the question of whether low-calcium diets reduce stone formation, it does show there is an alternative diet therapy that is more efficacious and likely better for general health.

For patients with frequent stones or whose stone disease persists despite dietary intervention, thiazide diuretics should be used to lower urine calcium. There are three prospective, placebo-controlled, 3-year trials of thiazide type diuretics, all of which show a significant reduction in stone formation in patients with recurrent kidney stones [5–7]. There has not been a comparison between the various thiazides to determine if one has a greater degree of anti-hypercalciuric effect than the others. Diet sodium restriction should be continued when thiazides are used, because excess salt in the diet will reduce the effectiveness of a thiazide. Thiazides cause potassium wasting; therefore, serum potassium should be monitored because hypokalemia can lead to hypocitraturia, creating a new risk factor for stone formation [8]. Thiazides also have an additional benefit in this population because they improve calcium balance and prevent osteopenia in hypercalciuric stone formers [9, 10].

Hyperoxaluria

Oxalate excreted in the urine is derived from both intestinal absorption of oxalate in the diet and from endogenous production of oxalate [11]. Oxalate is an end product of human metabolism; whatever oxalate is absorbed or produced by the body must be excreted by the kidneys. Because a significant portion of urine oxalate is derived from diet, low-oxalate diets are recommended for all hyperoxaluric stone patients, although the efficacy of a low-oxalate diet in preventing stone formation has not been studied. General guidelines for low-oxalate diets are available on the Internet [12]. Other dietary advice focuses on foods that have a secondary effect on oxalate excretion. Low-calcium diets can increase urine oxalate excretion because low calcium concentration in the intestinal lumen leaves more oxalate in the unbound state to be absorbed [11]. The magnitude of this effect in clinical practice is uncertain but it seems prudent to have patients on a diet with 1,000 to 1,200 mg of calcium per day. Endogenous production of oxalate may be increased by an increased intake of oxalate precursors. A number of amino acids can be metabolized to oxalate, so it is not surprising that high-protein diets have been shown to increase urine oxalate excretion in some patients with hyperoxaluria [13]. A recent study showed a 1,200-mg calcium, low-animal-protein, low-sodium diet reduced urine oxalate excretion by 30% in patients with mild hyperoxaluria [14]. Vitamin C can also be metabolized to oxalate, so stone patients should avoid high doses of vitamin C supplements [15].

There are no FDA-approved medications for hyperoxaluria at this time. Pyridoxine has been reported to lower urine oxalate in some patients with idiopathic hyperoxaluria, but there are no controlled trials showing that pyridoxine reduces stone formation in such patients [16]. Magnesium has been proposed as a therapy for stone disease because it may lower urine oxalate by complexing oxalate in the intestine and act as a crystal inhibitor in the urine. There has been only one controlled trial of magnesium supplements in calcium stone disease, and it did not show a benefit to therapy [7]. Currently under study is the use of oxalate degrading bacteria as probiotics [17, 18]. These agents would act by lowering intestinal oxalate concentration, limiting absorption and perhaps even increasing intestinal secretion of oxalate. However, further studies need to be done to prove their efficacy in humans with hyperoxaluric stone disease [19].

Enteric hyperoxaluria and primary hyperoxaluria can lead to severe hyperoxaluria and cause kidney failure in addition to stone disease. Enteric hyperoxaluria can be seen in patients with extensive small bowel disease or bowel resection. Recently, it has been shown that modern bariatric surgery can also cause enteric hyperoxaluria [20]. To lower urine oxalate, low-oxalate diets are prescribed, and calcium supplements are provided with meals to bind oxalate in the diet [21]. Calcium citrate is preferred over calcium carbonate as many bariatric procedures alter stomach anatomy, and there may not be sufficient acid exposure to dissolve calcium carbonate. If fat malabsorption is present, a low-fat diet should be recommended; cholestyramine may also lower oxalate absorption in patients with steatorrhea. Primary hyperoxaluria (PH) is a rare genetic form of hyperoxaluria. In PH type 1 (OMIM 259900), about 30% of patients will have a significant reduction in oxalate excretion with pyridoxine therapy [22]. If oxalate excretion cannot be lowered with pyridoxine, then patients should be treated with neutral phosphate salts and/or potassium citrate as well as high fluid intake [23, 24]. PH type 2 (OMIM 260000) does not respond to pyridoxine therapy but otherwise is treated the same as PH type 1. Recently, PH type 3 (OMIM 613616) was identified and found to be caused by mutations in the gene encoding 4-hydroxy-2-oxoglutarate aldolase [25]. Although no treatment trials for this specific form of PH have been performed, that the enzyme of interest is in the pathway of hydroxyproline metabolism suggests that lowering hydroxyproline, a known precursor of oxalate, may be of benefit.

Hypocitraturia

Citrate is a normal constituent of human urine that prevents calcium stone formation by forming a soluble complex with calcium, thereby reducing the free calcium ion concentration in the urine. Hypocitraturia may be seen with acidemic states such as renal tubular acidosis, hypokalemia, or it may be idiopathic in origin [8]. Urine citrate excretion is highly dependent on systemic acid–base status, increasing with alkali loading. Reducing dietary animal protein and increasing consumption of fruits and vegetables will increase urine citrate excretion [26], but dietary intervention is usually not sufficient to correct significant hypocitraturia. Some authorities have proposed using lemonade as a treatment for hypocitraturia because of the high citric acid content of lemon juice [27]. However, significant increases in urine citrate have not been found in all studies [28].

The standard treatment for hypocitraturia is alkali supplementation. Alkali may be provided as either citrate or bicarbonate, but citrate is most commonly used. Citrate is usually provided as potassium citrate, because sodium salts can increase urine calcium excretion. If the patient cannot tolerate a potassium load, then sodium alkali can be used, although dietary sodium restriction should be encouraged to minimize the increase in urine calcium. There have been two randomized placebo-controlled trials of citrate salts in the treatment of calcium stone disease, one with potassium citrate and the other using potassium–magnesium citrate [29, 30]. Both showed significant reductions in stone recurrence rates in the group receiving the active drug. Potassium citrate also reduced stone recurrence and growth of residual stone fragments in patients who had undergone extracorporeal lithotripsy [31]. In addition to the increase in citrate, alkali salts can also cause a mild reduction in the urine calcium excretion by buffering daily metabolic acid production. In fact, long-term treatment of calcium stone formers with citrate salts has been shown to increase BMD as well, presumably from the favorable effects on urine calcium excretion and calcium balance [32]. One potential adverse consequence of alkali therapy is an increase in urine pH, which, in patients with elevated urine calcium, can increase the risk of calcium phosphate stone formation. Such patients should have urine calcium controlled by the addition of a thiazide diuretic.

Drugs that inhibit carbonic anhydrase cause renal tubular acidosis and increase the risk of kidney stones. Topiramate inhibits carbonic anhydrase and is being increasingly used as a treatment for seizures and migraine headache. Use of topiramate has been associated with nephrolithiasis, and metabolic evaluation shows the expected alkaline urine and hypocitraturia [33]. To prevent continued stone formation, replacing topiramate with an alternative therapy is recommended. If topiramate cannot be discontinued, alkali therapy is recommended, although no trials have shown that alkali reduces stone formation.

Hyperuricosuria

Uric acid is an end product of purine metabolism, produced by the oxidation of xanthine via the enzyme xanthine oxidase. Hyperuricosuria promotes calcium oxalate crystallization in the urine by a salting out phenomenon [34]. Hyperuricosuria is most commonly due to diets high in purines, although some patients may have a metabolic defect that leads to overproduction of uric acid [35]. A low purine diet is a reasonable therapy for patients with hyperuricosuria, although its effectiveness in preventing stone formation has not been tested. Allopurinol, a xanthine oxidase inhibitor, has been shown to reduce stone formation in calcium oxalate stone formers with hyperuricosuria in a randomized prospective trial [36]. It has not been shown to be effective in treatment of patients without hyperuricosuria.

URIC ACID STONES

Three factors contribute to uric acid stone formation: urine flow rate, uric acid excretion rate, and urine pH [37]. Low urine pH (less than 5.8 in a 24-hour urine collection) is the most common abnormality found in uric acid stone formers [38]. Uric acid stones seldom form without a low urine pH, unless the patient has marked overproduction of uric acid from a metabolic defect. Overly acidic urine may be seen in patients with high intake of animal protein, chronic diarrheal states, chronic kidney disease, or in metabolic syndrome [39]. There are no prospective placebo-controlled trials for prevention of uric acid stones, nor are there likely to be, because increasing urine pH with alkali therapy is universally regarded as effective. Alkali at an initial dose of 40 to 60 meq per day in two or three divided doses, will be sufficient for most patients. The desired end point is an average 24-hour urine pH of 6.0 to 6.5. Excessive alkalinization does not offer additional protection from uric acid stone formation, but it will increase the risk of calcium phosphate stone formation. Low-purine diets will help lower uric acid excretion, and by also lowering animal protein intake, will decrease metabolic acid production. Allopurinol can be used for uric acid stones if the patient also has gout, very high levels of uric acid excretion, or if the patient cannot tolerate sufficient alkali to raise urine pH above 6.0. Generally, allopurinol is considered a second line therapy for uric acid stones.

CYSTINE STONES

Cystine is an amino acid formed by the linkage of two cysteine molecules via a disulfide bond. It is poorly soluble in urine, and patients with cystinuria (OMIM 220100) can develop severe, recurrent stone disease.

Therapy to reduce stone formation is focused on lowering cystine concentration in the urine or increasing urine cystine solubility. Patients with cystinuria are instructed to increase fluid intake and maintain a high urine flow rate in order to keep urine cystine concentration below 250 mg/l; most patients need to produce at least 3 liters of urine per day. The patient should awaken at least once per night to void and drink additional water. Dietary sodium and protein restriction lower urine cystine excretion moderately and should be encouraged in all patients [40, 41].

There are two treatment options to improve cystine solubility. Solubility increases as urine pH increases, although the effect is not significant until urine pH is above 7 [42]. Since the desired pH is higher than for other forms of stone disease, it may require larger doses of alkali, although the individual response is highly variable. Potassium alkali is preferred because of the undesirable effect of high sodium intake on urine cystine excretion, although sodium salts should be used if the patient is not able to excrete a high potassium load. The other way to increase solubility of cystine is to form a new disulfide complex that is more soluble than cystine itself. Tiopronin and d-penicillamine contain thiol groups and will undergo a disulfide exchange, leading to the formation of a drug-cysteine complex that is much more soluble than cystine. These medications have been shown to reduce cystine saturation in cystine stone formers [43]. Due to the high frequency of side effects [44], thiol-containing drugs are usually reserved for patients with a very high level of cystine excretion or those who continue to form stones despite dietary and alkali therapy. Captopril, an angiotensin-converting enzyme inhibitor, contains a thiol group and has been suggested as therapy for cystinuria. However, at the doses used, it is unlikely to complex sufficient cystine to alter stone risk, and studies conflict regarding the effectiveness of captopril [45, 46].

STRUVITE STONES

Struvite (magnesium–ammonium–phosphate) stones require elevated urine pH and high ammonium concentration to form. In normal human physiology, urine ammonium excretion falls when urine pH rises above 7; the only time human urine displays high pH and high ammonium is when there is infection with a urease-containing organism such as *P. mirabilis*. Struvite forms large staghorn stones that can lead to loss of renal function. Treatment requires a combined medical and surgical approach. The best outcomes require complete removal of all stone material because the stone itself often harbors the offending bacteria, and if stone is left in the urinary system, infection and stones will recur. Extracorporeal shock wave lithotripsy and percutaneous nephrolithotomy may be used alone or in combination in order to remove all stone material [47]. Stones should be cultured to guide the choice of antibiotics. Antibiotics should be employed to sterilize the urinary system. In patients who are not surgical candidates or in whom stones continue to recur, the urease inhibitor acetohydroxamic acid (AHA) may be considered. Although AHA will not eradicate infection, it does prevent the breakdown of urea and the change in the urinary environment that leads to struvite stone formation. There are three placebo-controlled trials that prove the effectiveness of AHA, but the significant number of side effects such as headache, tremulousness, and possibly deep venous thrombosis limit its utilization [48–50].

INTRODUCTION

Renal stones affect approximately 8% of the population by the seventh decade and are usually associated with a metabolic abnormality that may include hypercalciuria, hyperphosphaturia, hyperoxaluria, hypocitraturia, hyperuricosuria, cystinuria, a low urinary volume and a defect of urinary acidification [1–3]. The etiology of these metabolic abnormalities and of renal stones is multifactorial and involves interactions between environmental and genetic determinants [4–6]. The environmental determinants include dietary intake of salt, protein, calcium and other nutrients, fluid intake, urinary tract infections, socioeconomic status of the individual, lifestyle, and climate [7, 8]. This chapter will focus on the genetics of renal stones (Table 107.1) and in particular those associated with hypercalciuric renal stone disease (nephrolithiasis) in man.

GENETICS

The greatest risk factor for nephrolithiasis, after controlling for known dietary determinants, is having an affected family member [9]. Thus, between 35% and 65% of renal stone formers will have relatives with nephrolithiasis, whereas only 5–20% of nonrenal stone formers will have relatives with nephrolithiasis [9–11]. The first degree relative risk (λ_R) among recurrent stone formers has been estimated to be in the range of 2 to 16 [9, 12, 13]. The wide range of these estimates is largely due to differences in the study designs and the methods used to ascertain the occurrence of renal stones in relatives. Moreover, genetic contributions to nephrolithiasis and hypercalciuria have been confirmed by two studies that have investigated the occurrence of these conditions in twins and shown that the heritability (h^2) of kidney stones and urinary calcium excretion are 56% and 52%, respectively [14, 15]. Both of these studies support the notion that there is a strong genetic contribution to renal stone disease and in the regulation of renal calcium excretion. Progress in the identification of the responsible genes by linkage studies utilizing affected sibling pairs or small families in genome-wide searches has been slow because of the lack of availability of appropriate patients and their relatives, and also because of difficulties in correctly ascertaining the phenotype, which may require radiological investigations and 24-hour urine collections. However, investigation of some families with monogenic forms of hypercalciuric nephrolithiasis and a genome-wide association study in families from Iceland and the Netherlands have yielded insights into the renal tubular mechanisms regulating calcium excretion [16, 17]; these will be briefly reviewed.

MONOGENIC FORMS OF HYPERCALCIURIC NEPHROLITHIASIS

Idiopathic hypercalciuria

Families with idiopathic hypercalciuria (IH) and recurrent calcium oxalate stones usually reveal an autosomal dominant mode of inheritance [18]. Studies of such families have established linkage between hypercalciuric nephrolithiasis and loci on chromosome 1q23.3-q24 [19], which contains the human soluble adenylyl cyclase (*SAC*) gene [20]; chromosome 12q12-q14, which contains the vitamin D receptor (*VDR*) gene; and chromosome 9q33.2-q34.2 [21], from which an appropriate candidate gene remains to be identified.

Autosomal dominant hypocalcaemic hypercalciuria (ADHH) due to CaSR mutations

The human calcium-sensing receptor (CaSR) is a 1,078 amino acid cell surface protein, which is predominantly expressed in the parathyroids and kidney and is a member of the family of G protein-coupled receptors [22, 23]. The CaSR allows regulation of parathyroid hormone (PTH) secretion and renal tubular calcium reabsorption in response to alterations in extracellular calcium concentrations. The human CaSR gene is located on chromosome 3q21.1 and loss-of-function CaSR mutations have been reported in the hypercalcaemic disorders of familial benign (hypocalciuric) hypercalcaemia (FBHH), neonatal severe primary hyperparathyroidism (NSHPT) and familial isolated hyperparathyroidism (FIHP) [22, 23]. However, gain-of-function CaSR mutations result in autosomal dominant hypocalcaemia with hypercalciuria (ADHH), and Bartter's syndrome type V (see below) [24–27].

Patients with ADHH usually have mild hypocalcaemia that is generally asymptomatic but may in some patients be associated with carpopedal spasm and seizures [24]. The serum phosphate concentrations in patients with ADHH are either elevated or in the upper-normal range, and the serum magnesium concentrations are either low or in the low-normal range. These biochemical features of hypocalcaemia, hyperphosphatemia, and hypomagnesemia are consistent with hypoparathyroidism and pseudohypoparathyroidism. However, these patients have serum PTH concentrations that are in the low-normal range [24]. Thus, they are not hypoparathyroid, which would be associated with undetectable serum PTH concentrations, or pseudohypoparathyroid, which would be associated with elevated serum PTH concentrations. These patients were therefore classified as having autosomal dominant hypocalcaemia (ADH), and the association of hypercalciuria with this condition led to it being referred to as autosomal dominant hypocalcaemia with hypercalciuria [24, 28]. Treatment with active metabolites of vitamin D to correct the hypocalcemia has been reported to result in marked hypercalciuria, nephrocalcinosis, nephrolithiasis, and renal impairment, which was partially reversible after cessation of the vitamin D treatment [24]. Thus, it is important to identify and avoid vitamin D treatment in such ADHH patients and their families whose hypocalcaemia is due to a gain-of-function CaSR mutation and not hypoparathyroidism. More than 40 different CaSR mutations have been identified in ADHH patients, and over 50% of these are in the extracellular domain [23]. Almost every ADHH family has its own unique missense heterozygous CaSR mutation. Expression studies of the ADHH associated CaSR mutations have demonstrated a gain-of-function, whereby there is a leftward shift in the dose-response curve such that the extracellular calcium concentration needed to produce a half-maximal (EC_{50}) increase in the total intracellular calcium ions (or inositol trisphosphate, IP_3), is significantly lower than that required for the wild-type receptor [23, 24, 28].

Bartter syndrome

Bartter syndrome is a heterogeneous group of autosomal hereditary disorders of electrolyte homeostasis characterized by hypokalaemic alkalosis, renal salt wasting that may lead to hypotension, hyperreninemic hyperaldosteronism, increased urinary prostaglandin excretion, and hypercalciuria with nephrocalcinosis [23]. Mutations of several ion transporters and channels have been associated with Bartter syndrome, and six types (Table 107.1) are now recognized [23]. Thus, type I is due to mutations involving the bumetanide-sensitive sodium–potassium–chloride cotransporter (NKCC2 or SLC12A2); type II is due to mutations of the renal outer-medullary potassium channel (ROMK); type III is due to mutations of the voltage-gated chloride channel (CLC-Kb); type IV is due to mutations of Barttin, which is a beta subunit that is required for the trafficking of CLC-Kb and CLC-Ka (this form is also associated with deafness as Barttin, CLC-Ka, and CLC-Kb are also expressed in the marginal cells of the scala media of the inner ear that secrete potassium ion-rich endolymph); and type V is due to activating mutations of the CaSR. Patients with Bartter syndrome type V have the classical features of the syndrome, i.e., hypokalemic metabolic alkalosis, hyperreninemia, and hyperaldosteronism [25, 26]. In addition, they develop hypocalcemia, which may be symptomatic and lead to carpopedal spasm, and an elevated fractional excretion of calcium, which may be associated with nephrocalcinosis [25, 26]. Such patients have been reported to have heterozygous gain-of-function CaSR mutations, and *in vitro* functional expression of these mutations not only revealed a leftward shift in the dose-response curve for the receptor but also showed them to have a much lower EC_{50} than that found in patients with ADHH [25, 26]. This suggests that the additional features that occur in Bartter syndrome type V when compared to ADHH are due to severe gain-of-function mutations of the CaSR. Bartter syndrome type VI has been reported in one child from Turkey and was associated with a *CLCN5* mutation [27]; mutations in this gene are usually observed in Dent's disease (see below).

Dent's disease

Dent's disease is an X-linked recessive renal tubular disorder characterized by a low molecular weight proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, and eventual renal failure [29]. Dent's disease is also associated with the other multiple proximal tubular defects of the renal Fanconi syndrome, which include aminoaciduria, phosphaturia, glycosuria, kaliuresis, uricosuria, and impaired urinary acidification [29]. With the exception of rickets, which occurs in a minority of patients, there appear to be no extrarenal manifestations in Dent's disease [29]. The gene causing Dent's disease, *CLCN5*, encodes the chloride/proton antiporter, CLC-5 [30]. CLC family members, which are usually voltage-gated chloride channels, have important diverse functions that

include the control of membrane excitability, transepithelial transport, and regulation of cell volume [31]. CLC-5, which is predominantly expressed in the kidney and in particular the proximal tubule, thick ascending limb of Henle, and the alpha intercalated cells of the collecting duct, has been reported to be critical for acidification in the endosomes that participate in solute reabsorption and membrane recycling in the proximal tubule [32, 33]. CLC-5 is also known to alter membrane trafficking via the receptor-mediated-endocytic pathway that involves megalin and cubulin [34, 35]. CLC-5 mutations associated with Dent's disease impair chloride flow and likely lead to impaired acidification of the endosomal lumen, and thereby also disrupt trafficking of endosomes back to the apical surface [34–36]. This will result in impairment of solute reabsorption by the renal tubule and in the defects observed in Dent's disease [37]. Mice that are deficient for CLC-5 develop the phenotypic abnormalities associated with Dent's disease, but some patients with Dent's disease, who do not have CLC-5 mutations, have been reported to have mutations of the gene encoding an inositol polyphosphate 5-phosphatase, which also results in the Lowe syndrome [38, 39] (see below).

Occulocerebrorenal syndrome of lowe

Oculocerebrorenal syndrome of Lowe (OCRL) is an X-linked recessive disorder that is characterized by congenital cataracts, mental retardation, muscular hypotonia, rickets, and defective proximal tubular reabsorption of bicarbonate, phosphate, and amino acids [40, 41]. Some patients may also develop hypercalciuria and renal calculi [41]. The *OCRL1* gene is located on Xq25 and encodes a member of the type II family of inositol polyphosphate 5-phosphatases [42]. These enzymes hydrolyse the 5-phosphate of inositol 1, 4, 5-trisphosphate and of inositol 1, 3, 4, 5-tetrakisphosphate, phosphatidylinositol 4, 5-bisphosphate, and phosphatidylinositol 3, 4, 5-trisphosphate, thereby presumably inactivating them as second messengers in the phosphatidylinositol signaling pathway [42]. The preferred substrate of OCRL1 is phosphatidylinositol 4, 5-bisphosphate, and this lipid accumulates in renal proximal tubular cells from patients with Lowe syndrome [42]. OCRL1 has been localized to lysosomes in renal proximal tubular cells and to the trans-Golgi network in fibroblasts. OCRL1 has also been shown to interact with clathrin and indeed colocalizes with clathrin on endosomal membranes that contain transferrin and mannose 6-phosphate receptors [40]. Thus, it seems likely the *OCRL1* mutations in Lowe syndrome patients result in OCRL1 protein deficiency, which leads to disruptions in lysosomal trafficking and endosomal sorting [40, 43].

Hereditary hypophosphatemic rickets with hypercalciuria

Two different heterozygous mutations (Ala48Phe and Val147Met) in NPT2a (also referred to as *SLC34A1*), the gene encoding a sodium-dependent phosphate transporter, have been reported in patients with urolithiasis or osteoporosis and persistent idiopathic hypophosphatemia due to decreased renal tubular phosphate reabsorption [44]. When expressed in *Xenopus laevis* oocytes, the mutant NPT2a showed impaired function. However, these *in vitro* findings were not confirmed in another study using oocytes and OK cells, raising the concern that the identified NPT2a mutation could not explain the findings in the described patients [45]. However, homozygous ablation of *Npt2a* in mice (*Npt2a*–/–) results in increased urinary phosphate excretion, hypophosphatemia, an appropriate elevation in the serum levels of 1,25-dihydroxyvitamin D, hypercalcemia, decreased serum parathyroid hormone levels, increased serum alkaline phosphatase activity and hypercalciuria [46]. Some of these biochemical features are observed in patients with hereditary hypophosphatemic rickets with hypercalciuria (HHRH), but there are important differences [47]. Thus, HHRH patients develop rickets, short stature, with an increased renal phosphate clearance, and hypercalciuria but have normal serum calcium levels, an increased gastrointestinal absorption of calcium and phosphate due to an elevated serum concentration of 1, 25-dihydroxyvitamin D, suppressed parathyroid function, and normal urinary cyclic adenosine monophosphate (AMP) excretion [47]. However, HHRH patients do not have NPT2a mutations [48], and studies have demonstrated that HHRH patients harbor homozygous or compound heterozygous mutations of *SLC34A3*, the gene encoding the sodium–phosphate cotransporter NPT2c [49, 50]. These findings indicate that NPT2c has a more important role in phosphate homeostasis than previously thought.

Familial hypomagnesaemia with hypercalciuria and nephrocalcinosis due to paracellin-1 (claudin 16) mutations

Familial hypomagnesaemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive renal tubular disorder that is frequently associated with progressive kidney failure [51]. FHHNC often presents in childhood with seizures, or tetany due to hypocalcemia and hypomagnesemia. Other recurrent clinical manifestations include urinary tract infections, polyuria, polydipsia, and failure to thrive. Investigations reveal hypomagnesemia, hypocalcemia, hyperuricemia, hypermagnesuria, hypercalciuria, incomplete distal renal tubular acidosis, hypocitraturia, and renal calcification [52]. Treatment consists of high-dose enteral magnesium to restore normomagnesemia. Children with FHHNC who receive such treatment early develop normally. Linkage studies in 12 FHHNC kindreds localized the disease locus to chromosome 3q27, and positional cloning studies identified mutations in the gene encoding Paracellin-1 (PCLN-1), which is also referred to as claudin

16 (*CLDN16*) [52]. FHHNC patients were either homozygotes or compound heterozygotes for PCLN-1 mutations, consistent with the autosomal recessive inheritance of the disorder [52, 53]. The PCLN-1 mutations consisted of premature termination codons, splice-site mutations, and missense mutations [52, 53]. The PCLN-1 protein, which consists of 305 amino acids, has sequence and structural similarity to the members of the claudin family, and is therefore also referred to as CLDN16 [54, 55]. Claudins are membrane-bound proteins that form the intercellular tight junction barrier in a variety of epithelia [54,55]. They have four transmembrane domains and intracellular amino- and carboxy–termini. The two luminal loops mediate cell–cell adhesion via homo- and heterotypic interactions with claudins on a neighboring cell. In addition, claudins form paracellular ion channels, which facilitate renal tubular paracellular transport of solutes [54]. CLDN16 is exclusively expressed in the thick ascending limb of Henle's loop, where it forms the paracellular channels that are driven by an electrochemical gradient and allow reabsorption of calcium and magnesium [55]. Hence, loss of function of CLDN16 that would arise from FHHNC mutations would result in urinary calcium and magnesium loss and lead to hypocalcemia and hypomagnesemia, respectively. A CLDN16 missense mutation (Thr233Arg) has also been identified in two families with self-limiting childhood hypercalciuria [56]. The hypercalciuria decreased with age and was not associated with progressive renal failure. The Thr233Arg mutation resulted in inactivation of a PDZ-domain binding motif, and this disrupted the association with the tight junction scaffolding protein, ZO-1, with accumulation of the mutant CLDN16 protein in lysosomes and no localization to the tight junctions [56]. Thus, CLDN16 mutations may result in different abnormalities of renal tubular cell function and hence lead to differences in the clinical phenotype. A form of FHHNC with severe ocular involvement reported in one Swiss and eight Spanish/Hispanic families was recently mapped to chromosome 1p34.2 [53]. This region contains *CLDN19*, the gene that encodes claudin 19, a tight-junction protein expressed in the kidney and eye. A Gly20Asp mutation located in the first transmembrane domain of CLDN19 was identified in all but one of the Spanish/Hispanic families, and a Gln57Glu mutation in the first extracellular loop of CLDN19 was found in the Swiss family. In addition, a Leu90Pro mutation in CLDN19 was identified in a consanguineous family of Turkish origin with FHHNC and severe ocular involvement [53].

Distal renal tubular acidosis

In distal renal tubular acidosis (dRTA), the tubular secretion of hydrogen ions in the distal nephron is impaired, and this results in a metabolic acidosis that is often associated with hypokalemia due to renal potassium wasting, hypercalciuria with nephrocalcinosis, and metabolic bone disease. Distal RTA may be familial with autosomal dominant or recessive inheritance.

Autosomal dominant dRTA due to erythrocyte anion exchanger (band 3, AE1) mutations

The family of anion exchangers (AEs) are widely distributed and involved in the regulation of transcellular transport of acid and base across epithelial cells, cell volume, and intracellular pH [57]. For example, AE1, which is a major glycoprotein of the erythrocyte membrane, mediates exchange of chloride and bicarbonate [57]. AE1 is also found in the basolateral membrane of the α-intercalated cells of renal collecting ducts that are involved in acid secretion [57]. Patients with autosomal dominant dRTA, the majority of whom had hypercalciuria, renal stones, and nephrocalcinosis, and a few who had erythrocytosis, were found to have AE1 mutations [58]. These AE1 mutations resulted in several functional abnormalities that included reductions in chloride transport, and trafficking defects that lead to a cellular retention of AE1 or mistargeting of AE1 to the apical membrane. AE1 mutations may also be associated with autosomal recessive dRTA in Southeast Asian kindreds that have ovalocytosis [59].

Autosomal recessive distal renal tubular acidosis due to proton pump (H^+-ATPase) mutations

Proton pumps are ubiquitously expressed, and one such multi-unit H^+-ATPase is found in abundance on the apical (luminal) surface of the α-intercalated cells of the cortical collecting duct, which regulates urinary acidification. Failure of vectorial proton transport by these α-intercalated cells results in an inability of urinary acidification and in disorders of dRTA. The molecular basis of two types of autosomal recessive dRTA due to proton pump abnormalities have been characterized. The gene causing one type of autosomal recessive dRTA that was associated with sensorineural hearing loss was mapped to chromosome 2p13, which contained the ATP6B1gene that encodes the B1 subunit of the apical proton pump (H^+ATPase) [60]. Mutations, which would likely result in a functional loss of ATP6B1, were identified in over 30% of families with this form of autosomal recessive dRTA that occurred with deafness in more than 85% of families [60]. The association of dRTA and deafness is consistent with the renal and cochlear expression of ATP6B1. ATP6B1 plays a critical role in regulating the pH of the inner ear endolymph. Dysfunction of this would lead to an alkaline microenvironment in the inner ear, which has been proposed to impair hair cell function and result in progressive deafness. The gene causing autosomal recessive dRTA with normal hearing was localized to chromosome 7q33-q34, which contained the ATP6N1B gene that encodes the non-catalytic accessory subunit of the proton pump of the α-intercalated cells of the collecting duct. ATP6N1B mutations, which are predicted to result in a functional loss, were identified in more than

85% of kindreds with autosomal recessive dRTA associated with normal hearing; this is consistent with the expression of ATP6N1B in the kidney but not other organs. Approximately 15% of families with autosomal recessive dRTA were not found to have mutations in ATP6B1 or ATP6N1B mutations, and this indicates mutations in other genes are likely to be involved in the etiology of autosomal recessive dRTA.

CONCLUSIONS

Renal stone disease (nephrolithiasis) affects 5% of adults and is often associated with hypercalciuria. Hypercalciuric nephrolithiasis is a familial disorder in over 35% patients and may occur as a monogenic disorder or as a polygenic trait. Studies of monogenic forms of hypercalciuric nephrolithiasis, e.g., Bartter syndrome, Dent's disease, autosomal dominant hypocalcemic hypercalciuria, hypercalciuric nephrolithiasis with hypophosphatemia, and familial hypomagnesemia with hypercalciuria have helped to identify a number of transporters, channels, and receptors that are involved in regulating the renal tubular reabsorption of calcium. These studies have provided valuable insights into the renal tubular pathways that regulate calcium reabsorption and predispose to kidney stones and bone disease.

INTRODUCTION

Craniofacial skeletal elements are the most developmentally complex skeletal structures in mammals. We humans have distinct, identifying facial features, the result of small variations in craniofacial development. Such differences are usually benign and result in features that make us distinct individuals. However, variable effects of gene expression or environmental factors can lead to cosmetic and functional abnormalities. Craniofacial malformations are common birth defects among humans, occurring both in isolated forms and as part of malformation syndromes. Aberrations in normal embryogenesis cause both types of defects. In this chapter, we summarize current knowledge of normal craniofacial morphogenesis and the developmental basis of its major anomalies, focusing on craniofacial skeletal elements.

ORIGINS OF CRANIOFACIAL SKELETAL ELEMENTS

Mammalian craniofacial skeletal elements consist of more than 20 small bones and cartilages that are formed precisely during development to create functional structures—the face and the head. Most facial skeletal elements, collectively the viscerocranium, are derived from cranial neural crest cells (NCCs). These pluripotent cells are collectively sometimes called "the fourth germ layer" because of the diversity of tissues they form. In early craniofacial development, presumptive cranial NCCs arise in dorsal midline ectoderm of the midbrain and the hindbrain rhombomeres, undergo an epithelial-to-mesenchymal transition, delaminate, then migrate ventrolaterally between the ectoderm and endoderm [Fig. 108.1(A)]. While the rostral cranial NCCs develop the frontonasal skeleton and the skull vault, NCCs from each rhombomere faithfully take distinct pathways to populate different pharyngeal arches (PA), numbered rostrocaudally from 1 to 6. NCCs from rhombomeres 1 and 2 migrate into PA1 and the frontonasal process. PA1 gives rise to the incus and malleus of the ears, the mandible, and the maxilla. The frontonasal process gives rise to tissues in the upper half of the face, including the forehead, nose, eyes, and philtrum (the vertical groove between the nose and the upper lip). NCCs from rhombomeres 3 and 4 migrate into PA2, which gives rise to the stapes bone of the middle ear, the styloid process of temporal bone, and a part of the hyoid bone [Fig. 108.1(A)].

The rest of the mammalian craniofacial skeletal elements that enclose and support the brain and cranial sense organs are called the neurocranium [Fig. 108.1(B)]. They comprise the skull vault and base. While the ventral craniofacial bones and anterior skull base are derived from cranial NCCs, most of the bones at the back of the head, including the parietal bones and occipital bone, and

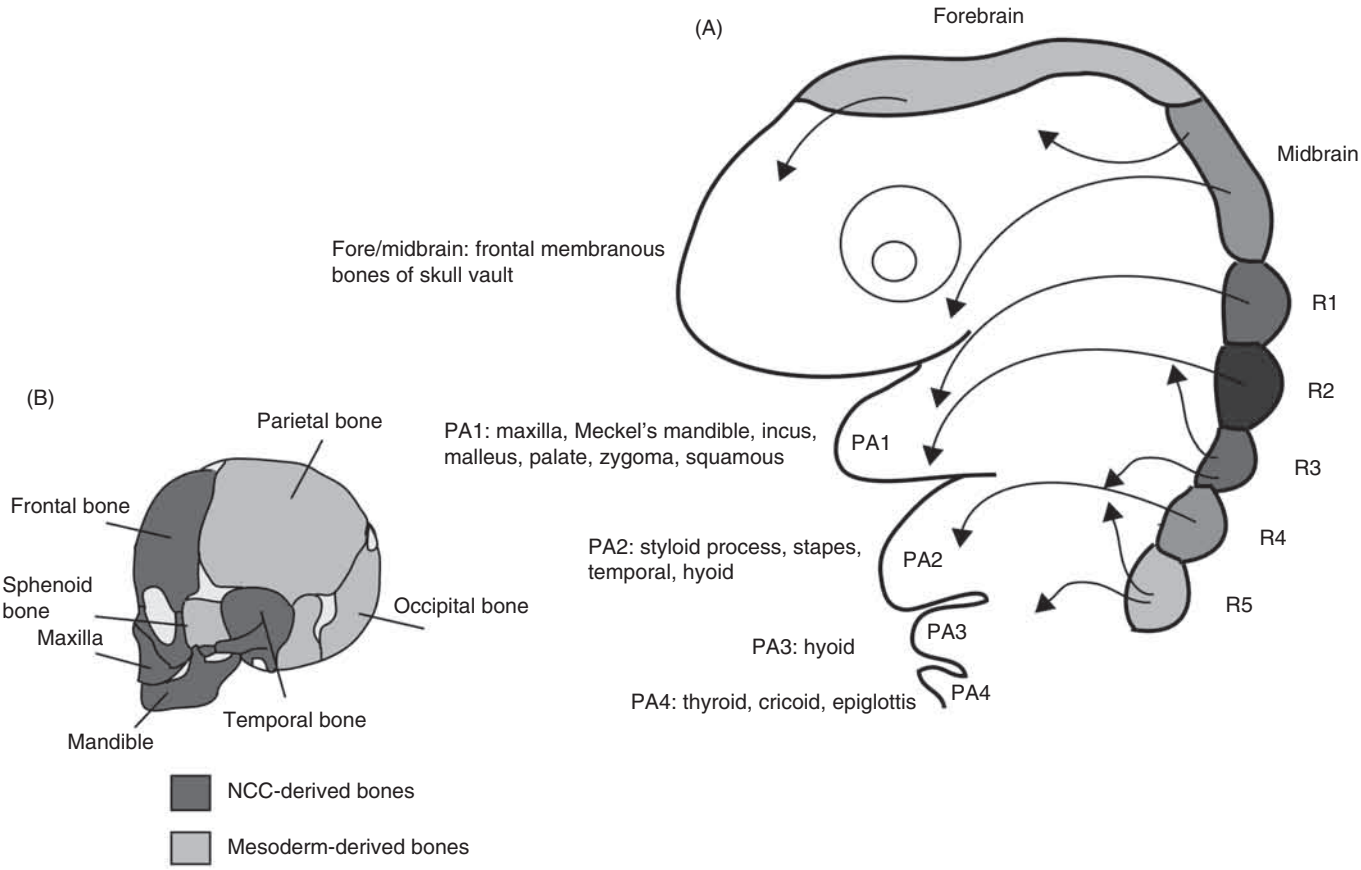

Fig. 108.1. Cranial NCC migration and NCC-derived cartilage and bones. (A) NCCs go through epithelial-mesenchymal transition and migrate ventrolaterally from rhombomeres (R) to populate pharyngeal arches (PA). NCCs in R3 and R5 merge with streams of NCCs from neighboring rhombomeres. Bones and cartilage derived from each PA are listed. (B) Facial and frontal bones are derived from NCCs. Posterior skull base and vault are mostly derived from somitic mesoderm.

the posterior part of the skull base are derived from both NCCs and paraxial mesoderm [1, 2]. The skull vault is formed through intramembranous ossification and the cranial base is formed through endochondral ossification [3].

PALATAL DEVELOPMENT

Palatogenesis is a dynamic process, with each step crucial for proper development of the palate. The palate is divided into two main parts: the primary and secondary palate. Both are mostly derived from NCCs of PA1. The primary palate develops from the intermaxillary segment, where the medial nasal processes fuse with the maxillary process, to form the most anterior part of the definitive hard palate [Fig. 108.2(A) and (B)]. Development of the secondary palate begins with downward protrusion of the two palatal shelves of the maxillary prominences on either side of the tongue, at the fifth week in humans and between embryonic day (E) 11.5 and E12.5 in mice [Figs. 108.2(B) and 108.3(A)]. Interactions between epithelial and mesenchymal cells influence the survival and continued proliferation of NCCs necessary for morphogenesis of palatal shelves [4].

The downward protrusions of the palatal shelves turn medially and elevate horizontally to meet and fuse at the midline, at about the eighth week in humans and E14.5 in mice. The tongue, meanwhile, moves downward to give enough space for the palatal shelves to elevate. The primary and secondary palates also fuse together to form the complete palate, compartmentalizing the oral and nasal cavities. Fusion of palatal shelves involves loss of medial edge epithelium (MEE) [Fig. 108.3(A)], and the cellular processes of apoptosis, epithelial migration, and epithelial-to-mesenchymal transition [5].

The ventral two-thirds of the secondary palate becomes the hard palate, containing bone, and the rest becomes the muscular soft palate. Postnatal development of the palate may be influenced by osteogenic responses to retain functional integrity against mechanical stress; for example, elevated masticatory load increased the bone density of secondary hard palate in growing rabbits [6].

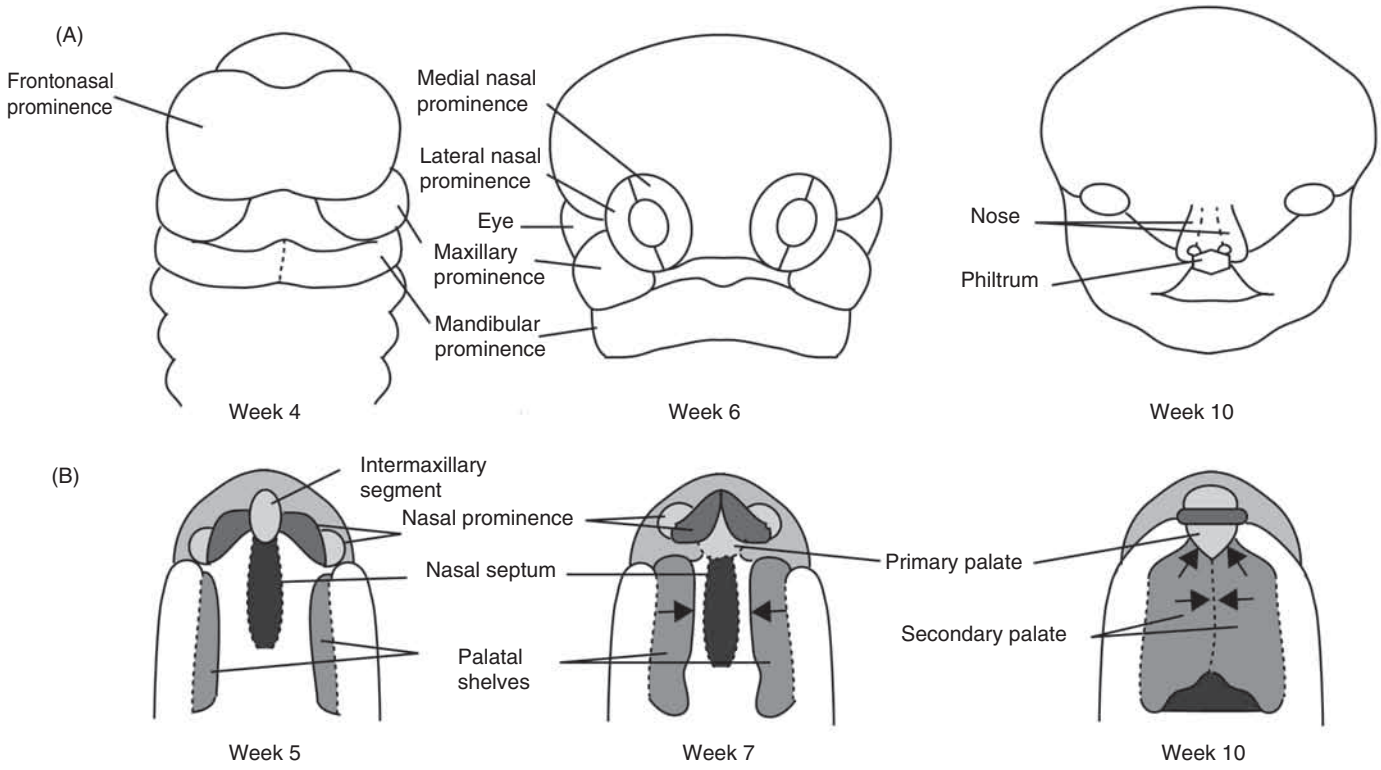

Fig. 108.2. Development of the face and the palate in humans. (A) Frontonasal, maxillary, and mandibular prominences form in the fourth week. By the sixth week, nasal prominences develop from frontonasal prominence. (B) Ventral view of palate development. Around the fifth week, palatal shelves from maxillary prominences grow downward on either side of the tongue. Growing palatal shelves start elevating medially in the seventh week. By tenth week, secondary and primary palates fuse together to form the complete palate.

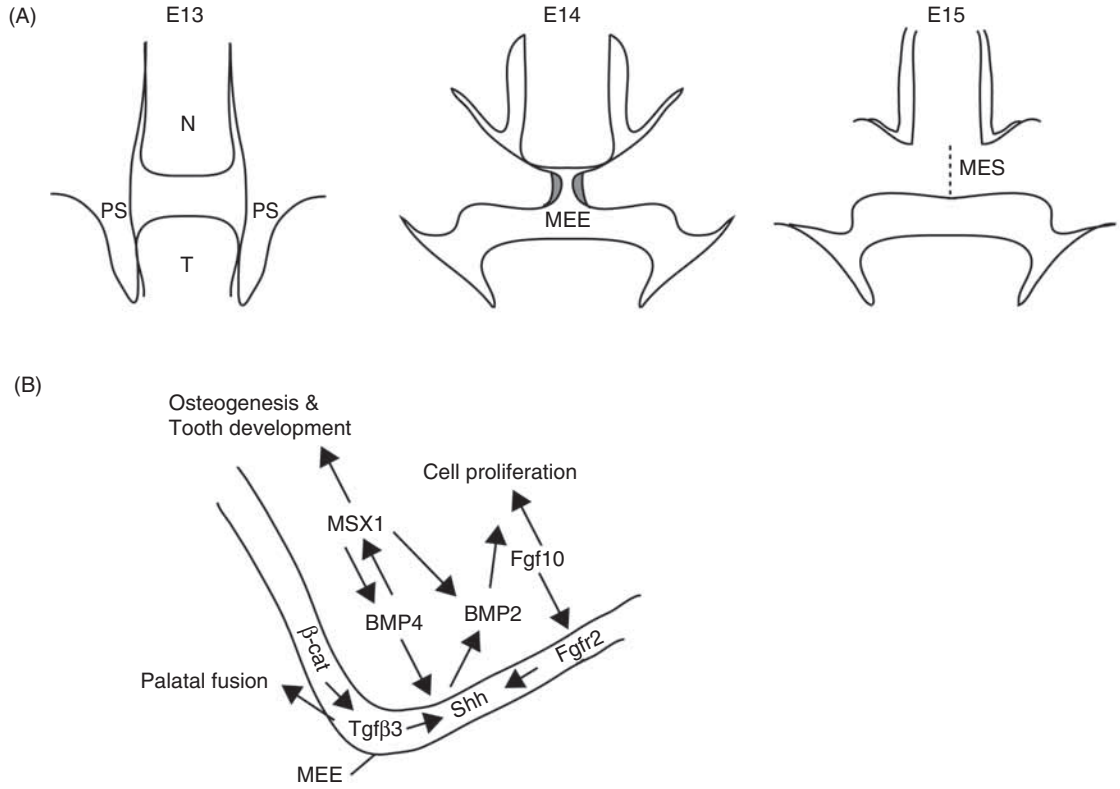

Fig. 108.3. Coronal view of palatogenesis and gene networks during palatogenesis. (A) Palatal shelf (PS), nasal septum (N), tongue (T), medial edge epithelium (MEE), medial edge seam (MES). (B) Complex gene networks in the palatal shelves. Molecular signaling events during epithelial-mesenchymal interactions of palatogenesis are depicted.

In addition to environmental risk factors, several genes and signaling pathways important for palatogenesis have been identified [Fig. 108.3(B)]. One key pathway involved in palatogenesis is bone morphogenetic protein (BMP) signaling. In early embryogenesis, BMPs influence cell migration, differentiation, proliferation, apoptosis, and condensation. Later, among other roles, BMP signaling promotes osteogenesis and chondrogenesis in skeletal formation throughout the body. For example, BMP signaling is important for mesenchymal condensation in progenitors of palatal bone [7]. Altering BMP signaling in NCCs or in the oral epithelium results in cleft palate (CP) [8, 9].

BMP2 and BMP7 expression in palatal mesenchyme is regulated by the Msx1 homeobox gene [Fig. 108.3(B)], which plays an important role in epithelial-mesenchymal interaction throughout embryogenesis. Msx1 null mice display multiple deformities in craniofacial skeletal elements, including secondary CP and abnormal tooth and mandible development [10]. Msx1 is also required for expression of Shh in the MEE, the site of palatal shelf fusion [11]. Expression of Shh and BMP2, as well as CP, in Msx1 mutant mice is rescued by transgenic expression of Bmp4, suggesting a gene network of BMP and Shh signaling pathways in development of palatal shelves [11].

The Hedgehog signaling pathway also interacts with fibroblast growth factor (Fgf) signaling in palatogenesis. Fgf10 is expressed in mesenchyme, while its receptor, Fgfr2b is expressed in epithelium. Fgf10 is required for Shh expression in epithelium. Loss of either can cause CP due to insufficient survival or proliferation of NCCs [4].

Current models suggest that apoptosis is the major cellular mechanism for palatal fusion [12–14]. Transforming growth factor-β-3 (Tgfβ3) promotes apoptosis in juxtaposed MEE to form a single layered medial edge seam (MES) [Fig. 108.3(A)]. Tgfβ3 expression in MEE is regulated by Wnt/β-catenin signaling [15]. Table 108.1 shows the expression of some of key genes during palatogenesis.

Table 108.1. Expression of Key Genes during Palatogenesis

Stage	Mesenchyme	Epithelium
E12-E13 Palatal shelf growth	*Fgf10, Fgf7, Msx1*	*Fgfr2b, Shh*
E13-E14 Palatal shelf elevation	*Fgf10, Fgfr1b, Fgf2b, Msx1, TGFβ1, TGFβ2*	*Fgfr1, Fgfr2b, Shh, Wnt11*
E14-E15 Palatal fusion	*Bmp2, Bmp3, Bmp4, Fgf10, Msx1*	*Bmp3, Fgfr2, Shh, TGFβ3*

OROFACIAL CLEFT

Orofacial clefts, among the most common congenital malformations, result from failure in the joining of bilateral facial structures during development. They are divided in three large groups, cleft lip with cleft palate (CL/P), cleft lip (CL) only, and CP only. Approximately half of the CL patients also manifest CP, considered a secondary consequence of the primary imperfection of premaxillary fusion. Thus, CP only may be etiologically distinct from CL/P. CP emanates from defective unification of the palatal shelves. Mechanisms leading to this failure include defects in palatal shelf growth, palatal elevation, and palatal shelf adhesion.

CP is subdivided into hard palate cleft, soft palate cleft, complete palate cleft, and bilateral palate cleft (Fig. 108.4). Patients often suffer from complications causing speech and feeding difficulties, frequent ear infections, dental problems as well as problems in psychological development [16]. About 70 percent of orofacial clefts arise as an isolated form where no other anomalies are associated in those patients, while the remaining cases occur in syndromes; about 400 syndromes are known to cause orofacial clefts [17]. Recent studies show that genes causing syndromic CL/P have a significant overlapping etiology with non-syndromic clefting [16]. Studying those genes and related molecular pathways will help us further understand pathogenesis of human facial clefts.

In addition to genetic factors associated with orofacial clefts, numerous nongenetic risk factors have been identified. Maternal smoking during the periconceptional period increased the incidence of CL/P and CP by twofold [18]. Smoking during pregnancy also increases the chance of causing orofacial clefts in fetuses with certain susceptibility loci [19]. In addition, the Food and Drug Administration (FDA) recently announced that certain types of antiepileptic medications increase the risk of CL/P and CP.

MANDIBULAR DEVELOPMENT

The mandible develops through unique steps. Bilaterally symmetric mandibular buds of PA1, stuffed with mesenchymal NCCs and paraxial mesoderm and enclosed by endodermal and ectodermal epithelial layers, dramatically grow and fuse to each other at the midline [20]. Within this fused mandibular process arises Meckel's cartilage (MC), a rod-shaped transient structure that functions as a template for mandibular formation. NCCs surround MC to form a membranous sheath, which later undergoes intramembranous ossification to form the mandible proper. The distal portion of MC undergoes endochondral ossification to become a part of the mandibular bone supporting the incisors, whereas the proximal portion contributes to the inner ear ossicles. The central part of MC disappears soon after birth [21]. MC

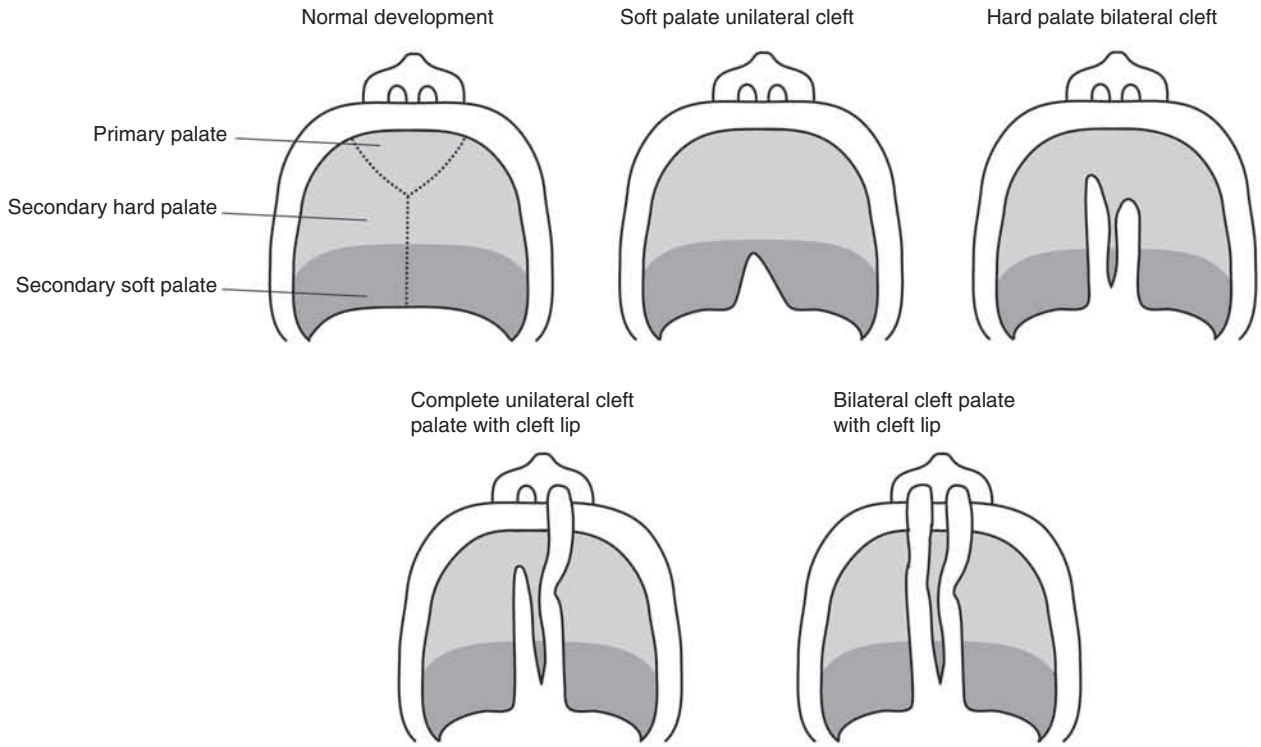

Fig. 108.4. Normal palate morphology and types of cleft palate. The palate is composed of the primary palate and secondary palate. The secondary palate is further subdivided into the hard palate and the soft palate. The degree of severity varies case by case; some only affect the soft palate while others affect both the secondary and primary palates as well as lip formation.

degradation may be induced by feed-forward secretion of interleukin-1β by infiltrating macrophages and chondrocytes [22].

Proper mandibular morphogenesis requires signaling interactions between mesenchyme and epithelial cells in PA1. In addition, signaling from pharyngeal endoderm plays a significant role in mandibular growth. The survival of mesenchyme, MC outgrowth, and osteogenesis of mandibular bones is closely regulated by stage- and region-specific roles of BMP and FGF signaling pathways [23–25]. For example, ectopic BMP4 application to mandibular explants increases apoptosis and represses Fgf8 transcription. Fgf8 signaling is considered as a source of survival signaling for mesenchyme in PA1. Mouse embryos lacking the BMP antagonists Chordin and Noggin show reduced Fgf8 in the pharyngeal ectoderm and increased apoptosis, resulting in a whole spectrum of mandibular outgrowth defects [26]. Perturbing FGF receptor 3 (FGFR3) in MC before chondrogenic and osteogenic condensations results in defects in development of the mandibular process and MC and a lack of mandibular bones [25].

MICROGNATHIA

Micrognathia, characterized by mandibular hypoplasia, is another example of a common craniofacial structural malformation. It is generally considered a defect in which too few NCCs populate PA1 due to insufficient production or migration during the fourth week of human gestation. Such NCC defects are often caused by misregulation of signaling pathways elicited by genetic and environmental factors. Patients who are affected show a wide range of malformation, from almost normal to agnathia, a complete lack of the lower jaw. While multiple syndromes include micrognathia, isolated micrognathia may cause sequential deformities. A hypoplastic mandible can displace the tongue posteriorly, which in turn prevents elevation of palatal shelves, leading to CP or CL/P as in Pierre Robin sequence [27]. Children with micrognathia often have problems with feeding and upper airway breathing as well as sleep apnea. In severe cases, surgical intervention may be required to allow the mandibular bone to elongate [28]. Although it has been believed that in some cases of mandibular hypoplasia, outgrowth may eventually attain normal proportions during childhood, recent findings suggest the underdeveloped mandible generally remains small [29, 30].

DEVELOPMENT OF THE NEUROCRANIUM

The neurocranium is composed of two parts: the skull vault and the base. The skull vault consists of multiple

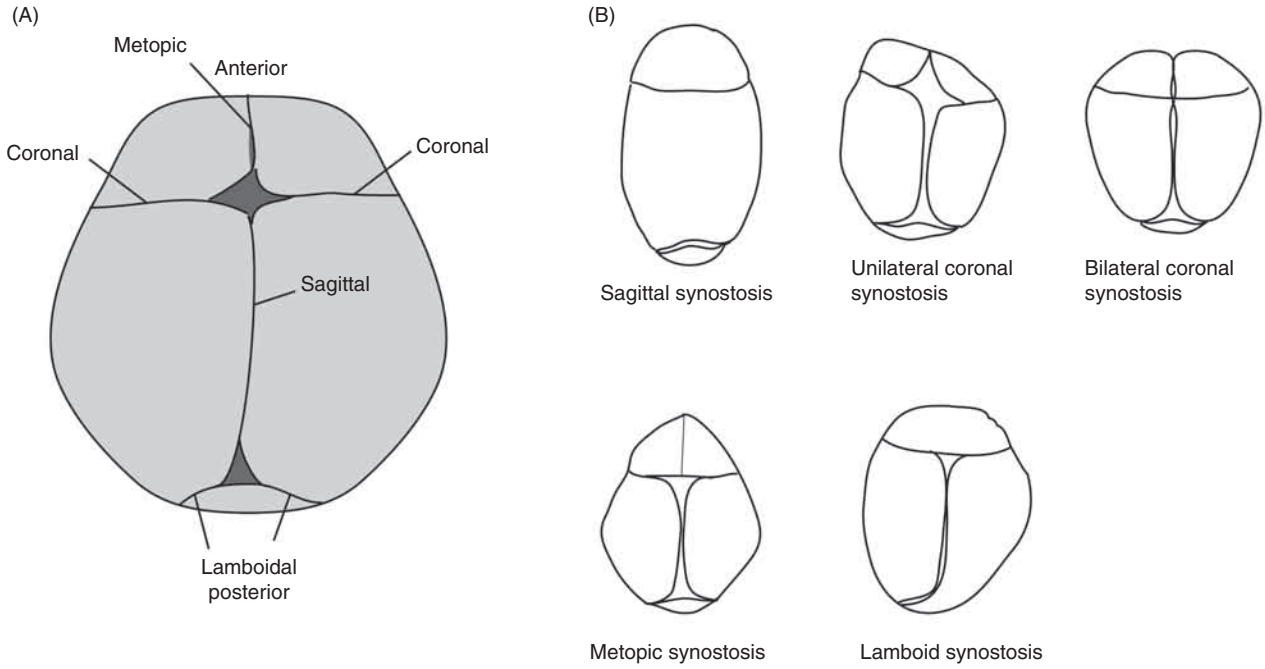

Fig. 108.5. Cranial sutures and types of craniosynostosis viewed from above. (A) Positions of the major cranial sutures. (B) Diagnostic features of craniosynostosis. Sagittal synostosis results in a long and narrow head. Right unilateral coronal synostosis shows a flattened forehead on the affected side. Bilateral coronal synostosis causes a flattened head. Metopic synostosis displays hypotelorism and a pointy forehead. Lamboid synostosis causes a flattening of the back of the head.

separate membranous bones—frontal, parietal, and a part of the occipital bones. The frontal bones are derived from NCCs, while others are mostly derived from mesoderm cells [1, 2]. Connective tissues called cranial sutures articulate these bones, resulting in formation of fontanelles at the boundaries of the cranial bones [Fig. 108.5(A)]. These sutures are the primary sites of osteogenesis during skull development. Cranial sutures are formed between neighboring membranous bones when cells at the osteogenic front proliferate. Tissue and molecular signaling interactions with underlying dura mater influence the development and maintenance of cranial sutures. Dura mater releases and takes up cytokines, mediates biochemical signaling, and contributes cells to suture mesenchyme. FGFs are expressed in dura mater just below the forming sutures. FGF signaling is critical for cranial suture biology [31, 32]. Maintenance of suture patency at birth helps the skull of a baby go through the birth canal and, until 12–18 months of age, is essential for proper brain growth and development [33].

The skull base includes midline structures such as the ethimoid, sphenoid, basioccipital bones, and parts of the temporal bones. These bones play an important role in supporting the brain. The anterior-most skull base is derived from NCCs, while the posterior skull base is derived from paraxial mesoderm [34]. The timing of growth, ossification, and maturation of the anterior and posterior skull base is not synchronous. A distinct feature of skull base bones is that, unlike other craniofacial skeletal elements, these bones develop through endochondral ossification. The skull base first forms from multiple paired cartilaginous anlagen from caudal to rostral. These grow, extend, and fuse together, resulting in formation of skull base sutures between each cartilaginous element. Eventually, they form a single perforated baseplate. Chondrogenesis in neural crest derived cartilages requires Sox9. Mesoderm-derived occipital bone is present while NCC-derived sphenoid bone is absent in mice lacking Sox9 [35]. The development of the skull base is also critical for facial growth. The size and shape of the skull base affect the position of mandible and may cause consequential craniofacial deformities such as CP [36–39].

CRANIOSYNOSTOSIS AND SKULL BASE DEFORMITIES

Premature suture fusion, craniosynostosis, occurs 1 in 2,500 human births [40] (Table 108.2). The form of craniosynostosis depends on the affected suture(s) [Fig. 108.5(B)]. The nature of the alteration in cranial vault shape depends on which sutures are fused prematurely. Different types of craniosynostosis involve distinct etiologies.

Table 108.2. Syndromes with Craniosynostosis and Implicated Genes

Gene	Syndromes
Fgfr1	Jackson-Weiss syndrome, Kallmann syndrome 2, Pfeiffer syndrome
Fgfr2	Apert syndrome, Crouzon syndrome, Jackson-Weiss syndrome, LADD syndrome, Saethre-Chotzen syndrome
Fgfr3	Crouzon syndrome, LADD syndrome, Muenke syndrome
Twist1	Saethre-Chotzen syndrome
Fbn1	Marfan syndrome, MASS syndrome
Tgfbr1 & *Tgfbr2*	Loeys-Dietz syndrome

Primary craniosynostosis is caused by premature ossification of the skull vault and union of one or more cranial sutures. Accordingly, an abnormal shape of the cranial vault and/or premature closure of the fontanelles result. In contrast, secondary craniosynostosis is caused by insufficient brain growth, which is usually caused in turn by the failure of cephalic neural tube closure in the first month of human embryonic development. More than 180 syndromes include craniosynostosis in humans, including Apert, Crouzon, and many others [41] (Table 108.2). Mutations in FGFs, genes involved in FGF signaling, and the osteogenic transcription factor Runx2 have been identified as the molecular lesions underlying syndromes with craniosynostosis [42].

The frequency of deformities in the skull base is less than that of defects in other parts of the craniofacial skeleton. The NCC-derived anterior skull base is more susceptible to defects than the posterior mesoderm-derived skull base [36]. Abnormalities of the skull base can affect the position of the jaws. One study suggested correlations between anterior skull base morphology and midfacial retrusion [43]. Some cases of skull base deformities are also observed in the syndromes that cause craniosynostosis [36]. Research so far has been unable to conclude if skull base abnormalities are the cause or consequences of craniosynostosis or craniofacial deformities. Defects in the skull base are often observed in skull base sutures and cartilage growth plate called synchondroses. The location and timing of premature skull base fusion and synchondroses can influence the craniofacial symmetry of a child. Premature skull base closures and abnormal growth in synchondroses are recognized in many syndromes such as Crouzon and Apert [44]. However, as Goodrich suggests [44], the development of each unit—the skull vault, facial skeleton, and the skull base—influences the other units of the head skeleton. Thus, it is critical to maintain proper regulation of gene expression, tissue growth, and patterning for development of craniofacial skeletal elements.

CONCLUSION

Among the congenital deformities found in newborns, craniofacial defects such as orofacial clefts, micrognathia, and craniosynostosis occur at a frequency second only to congenital heart defects. The severity of craniofacial deformities varies case by case. The deformities frequently occur as part of genetic syndromes. They also appear sporadically as isolated forms. In some cases, teratogenic chemicals are responsible. Such craniofacial deformities may be fatal, but more often impact quality of life because they affect normal breathing and feeding. Unfortunately, there are often negative social responses to the deformities, which take a psychological toll on the affected person. The etiology of most congenital craniofacial anomalies has just begun to be understood. It is essential to clarify the normal and pathological development of craniofacial skeletal elements and the underlying molecular and cellular mechanisms. This knowledge will enhance our ability to design strategies for future treatment and prevention of craniofacial birth defects.

INTRODUCTION

Tooth development or odontogenesis is the complex process by which dental mineralized tissues form from embryonic cells that differentiate into ameloblasts that secrete enamel, odontoblasts that produce dentin, and cementoblasts that make cementum. Enamel is of epithelial origin and covers the crown of each tooth. In contrast, dentin and cementum are of mesenchymal origin. Dentin forms the bulk of the tooth and extends within both the crown and root. It has a yellow color, in contrast to the much whiter and harder enamel. Cementum is deposited only in the root area on the recently mineralized dentin matrix. The tooth is anchored onto its socket (alveolar bone) by the periodontal ligament (PDL), a connective tissue structure that surrounds the tooth root and connects each tooth to the alveolar bone through a specialized set of collagen fibers.

STAGES OF TOOTH MORPHOGENESIS AND ITS MOLECULAR CONTROL

Mammalian teeth have distinctive crown and root morphologies, which are highly adapted to their particular masticatory function. The generation of individual teeth relies upon interactions between the oral epithelium and mesenchymal cells that are derived from the cranial neural crest cells (CNCCs). Their formation involves a precisely orchestrated series of molecular and morphogenetic events. Although many diverse types of teeth exist in different species, non-human tooth development is largely the same as in humans. Therefore, we have used here examples of mouse tooth development as a prototype model for understanding human tooth formation. When possible we tried to make connections to human pathologies.

Morphologically, tooth development begins with a thickening of the oral epithelium that forms a structure known as the dental lamina. Within the dental lamina, cells start to proliferate and to invaginate the underlying mesenchyme in precise positions to form the dental placodes (which define where the teeth will be positioned into the jaws). Tooth development proceeds through a series of morphological stages that necessitate sequential and reciprocal interactions between the oral epithelium and the underlying cranial neural crest-derived mesenchyme. In mice, the oral epithelium starts thickening at embryonic day 10.5 (E10.5) and progressively acquires the bud (E13.5), cap (E14.5), and bell (E16.5) configurations (Fig. 109.1). At the bell stage, two mesenchymal cell populations can be distinguished: the dental follicle and dental pulp. Dental pulp cells adjacent to the dental epithelium differentiate into odontoblasts, while epithe-

The most important signaling molecules (in bold capital letters) and transcription factors (in italic letters) that are expressed in tooth epithelium (red) and mesenchyme (variations of blue) are shown.

lial cells juxtaposing the dental pulp differentiate into ameloblasts [1, 2]. Dental follicle gives rise to specialized PDL cells.

Signaling molecules control all steps of tooth formation by coordinating cell proliferation, differentiation, apoptosis, extracellular matrix synthesis, and mineral deposition. The same molecules are repetitively used during the different stages of tooth development and are regulated according to a precise timing mechanism [3, 4]. Signals produced at a wrong time lead to abnormal cell proliferation, differentiation, apoptosis, thus affecting the overall tooth development and shape.

Numerous studies during the past 20 years have shown that bone morphogenic proteins (BMPs) regulate epithelial-mesenchymal interactions during tooth initiation [3], Wnts [4], and Sonic hedgehog (Shh) [5] regulate cell proliferation, migration, and differentiation, and fibroblast growth factors (FGFs) regulate tooth specific gene expression and cell proliferation [6] (Fig. 109.1).

The territory of the mammalian dentition is defined early, before any obvious sign of tooth development. The earliest marker that defines the oral epithelial area where teeth will grow is the transcription factor *Pitx2* [7]. Mutations of *PITX2* in humans result in Rieger's syndrome, which is characterized by eye and tooth defects, including anodontia (lack of teeth).

The mesenchyme of teeth is derived from CNCCs that form a pool of multipotent progenitors. CNCCs migrate from the dorsal part of the neural tube and subsequently generate craniofacial structures of unique morphology and function, such as teeth [8]. Malformations and syndromes that arise due to defects in neural crest cell development are collectively called neurocristopathies in humans.

Dental fields within the oral epithelium are established by epithelium-derived signals that form morphogenic gradients, providing positional information [1]. These signals determine the display and fate of the CNCCs, leading to the generation of distinct tooth shapes. As an example, ectodysplasin (Eda) signaling molecules have been shown to be involved in the determination of the size of the dental fields in the oral epithelium, and thus in the proportion of the size and number of teeth [9]. Non-syndromic hypodontia or congential absence of one or more permanent teeth is a common anomaly of dental development in humans.

Mutations in the EDA gene are related with X-linked recessive hypohidrotic ectodermal dysplasia (XLHED). XLHED is a genetic disease characterized by the defective morphogenesis of teeth, hair, and sweat glands [10].

SIGNALS CONTROLLING DENTAL CELL DIFFERENTIATION

Dental cell differentiation results in the formation of the three dental mineralized tissues (enamel, dentin, cementum) (Fig. 109.2,) which are connected through the periodontal ligament (PDL) to the alveolar bone.

The specification of the various dental cell types during dental cell differentiation (i.e., stratum intermedium, stellate reticulum, outer and inner dental epithelial cells, ameloblasts, dental pulp fibroblasts, odontoblasts, periodontal ligament fibroblasts) involves differential expression of specialized genes with restricted developmental and circadian patterns during odontogenesis. It is possible that the determination of cell fates in teeth occurs via inhibitory interactions between adjacent dental cells. These interactions seem to be mediated mainly through the Notch signaling pathway.

BMPs and FGFs have opposite effects on the expression of Notch receptors and ligands (i.e., Delta and Jagged) in dental tissues [11], indicating that cell fate choices during odontogenesis are under the concomitant control of the Notch and BMP/FGF signaling pathways. Notch-mediated lateral inhibition has a pivotal role in the establishment of the tooth morphology, as shown in *Jagged2* mutant mice where the overall development and structure of their teeth is severely affected [12].

Mutations in Notch signaling pathway members cause developmental phenotypes that affect the liver, skeleton, heart, eye, face, kidney, and vasculature in humans [13]. The tooth phenotype is still unclear in these patients. In addition, genetic findings have shown that Tbx1, a Notch signaling target, plays a significant role in the early determination of epithelial cells to adopt the ameloblast fate. Indeed, hypoplastic incisors that lack enamel are observed in mice where the *Tbx1* gene was deleted [14]. Furthermore, TBX1 mutations in humans are associated with the DiGeorge syndrome, which is characterized by abnormal cell differentiation resulting in defects of many organs inclunding heart and tooth [15].

DENTAL MINERALIZED TISSUES FORMATION

Dentin

During tooth development, dental pulp cells start to differentiate into odontoblasts at the dental-enamel junction (DEJ) under the future cusp tip. Young odontoblasts are columnar cells that secrete an mantle matrix, called predentin, which is rich in type I collagen and matrix vesicles. After predentin deposition, the basal lamina associated with the inner enamel epithelium disintegrates [16] followed by a major upregulation in the production and secretion of enamel matrix proteins and metalloproteinase-20 (Mmp-20) [17].

Dentin is tough and elastic, and its prime feature is its penetration by odontoblast tubules, which radiate out from the dental pulp to the periphery (Fig. 109.3A, B). These, with their many side branches that remain in the

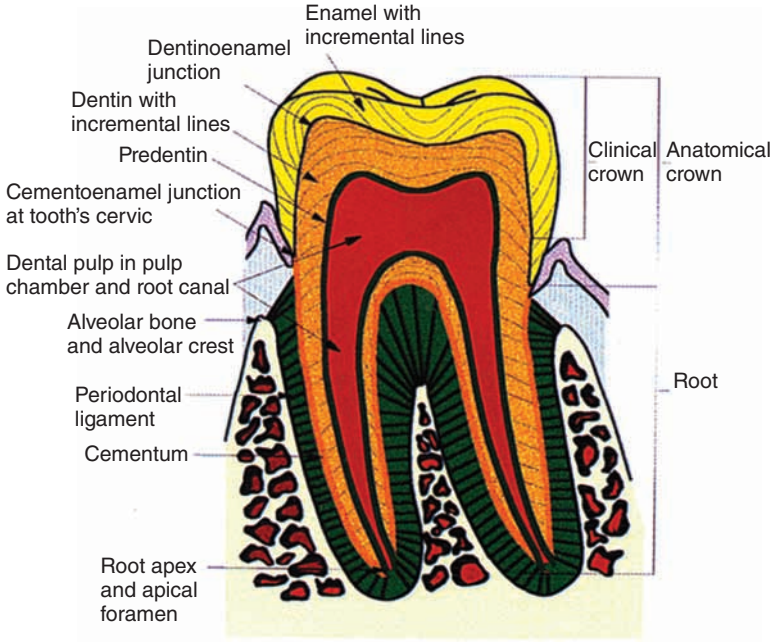

Fig. 109.2. Schematic representation of dental mineralized tissues and their structural organization.

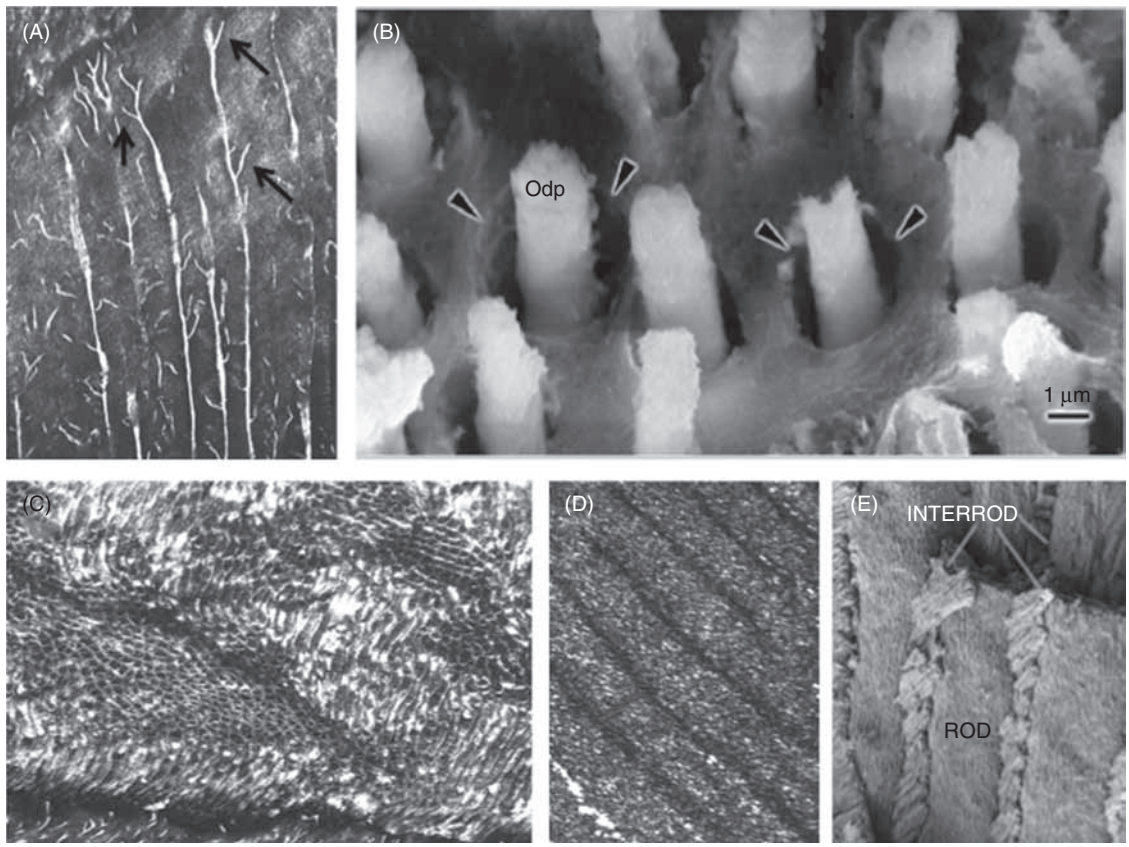

Fig. 109.3. (A) Dentin processes transverse the whole primary dentin matrix. Many ramifications are observed (arrows). (B) Close capture of odontoblast processes. Peritubular (arrowheads) and intertubular dentin can be seen. (C) Decussation (crossing in an "X" fashion) of the enamel prisms, with zones of prisms with contrasting 3D courses forming the Hunter-Schreger bands can be seen. (D) Enamel prisms. (E) Enamel rods and interrod enamel. Crystals in rod and interrod enamel are structurally similar, but have different orientations. Odp: Odontoblast process.

tubules within the dentin, are analogous to the canaliculi that house osteocyte processes in bone. Functional odontoblasts are highly polarized cells with a specialized cellular process, the odontoblast process, which transverses the heterogeneous layers of primary dentin within the dentin tubules [18].

Primary dentin forms most of the tooth prior to root eruption. Primary dentin is composed of peritubular or intratubular dentin (which creates the wall of the dentinal tubule); intertubular dentin found between the tubules; mantle dentin (which is the first predentin that forms within the tooth and is devoid of tubules); and circumpulpal dentin (which is the inner layer of dentin around the outer pulpal wall). The continuous secretion of dentin matrix (called "orthodentin") is associated with the progressive lengthening of the odontoblast cell process and retraction of the odontoblasts toward the dental pulp. In contrast, during physiopathological situations in humans, several other types of dentin are formed, i.e., sclerotic/reactionary orthodentin, where tubules may be obliterated; fibrodentin; and also osteodentin.

Odontoblasts secrete tooth-related proteins, such as dentin sialoprotein (DSP), dentin phosphoprotein (DPP), and dentin glycoprotein (DGP), which are encoded by a single gene called dentin sialophosphoprotein(DSPP) [19]. However, the majority of dentin is composed of proteins common to both dentin and bone. These proteins include type I, III, and V collagens, bone sialoprotein (BSP), osteopontin (OPN), dentin matrix protein-1 (DMP-1), osteocalcin (OC), and osteonectin (ON) [20]. Several proteins involved in calcium and phosphate handling are also synthesized jointly by osteoblasts and odontoblasts, including calbindin-D28k [21], calcium pump [22], and alkaline phosphatase [23].

Dentin continues to be slowly deposited even after tooth eruption and complete root formation. This dentin could be either the regularly deposited secondary dentin or irregular tertiary dentin, as a response of the pulp-dentin complex to attrition or disease [24]. Nerves pass from the dental pulp between odontoblasts and extend into the dentin tubules for variable distances.

The dental pulp shows signs of aging [25], which may include diffuse or local calcifications and the formation

of dental stones as well as limited reparative dentin formation.

Enamel

Dental enamel is the highest mineralized tissue found in mammals. Mature enamel contains less than 1% of organic material, and it is acellular and contains no collagen. Enamel forms in an extracellular space lined by ameloblasts, which control both the ionic and the organic contents of the enamel extracellular space [26]. Enamel mineral is mainly formed by calcium hydroxyapatite, exhibiting peculiar dimensions and organization of its crystallites. Enamel crystals are only approximately 25 nm thick and 65 nm wide but are believed to extend uninterrupted from the DEJ to the surface of the tooth [27]. The secretory end of the ameloblast ends in a six-sided pyramid-like projection known as the Tomes' process. Tomes' processes organize the enamel crystallites into rods (prisms; Fig. 109.3D). The angulation of the Tomes' process is significant in the orientation of enamel rods (Fig. 109.3E). Enamel formation is divided into secretory, transition, and maturation stages [28, 29]. The stages are shown in Fig. 109.4B [30].

During the secretory stage, enamel matrix deposition is orchestrated by both pre-ameloblasts and secretory ameloblasts. Ameloblast differentiation initiates at the cusps of the tooth germ, where the first epithelial cells differentiate into pre-ameloblasts. The signals driving ameloblast differentiation derive from the recently differentiated odontoblasts [18]. Pre-ameloblasts are secretory cells that have not yet formed a Tomes' process and deposit a thin layer of aprismatic enamel on the dentin surface. Thereafter, secretory ameloblasts initiate prismatic enamel deposition. During the secretory stage, mineral is deposited rapidly on the tips of the crystals and very sowly on the crystals sides (for review, see Ref. 31). As the crystals extend, the enamel layer expands. During the secretory stage, ameloblasts secrete mostly amelogenin, enamelin, and ameloblastin [32]. These enamel specific proteins catalyze the extension of ribbon-like enamel crystallites comprising the mineral calcium hydroxyapatite. Amelogenins are the predominant enamel matrix proteins and assemble into spheres that occupy the spaces between the crystal ribbons, serving to separate and support them [33]. Ameloblastin is thought to be important for ameloblasts attachment to the mineralizing matrix [34]. Enamelin is probably responsible for initiation of mineralization at the mineralization front [35]. As ameloblasts secrete enamel proteins and extend the mineral ribbons, they retreat from the existing enamel surface, thus increasing the thickness of the enamel extracellular space (Fig. 109.4C). Unlike collagen-based mineralization processes, which are two-step processes (secretion of an organic matrix followed by matrix mineralization), enamel secretion and mineralization occur in a single step.

During the maturation stage, mineral is deposited exclusively on the sides of the crystals. Crystals grow in width and thickness until further growth is prevented by contact with adjacent crystals. Maturation stage ameloblasts oscillate between smooth-ended and ruffle-ended morphologies (Fig. 109.5C). Rapid mineralization occurs beneath the ruffle-ended ameloblasts, which is associated with a substantial drop in pH (acidity is generated by mineral deposition) [36]. Smooth-ended ameloblasts neutralize this acid by secreting bicarbonate.

Ameloblasts create the space necessary for continued increase in the volume of mineral by gradually removing of enamel proteins progressively degraded by stage specific proteases [i.e., Mmp-20 at the secretory stage and kallikrein 4 (klk4) at the maturation stage] [37]. Maturation stage ameloblasts secrete and assemble a specialized basal lamina that securely attaches them to the enamel surface to assure its mineralization [38]. Two ameloblast-specific basal lamina proteins have recently been characterized: amelotin (*AMTN*) and Apin (*ODAM*) [39]. Transition and maturation stage ameloblasts also express genes necessary for enamel mineralization such as carbonic anhydrase II (CA2), which allows the cells to secrete bicarbonate to neutralize the acid generated by hydroxyapatite formation; calcium binding protein (Calb1); calcium-sensing receptor (CaSR); anion exchanger Ae2 (SLC4a4), and alkaline phosphatase (TNAP). The expression of several growth factors, hormones, and transcription factors is also characterized during amelogenesis [40]. Of interest, genes initially found to be expressed only in ameloblasts were also detected in odontoblasts (Fig. 109.4A) [41], and, conversely, odontoblast-specific genes were found to be expressed in ameloblasts [42].

As ameloblasts move away from the dentin, they travel in groups across the surface that they make. This results in decussation (crossing in an "X" fashion) of the enamel prisms, with zones of prisms with contrasting three-dimensional (3D) courses forming the Hunter-Schreger bands (Fig. 109.3C). The unerupted enamel is protected from resorption by a layer of cells termed the "reduced enamel epithelium," generated of mature ameloblasts remnants. These cells disappear once the tooth erupts.

Cementum and periodontal ligament

The dental follicle, a sac of loose connective tissue that separates the developing tooth from its bony crypt, is essential for eruption and will become the periodontal ligament (PDL) on tooth eruption.

The cementum is an avascular and unnerved mineralized tissue with ultrastructural similarity to bone that covers the entire root surface (Fig. 109.5A). It is the interface between the dentin and the periodontal ligament and contributes to periodontal tissue repair and regeneration after damage. The organic extracellular matrix of cementum contains proteins that selectively enhance the attachment and proliferation of cell populations residing within the PDL space [43].

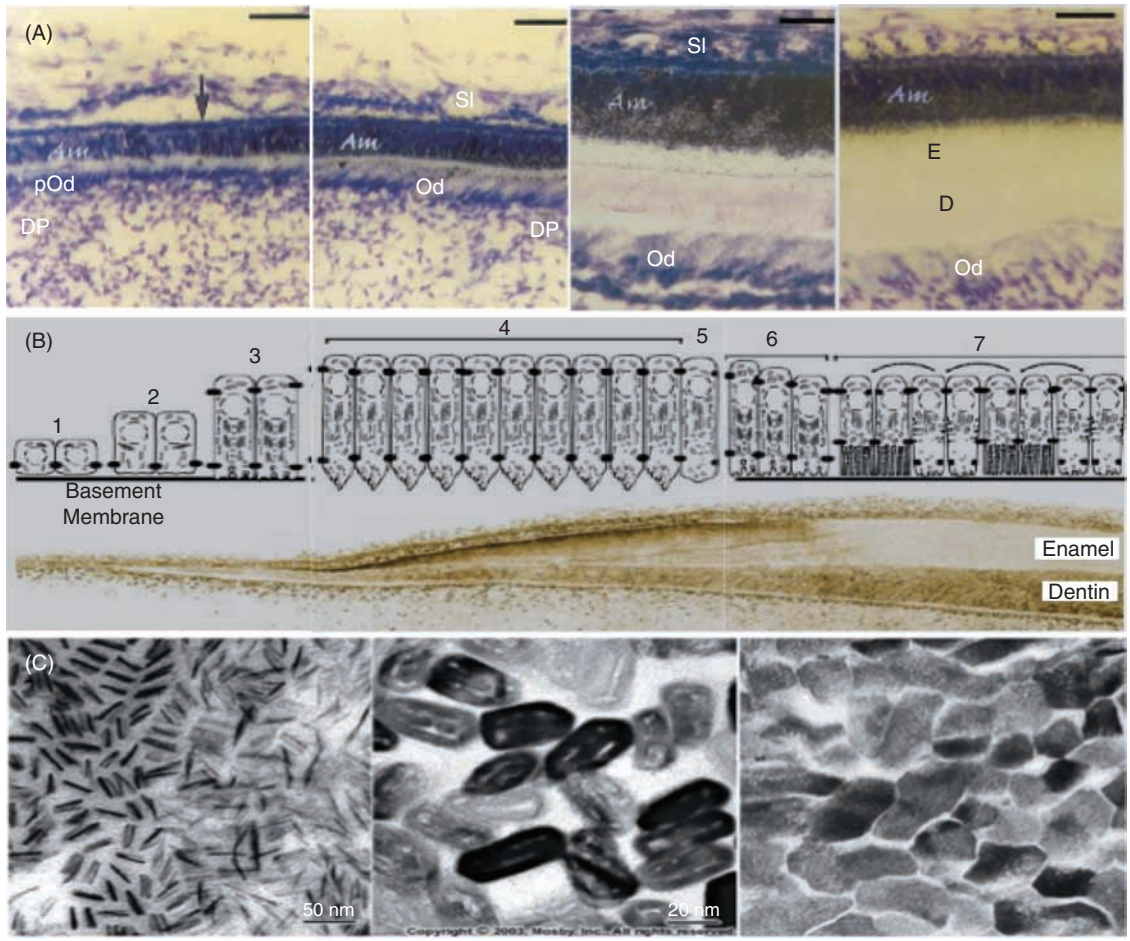

Fig. 109.4. (A) Stage-specific gene expression is a characteristic of amelogenesis. Here, as an example, amelogenin mRNA shows low expression in pre-ameloblasts and maturation stage ameloblasts. In contrast, secretory stage ameloblasts show strong expression of amelogenin mRNA using *in situ* hybridization (black spots). Am: ameloblasts; Od: odontoblasts; pOd: pre-odontoblasts; E: enamel; D: dentin; SI: stratum intermedium. (B) Ameloblast changes during enamel formation. The epithelial cells of the inner enamel epithelium (1) rest on a basement membrane. These cells increase in length as the ameloblasts differentiate above the predentin matrix (2). Presecretory ameloblasts send processes through the degenerating basement membrane as they initiate the secretion of enamel proteins on the dentin surface (3). After establishing the DEJ and mineralizing a thin layer of aprismatic enamel, secretory ameloblasts develop a secretory specialization, or Tomes' process. Along the secretory face of the Tomes' process, in place of the absent basement membrane, ameloblasts secrete proteins at a mineralization front where the enamel crystals grow in length. Amelogenin (Amel), Ameloblastin (Ambn), Enamelin (Enam) and metalloproteinase-20 (Mmp-20) are genes specifically expressed in secretory ameloblasts (4). At the end of the secretory stage, ameloblasts lose their Tomes' processes and produce a thin layer of aprismatic enamel (5). At this point the enamel has achieved its final thickness. During the transition stage of amelogenesis, ameloblasts undergo a major restructuring that diminishes their secretory activity and changes the types of proteins secreted. Carbonic anhydrase II (CA II), calbindin-D 28K (Calb1), alkaline phosphatase, as well as calcium receptor and anion exchanger Ae2 epitopes are preferentially expressed during the maturation stage of enamel formation (6). Kallikrein-4 (KLK4) is secreted in the matrix, which degrades the accumulated enamel proteins, and amelotin (AMTN) is secreted as part of the new basement membrane. During the subsequent maturation stage, ameloblasts modulate between ruffled- and smooth-ended phases (7). Their activities harden the enamel layer by promoting the deposition of mineral on the sides of enamel crystals laid down during the secretory stage. (C) Enamel crystals are very thin at the secretory stage (left panel). Enamel crystals thicken during the maturation stage (center and right panels).

Cementum is deposited initially on the newly mineralized dentin matrix of the root by cells derived from the dental follicle and/or by the epithelial-mesenchymal transition of root sheath epithelial cells [44]. Secretory proteins from the cells of the epithelial root sheath may be included in the first-formed cementum matrix. Embryologically, there are two types of cementum. These are the primary cementum (which is acellular and develops slowly as the tooth erupts) and the secondary cementum (which is formed after the tooth is in occlusion). Where cementum is deposited very rapidly, it is cellular, containing cementocytes that resemble the osteocytes of bone.

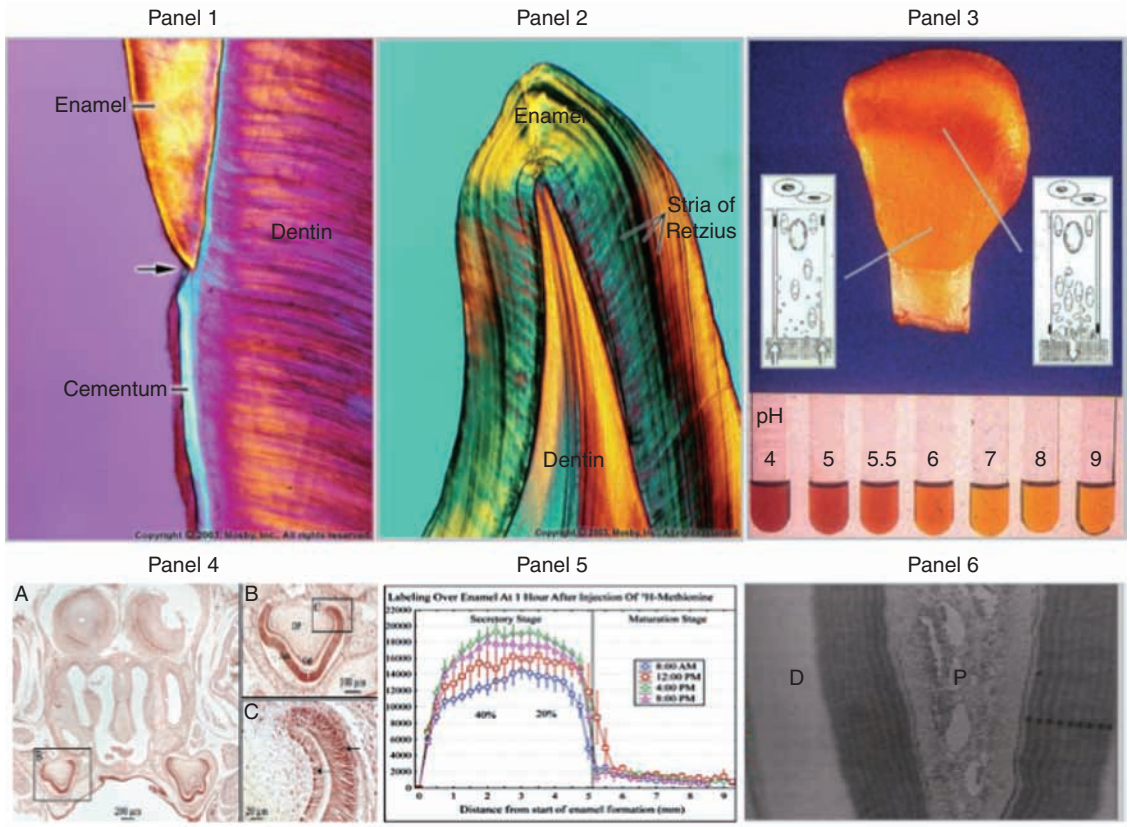

Fig. 109.5. (Panel 1) Enamel, dentin, and cementum constitute the three dental mineralized tissues. All three tissues are controlled by circadian rhythms. (Panel 2) Striae of Retzius (SR) lines also called "long-period incremental lines" are seen in enamel. About seven cross-striations are observed as vertical lines between the SR. (Panel 3) Maturation ameloblasts cycle between ruffle-ended (and smooth-ended) phases. Beneath the ruffle-ended ameloblasts the crystals rapidly mineralize and the pH drops below 6 (red). Beneath smooth-ended ameloblasts, the enamel is neutralized and rises above 7.0 (orange). (Panel 4) Immunohistochemistry of clock protein in a postnatal day 4 mouse. (A) Clock protein expression was detected in the developing first molars. (B) , (C) Higher magnifications showing that the nuclei (arrows) of ameloblasts (AM) and odontoblasts (OD) have strong clock expression relative to the dental pulp (DP) cells. (Panel 5) Daily variation in ameloblast secretion of proteins containing methionine. The graph of means with a ±95% confidence interval illustrates the total amount of newly synthesized proteins released into developing enamel on rat mandibular incisors by 1 hour after a single intravenous injection of 3H-methionine administered at different times of the day. Substantially greater amounts of secretory activity for enamel proteins occur in the late afternoon (4 p.m., diamonds) compared with early morning (8 a.m., circles) throughout the secretory stage. These differences are noticeably larger (up to 40%) for inner enamel formation (distance, 0.5–3.0 mm) than for outer enamel formation (20%). (Panel 6) Similar to enamel, dentin also contains marks of short- and long-period growth lines. Lines of Owen, the equivalent of SR, can be traced over considerable distances and are deposited 6 to 10 days apart in different individuals. A radiograph of a transverse dentin section shows nine densely labeled circumpulpal bands after infusion with labeled proline for 10 days.

The main collagen of both the extrinsic and intrinsic fibers is type I. The non-collagenous proteins of cementum identified are similar to bone matrix proteins making it difficult to distinguish cementum from other calcified connective tissues. So far only the cementum attachement protein (CAP) may be specific to cementum but its specificity is controversial.

During root development, the dental follicle becomes rapidly organized into the PDL that supports the tooth, provides nutrition and mechanosensation, and allows physiological tooth movement. PDL is unique among the various ligament and tendon systems of the body, in the sense that it is the only soft tissue to span between two distinct hard tissues, namely the cementum of the dental root and the alveolar bone [45].

Through the groups of fibers of the periodontal ligament, comprising type I and type III collagen, functioning teeth are linked to each other, the gingiva, and the alveolar bone. The principal fibers of the ligament are incorporated on either side of each root within the cementum and alveolar bone. Within the ligament, there is constant adaptive remodeling of the soft tissue. The PDL collagen fibers are categorized according to their orientation and location along the tooth. The completeness and vitality of the PDL fibers are essential for the functioning of the tooth. Damage to the PDL fibers may result in ankylosis

of the tooth, making the tooth lose its continuous eruption ability. Dental trauma, such as subluxation, may cause tearing of the PDL fibers and pain during mastication. The pathological damage of the periodontal tissues due to inflammatory conditions is termed "periodontitis." This disease may eventually lead to extraction or loss of the adult tooth due to lack of supporting tissue.

The alveolar bone is a part of the periodontal tissues, functioning as an anchorage of the tooth root to the alveoli and resorbing the forces generated by the function of mastication. Progenitor cells, which are responsible for alveolar bone formation, lie in the periosteal region, the PDL, or around the blood vessels. Alveolar bone marrow is considered as a useful and easily accessible source of progenitor cells, as they have similar osteogenic potential to those derived from the iliac crest [46]. The periosteum is also considered a suitable cell source for bone regeneration.

As the permanent tooth erupts, the alveolar bone is resorbed to allow its passage, its root develops, and the crown transverses the oral mucosa that contributes to a tight ring seal of epithelial cells on the enamel close to the junction of crown and root. The complex molecular signaling cascades that control eruption and root growth are unclear. At eruption, the root of the tooth is not yet fully formed, and root completion in humans takes about 18 months more in the deciduous teeth and up to 3 years in the permanent teeth. Cementum in permanent teeth sees little remodeling, but the surface of alveolar bone is continually resorbing and forming to allow the tooth to move in response to eruption, growth drift, or changing functional forces. Resorption of deciduous tooth roots begins shortly after their completion, appearing first and most extensively on the aspect adjacent to the successional tooth.

Circadian formation of dental mineralized tissues

Dental mineralized tissues form by additive modes of growth that preserve within the hard tissues short- and long-period lines of incremental growth. In dental enamel there are two regularly occurring incremental markers: daily cross-striations and long-period striae of Retzius (SR). These lines correspond to what was, at precise points in time during the secretory stage of amelogenesis, the enamel surface (Fig. 109.5, Panel 2). Daily incremental lines (called von Ebner's lines) are also observed in dentin (Fig. 109.5, Panel 6). Cross-striations in enamel and von Ebner's lines in dentin delineate the amount of mineral deposited in a single day. Circadian rhythms have been demonstrated using ^{3}H-proline tracers that label collagen in dentin formation [47]. Twice as much collagen is secreted during the daylight 12 hours as during the night time 12 hours (Fig. 109.5, Panel 6). Similarly to collagen, enamel proteins (Fig. 109.5, Panel 5) and amelogenin show circadian rhythms [48, 49]. Consistently, ameloblasts and odontoblasts strongly express clock genes [50].

Although cementum is laid down centrifugally from the cementum-dentin junction and is marked by incremental lines, close to nothing is known regarding the circadian control of cementum formation.

Elucidating the role of circadian control on dental mineralized tissue formation may help in understanding the phenotypic differences in tooth structure and form among individuals. Altered expression or polymorphisms of clock genes may also be related to dental disease predisposition, as it has shown for other pathological situations such as diabetes and cancer.

STEM CELLS DURING TOOTH REPAIR

Stem cells play a critical role in tissue homeostasis and repair. Their fate is regulated by cell intrinsic determinants and signals from a specialized microenvironment. The reparative mechanisms following dental injury involve a series of highly conserved processes that share genetic programs that occur throughout embryogenesis (reviewed in Ref. 51). In a severe injury, the dying odontoblasts are replaced by stem/progenitor cells, which differentiate into a new generation of odontoblasts that produce the reparative dentin [51]. Signaling molecules released at the injury site may attract dental pulp stem cells and thus initiate the healing process. Notch molecules and nestin are involved in the dynamic processes triggered by pulp injury [51]. Notch expression is activated in cells close to the injury site, as well as in cells located at the root apex, suggesting that these sites represent stem cell niches within the dental pulp. Activation of the Notch molecules in endothelial cells after injury may reflect another pool of stem cells. Epithelial stem cells also exist in human teeth in the root area (Athanassiou et al., unpublished data) and may be implicated in the regeneration of cementum and PDL tissues [52].

CONCLUSION

Elucidating the controls of tooth initiation, pattern, and mineralization necessitates a thorough understanding at the cellular and molecular level. Understanding when and how signaling molecules control these events will open new horizons and create new challenges. Although much has been discovered on the signaling pathways that dictate tooth morphogenesis, very little is known on the control of dental cells differentiation and subsequent matrix formation. Multiscale mathematical modeling of complex pathway interactions during tooth morphogenesis and differentiaion may result in a better understanding of development and diseases [48]. Novel scientific knowledge together with tissue engineering approaches are likely to support development of novel therapies in dentistry.

GENETIC DISORDERS AFFECTING THE DENTITION

The skeleton contains two of the five mineralized tissues in the body: bone and calcified cartilage. The other three mineralized tissues—dentin, enamel, and cementum—are found in teeth. The mineral in each of these hard tissues is a biological apatite resembling calcium hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ in structure, with the most common substitutions being carbonate (CO_3^{2-}) for phosphate (PO_4^{3-}), and fluoride (F^-) for hydroxyl (OH^-). Therefore, disorders involving the regulation of calcium and phosphate metabolism potentially affect multiple hard tissues. In every mineralizing tissue, biomineralization occurs in a defined extracellular space. Establishing these extracellular mineralizing environments involves the synthesis and secretion of extracellular matrix proteins, the transport of ions, and the regulated deposition of mineral. While each mineralizing tissue is in many ways unique, there are common elements that, when defective, lead to pathologies in multiple hard tissues. Changes in the dentition and its supporting oral structures may occur in response to disorders of mineral metabolism. The clinical presentations in these disorders may vary from mild asymptomatic changes to alterations that severely alter the form and function of craniofacial structures. In some cases, the oral phenotype may be the earliest or most obvious sign of a broader syndrome involving bone and mineral metabolism and lead to the original diagnosis. This chapter provides a concise overview of the dental manifestations of selected disorders of bone and mineral metabolism (Table 110.1).

Genetic diseases affecting the number of teeth: Familial tooth agenesis and supernumerary teeth

The initiation of tooth development depends on interactions between oral epithelium and mesenchyme derived from cranial neural crest cells [1]. The initiation step in tooth development is formation of a dental placode, or local thickening of the oral epithelium. Similar ectodermal placodes initiate the development of hairs and nails, as well as the mammary, salivary, sweat, and sebaceous glands [2]. The principal molecular participants in the epithelial-mesenchymal interactions that initiate formation of ectodermal organs are signaling molecules, their receptors, and transcription factors. Some of the specific regulatory molecules involved contribute to the formation of multiple ectodermal organs. Genetic diseases affecting early events in tooth formation typically are manifested as misshapen teeth and by alterations in tooth number, as in supernumerary teeth or familial tooth agenesis. These dental phenotypes may occur in isolation or be associated with other developmental anomalies.

Hypohidrotic ectodermal dysplasia (HED) is an inherited condition featuring missing teeth, thin and sparse hair, missing sweat glands, and defective nails and salivary glands. HED is caused by mutations in ectodysplasin (*EDA*, Xq12-q13.1). In mild cases, hypodontia is the

Table 110.1. Inherited Conditions Affecting the Dentition

Familial Tooth Agenesis	
Isolated (Oligodontia)	*AXIN2* (17q24); *MSX1* (4p16.1); *PAX9* (14q12)
Syndromic	
Hypochidrotic ectodermal dysplasia (HED)	*EDA* (Xq12)
Aplasia of the lacrimal and salivary glands (ALSG)	*FGF10* (5p13)
Lacrimo-auriculo-dento-digital syndrome (LADD)	*FGFR3* (4p16.3); *FGFR3* (4p16.3)
Supernumerary Teeth	
Adenomatous polyposis of the colon (APC)	*APC* (5q21)
Cleidocranial dysplasia (CCD)	*RUNX2* (6p21)
Inherited Dentin & Enamel Defects	
Dentinogenesis imperfecta (DGI) types II and III	*DSPP* (4q21.3)
Dentin dysplasia (DD) type II	*DSPP* (4q21.3)
Amelogenesis imperfecta (AI)	
X-linked AI	*AMELX* (Xp22.3)
Autosomal-dominant AI (ADAI)	*ENAM*(4q13.3)
Autosomal-dominant hypocalcified AI (ADRCAI)	*FAM83H* (8q24.3)
Autosomal-recessive AI (ARAI)	*MMP20* (11q22.3); *KLK4* (19q13.41); *WDR72* (15q21.3)
Mucopolysaccharidosis Type IVA	*GALNS* (16q24.3)
Cherubism	*SH3BP2* (4p16.3)
Vitamin D-Dependent Rickets Type I	*CYP27B1* (12q13.3)
Hypophosphatasia	*ADHR* (12p13), *PHEX*(Xp22.2); *DMP1* (4q21)
Hypophosphatasia	*ALPL* (1p36.1)

only phenotype [3]. Several related syndromes are caused by mutations in *FGF10* (5p13) and its receptors (i.e., *FGFR3*, 4p16.3), such as aplasia of the lacrimal and salivary glands (ALSG) [4] and lacrimo-auriculo-dento-digital syndrome (LADD) [5]. LADD features aplasia or hypoplasia of the lacrimal and salivary systems associated with a variety of dental phenotypes: agenesis of the lateral maxillary incisors (hypodontia), small (microdontia) and peg-shaped laterals, mild enamel dysplasia, and delayed tooth eruption.

Especially noteworthy among the genetic disturbances affecting early tooth formation are those that disrupt the Wnt signaling system. Wnt signaling is processed by a cytosolic complex of proteins consisting of axis inhibition protein 2 (AXIN2), glycogen synthase kinase-3β (GSK-3ß) and adenomatous polyposis coli (APC), which dephosphorylate and stabilize β-catenin. β-catenin translocates into the nucleus and regulates the activity of key transcription factors. Mutations in *APC* (5q21-q22) cause adenomatous polyposis of the colon, a syndrome featuring radiopaque lesions in the jaw, that are composed of clumped toothlets (odontomas) and gastrointestinal polyps that usually undergo malignant change by the fourth decade [6]. *AXIN2* (17q24) mutations cause a severe form of familial tooth agenesis also associated with gastrointestinal polyps that turn malignant by the fourth decade [7]. *APC* and *AXIN2* phenotypes are inherited in an autosomal dominant pattern. The discovery of odontomas or familial tooth agenesis on panorex radiographs should raise concerns about gastrointestinal polyps, especially when the oral phenotype appears to have arisen spontaneously (not observed in either of the parents), as the family will not show a history of intestinal cancer.

Familial tooth agenesis occurs in the absence of other phenotypic features [8]. Msh homeobox 1 (*MSX1*, 4p16.1) and paired box 9 (*PAX9*, 14q12-q13) express interacting transcription factors that are critical for the progression of tooth development beyond the bud stage [9, 10]. Mutations in *MSX1* and *PAX9* cause similar patterns of familial tooth agenesis, with *PAX9* mutations being more likely to include second molars, while *MSX1* mutations are more likely to include maxillary first bicuspids among the teeth missing [11].

Cleidocranial dysplasia is an autosomal dominant condition featuring skeletal and dental anomalies, caused by mutations in the transcription factor gene *RUNX2* (6p21). The most notable feature is hypoplasia or aplasia of the clavicles, permitting abnormal apposing of the shoulders. Exfoliation of the primary dentition is delayed or fails, and multiple supernumerary teeth, which typically fail to erupt, are observed on dental radiographs [12].

Genetic diseases affecting dentin: Osteogenesis imperfecta, dentinogenesis imperfecta, and dentin dysplasia (DD)

Defects in either the alpha 1 chains or alpha 2 chain of type I collagen can cause osteogenesis imperfecta or OI

(see Chapter 99). OI is associated with assorted dentin defects that are collectively designated as dentinogenesis imperfecta (DGI) [13]. In rare cases, the dentin defects are the only prominent phenotype in OI [14]. It has been reported that 10–50% of patients afflicted with OI also have dentinogenesis imperfecta (DGI). This assessment, however, may underestimate the true prevalence, since mild forms of DGI may require microscopic analysis for diagnosis [15]. The range of dental defects observed in OI are similar to those observed in kindreds with DGI and dentin dysplasia (DD).

The most abundant non-collagenous proteins in dentin are proteolytic cleavage products of a large chimeric protein known as dentin sialophosphoprotein (DSPP). The N-terminal cleavage product is dentin sialoprotein (DSP), a proteoglycan with both N- and O-linked glycosylations and two glycosaminoglycan attachments [16, 17]. The C-terminal cleavage product is dentin phosphoprotein (DPP), a highly phosphorylated protein with the lowest (most acidic) isoelectric point (approximately 1) of any known protein [18]. DPP is thought to participate in the nucleation of hydroxyapatite crystallites on collagen [19]. To date, 35 different *DSPP* (4q21.3) mutations have been shown to cause DD-type II, DGI-type II, and DGI-type III [20]. The dentin defects appear to result from pathology caused by the mutant protein, rather than from a loss of DSPP function [21].

The clinical classification system most often used to categorize inherited defects of dentin was established over 30 years ago, prior to recent discoveries concerning their genetic etiologies, and divided the phenotypes into two disease groups with five subtypes: dentinogenesis imperfecta (DGI, types I–III) and dentin dysplasia (DD, types I and II), with all forms showing an autosomal dominant pattern of inheritance [22]. Type I DGI is a collective designation for OI with DGI and has largely been abandoned in deference to the current OI classification system. An alternative designation for isolated inherited dentin defects is hereditary opalescent dentin [23]. Type II DGI is the most prevalent inherited dentin phenotype. Clinically, the teeth of individuals with DGI are characterized by an amber-like appearance (Fig. 110.1). The teeth are narrower at the cervical margins and thus exhibit a bulbous or bell-shaped crown. Microscopic anomalies of affected dentin include fewer and irregular dentin tubules containing vesicles and abnormally thick collagen fibers [24]. The mineral content of DGI teeth is reduced, being about 30% less than normal dentin. Intrafibrillar collagen mineralization is absent. The structurally abnormal dentin may not provide adequate support for the overlying enamel. The enamel is usually chemically and structurally normal in individuals with DGI and a lack of support from dentin leads to fracturing and severe attrition of the teeth, the distinguishing clinical feature of type II DGI. Type III DGI is a rare form that is also known as the "Brandywine isolate," after the prototype kindred identified in Brandywine, Maryland. This form features multiple pulp exposures in the deciduous teeth, which show considerable variation radiographically, ranging from shell teeth, to normal pulp chambers, to pulpal obliteration. The permanent teeth are the same as in type II DGI. In type I dentin dysplasia both the permanent and deciduous teeth appear to have a normal shape and color clinically. Dental radiographs, however, show the teeth have short roots with periapical radiolucencies in non-carious teeth (Fig. 110.2). The primary teeth show total obliteration of the pulp. Type II dentin dysplasia appears to be a mild form of type II DGI, featuring amber tooth coloration with total pulpal obliteration in the primary teeth and a thistle-tube pulp configuration with ubiquitous pulp stones and normal to near normal coloration in the permanent teeth [22, 25, 26].

Fig. 110.1. Dental manifestations of teeth from a patient with dentinogenesis imperfecta. The permanent teeth of this patient exhibit the characteristic blue-gray or opalescent appearance associated with dentinogenesis imperfecta.

Fig. 110.2. Radiograph of teeth from a patient with dentin dysplasia type I. The roots are abnormally short or absent (arrows) and the pulp chamber is obliterated (courtesy of Dr. Sharon Brooks).

Genetic diseases affecting enamel: Amelogenesis imperfecta

Amelogenesis imperfecta (AI) is a heterogeneous group of isolated inherited defects in the enamel layer of teeth [27]. The enamel may be thin, soft, rough, and/or pigmented. When the various enamel phenotypes and the pattern of inheritance are considered, 14 subtypes are recognized [28]. Enamel formation is regulated by a toolbox of specialized extracellular matrix molecules. Amelogenin (*AMELX*, Xp22.3) mutations cause X-linked AI, with females showing vertical bands of normal and defective enamel, while males usually have little or no enamel at all [29]. Enamelin (*ENAM*, 4q13.3) mutations cause autosomal dominant AI, with distinctive horizontal bands often evident in the cervical third of the crown [30]. Truncation mutations in the last exon of *FAM83H* (family with sequence similarity 83 member H; 8q24.3) cause autosomal-dominant hypocalcified AI (ADHCAI) [31]. Mutations in WD (tryptophan-aspartate, a two-amino-acid sequence that is commonly found in the conserved domain of this family of proteins) repeat-containing protein 72 (*WDR72*; 15q21.3) and the genes that encode the proteolytic enzymes enamelysin (*MMP20*, 11q22.3) and kallikrein 4 (*KLK4*, 19q13.41) cause autosomal recessive AI, featuring relatively soft, pigmented enamel, usually of normal thickness, that may tend to chip off during function [32–34]. AI has also been used to describe enamel defects associated with inherited syndromes. There are over 70 such conditions. Recently it has been learned that recessive mutations in the metal ion transporter cyclin M4 (*CNNM4*; 2q11) cause cone-rod dystrophy and AI [35, 36] and mutations in family with sequence similarity 20 member A (*FAM20A*; 17q24.2) cause AI and gingival fibromatosis syndrome [37].

Mucopolysaccharidoses

Lysosomal storage disorders comprise over 50 inherited diseases that are caused primarily by defects in genes encoding lysosomal enzymes [38]. Among the lysosomal storage disorders are the mucopolysaccharidoses (MPS), which are characterized by the accumulation of partially degraded glycosaminoglycans (previously called mucopolysaccharides) within lysosomes, as well as in the urine. There are 10 enzymes involved in the stepwise degradation of glycosaminoglycans, and deficiencies in these activities give rise to the MPS. There are seven MPS types: I, II, III, IV, VI, VII, and IX (types V and VIII have been retired, and type IX is extremely rare). Although heterogeneous, several craniofacial characteristics are similar between the different types. The oral manifestations may include a short and broad mandible with abnormal condylar development and limited temporomandibular joint function. The teeth are often peg-shaped and exhibit increased interdental spacing, perhaps due to the frequently observed gingival hyperplasia and macroglossia. Some forms of MPS have abnormally thin enamel covering the clinical crowns or radiographic evidence of cystic lesions surrounding the molar teeth that contain excessive dermatan sulfate and collagen [39–42].

Mucopolysaccharidosis type IVA (Morquio A syndrome, MPS IVA) is an autosomal recessive disorder caused by deficiency of the lysosomal hydrolase, N-acetylgalactosamine 6-sulfatase (GALNS), encoded by a gene on human chromosome 16q24.3 [43]. Mucopolysaccharidosis type IVA is the only MPS associated with dental enamel malformations [44], although mucopolysaccharides accumulate in the developing teeth in other MPS syndromes, such as Hurler (MPS I) [45], Hunter (MPS II), and Maroteaux-Lamy (MPS VI) syndromes. In MPS IVA, enamel malformations are a consistent feature. The enamel is dull gray in color, thin, pitted, and tends to flake off from the underlying dentin. The thin enamel layer is of normal hardness and radiodensity. MPS IVA patients often show severe bone dysplasia and dwarfism. The identification of the genes involved and the invention of new molecular biology tools are leading to the development of specific enzyme replacement therapies (ERTs) for some of the mucopolysaccharidoses [46].

Cleft lip and palate

Cleft lip and/or palate are relatively common craniofacial malformations (1 in 700 births) that can have profound impact on nutritional, speech, dental, and psychological development. The causes of these disorders are complex and are known to involve both genetic and environmental factors. Most of these facial clefting birth defects are multifactoral and non-syndromic. Although genetics may play a role in the cause of cleft lip and/or palate, they are not associated with well-defined syndromes. Between 15% and 50% of cleft lips and/or palates are associated with defined syndromes. In fact, there are nearly 300 recognized syndromes that may include a facial cleft as a manifestation. However, only about 10 genes have been identified as associated with these syndromes. Common syndromes with cleft palates include Apert's, Stickler's, and Treacher Collins. Van der Woude's and Waardenberg's syndromes are associated with cleft lip with or without cleft palate. In at least one condition—Van der Woude's syndrome—a haplotype gene test may be used to identify variants in the interferon regulatory factor 6 gene and provide a correlation with an increased risk of facial clefting [47].

Cherubism

Cherubism is an autosomal dominant condition caused by mutations in *SH3BP2* (4p16.3) [48]. SHF3BP2 expresses

a protein that binds to c-Abl, a tyrosine kinase involved in diverse cell signaling cascades. In patients with cherubism, multiple cystic giant cell lesions of the jaw appear typically between 2 and 5 years of age. The cysts replace bone and cause enlargement of the maxilla and mandible, which stabilizes or remits after puberty. Teeth are displaced during development, with root resorption, tooth agenesis, retention of deciduous teeth, ectopic eruption, and malocclusion observed as sequelae [49].

ORAL MANIFESTATIONS OF METABOLIC BONE DISEASES OF GENETIC ORIGIN

Metabolic diseases of bone are disorders of bone remodeling that characteristically involve the entire skeleton and are often manifest in the oral cavity, which can lead to the diagnosis of the underlying systemic disease. Numerous studies suggest that subclinical derangements in calcium homeostasis and bone metabolism may also contribute to a variety of dental abnormalities including alveolar ridge resorption and periodontal bone loss in predisposed individuals. The significance of this spectrum of diseases and their overall impact on oral health and dental management are likely to increase as the elderly segment of the population increases in the coming decades [50].

Vitamin D deficiency

In vitamin D-resistant rickets (see Chapter 75), the primary oral abnormality is similar to dentin dysplasia. Enamel is usually reported to be normal, but in some instances may be hypoplastic. Patients also suffer from delayed tooth eruption, and radiographically, teeth often display enlarged pulp chambers. Other salient radiographic findings include decreased alveolar bone density, thinning of bone trabeculae, loss of lamina dura, and retarded tooth calcification [51].

Vitamin D-dependent rickets type I is an autosomal recessive defect in vitamin D metabolism caused by mutations in the *CYP27B1* gene (12q13.3-q14) encoding 25-hydroxyvitamin D-1-alpha-hydroxylase. Decreased $1,25(OH)_2D$ results in teeth with yellow-brown color, pitted enamel, short roots, and a tendency to develop chronic periodontal disease [52].

Hypophosphatemia

Phosphorus homeostasis is incompletely understood and regulated by the actions of many hormones, including parathyroid hormone (PTH), calcitonin, and Vitamin D. Recently, however, a new set of important phosphate-regulating factors have been discovered. Fibroblast growth factor 23 (FGF23) is secreted by osteocytes into the circulation and inhibits phosphate reabsorption and $1,25(OH)_2D$ production by the kidney. Specific defects in the FGF23 gene (*ADHR*, 12p13) cause autosomal dominant hypophosphatemic rickets, although deletion of the gene encoding FGF23 in mice causes hyperphosphatemia. PHEX, an endopeptidase, and dentin matrix protein 1 (DMP1), a proteoglycan involved in bone mineralization, are synthesized by osteocytes and both inhibit FGF23 expression. Mutations in *PHEX* (Xp22.2) and *DMP1* (4q21) cause X-linked and autosomal recessive hypophosphatemia, respectively [53–55]. It is increasingly clear that autosomal dominant, autosomal recessive, and X-linked hypophosphatemia involve various aspects of a common pathophysiologic mechanism that reduces phosphate reabsorption by the renal tubuli and lowers $1,25(OH)_2D$ levels. This leads to chronic hyperphosphaturia and hypophosphatemia, and causes rickets in children and osteomalacia in adults [56].

In familial hypophosphatemia (see Chapter 74), dental findings are often the first clinically noticeable signs of the disease and resemble those seen in rickets and osteomalacia. Patients may present with abscessed primary or permanent teeth that have no signs of dental caries [57]. Although the enamel is reported to be normal, microbial infection of the pulp is thought to occur through invasion of dentinal tubules exposed by attrition of enamel or through enamel microfractures [58]. A better understanding of the mechanisms of phosphate homeostasis is providing new insights into the genetic etiologies of hypophosphatemias [59].

Hypophosphatasia

Hypophosphatasia is an inherited disorder caused by a defect in the alkaline phosphatase (*ALPL*, 1p36.1-p34) gene. Osteoblasts show the highest level of ALPL expression, and profound skeletal hypomineralization occurs in the severest forms of hypophosphatasia. The hard tissue that appears to be most sensitive to an *ALPL* defect is cementum [60]. The classic oral presentation of childhood hypophosphatasia is the premature loss of fully rooted primary teeth (Fig. 110.3). Histological examination indicates that these teeth lack cementum on their root surface, so that the attachment apparatus fails to develop properly. The periodontal ligament fibers do not connect the alveolar bone to the root and the teeth exfoliate prematurely. In the permanent teeth, large pulp spaces, late eruption and delayed apical closure are often observed. Bone loss is primarily horizontal, and in the adult form of the disease there may be widespread dental caries.

The URL for data presented herein is as follows:

Online Mendelian Inheritance in Man (OMIM), http://www.ncbi.nlm.nih.gov/Omim/

Fig. 110.3. Exfoliation of fully rooted primary teeth in hypophosphatasia. Oral photographs show the dental condition of a patient with childhood hypophosphatasia at age 6. The maxillary cuspid and incisor (upper right) were brought by the parents to the visit and had fallen out naturally about 2 years previously. This patient also showed periodontal attachment problems in her primary posterior teeth, which were mobile. Some childhood hypophosphatasia patients present with enamel hypoplasia. These dental findings are diagnostic of childhood hypophosphatasia and are often the first symptoms leading to the diagnosis (contributed by Dr. Jan C-C Hu).

INTRODUCTION

The mandible and maxilla are unique among the bones in that they contain an overlying osseous structure—the alveolar process—that functions, in the adult, to support 32 highly specialized hard tissue organs, the teeth. The teeth, composed of unique hard tissues that are not found anywhere else in the body (enamel, dentin, and cementum), develop through a process involving sequential and reciprocal interactions between oral epithelium and ectomesenchyme. By necessity, because growth of the jaws requires the sequential formation of two sets of dentition, this process occurs over a period extending from the fetal period to the late teens.

As a result of the unique developmental processes involved in the formation of teeth and the fact that these specialized mineralized tissues are continuously exposed to the harsh oral environment, the mandible and maxilla are home to a distinctive set of pathologic entities. This chapter provides a concise review of the more common and interesting of these entities: tooth demineralization, dental caries, and odontogenic cysts and tumors.

TOOTH DEMINERALIZATION AND CARIES

Dental caries ("tooth decay") is one of the most prevalent chronic diseases affecting modern society. Once viewed as a disease primarily of children, it has become evident that as a result of the reduction in tooth loss over the past 30 years, adults today are equally as susceptible as children to developing dental caries [1, 2, 3].

The caries process represents the end result of a complex interaction between transmissible cariogenic oral microflora, primarily *Streptococcus mutans* and *Lactobacillus* spp., and fermentable dietary carbohydrates [4]. Oral microflora, vertically transmitted to the child through the mother, colonize the teeth through a process involving adhesion of bacterial surface proteins to salivary products adsorbed on the enamel surface [5]. Through the action of *Streptococcus mutans*-derived glucosyl transferase, an adherent extracellular polysaccharide matrix composed of water insoluble glucan is produced [4]. Within this dental biofilm, refined carbohydrates such as sucrose are metabolized, resulting in lactic acid production. The resultant drop in pH at the biofilm–tooth interface results in dissolution of the mineral component of the tooth. This process is a dynamic one, in which demineralization is countered by remineralization as the local pH level returns to normal through the buffering capacity of saliva. During the remineralization phase, diffusion of phosphate and calcium ions back into the hydroxyapatite mineral component of the tooth predominates. The progression of caries results when the rate of demineralization exceeds that of remineralization (Fig. 111.1).

In addition to the frequency and duration of exposure to fermentable dietary carbohydrate, other factors involved in an individual's risk of developing caries include the virulence of the specific pathogenic geno-

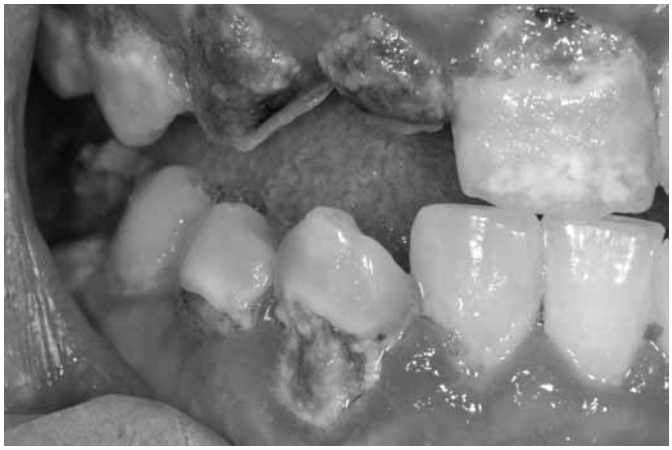

Fig. 111.1. Patient with rampant caries. This patient was a chronic methamphetamine abuser [6].

types of colonizing *S. mutans*, host immune response, and the buffering capacity and protein and mineral composition of saliva [7]. By disrupting the tooth surface biofilm, oral hygiene practices such as brushing and flossing can reduce the caries risk.

On exposure to trace quantities (approximately1 ppm) of fluoride ion, fluoridated hydroyapatite and fluorapatite are formed. These are significantly more resistant to acid dissolution than hydroxyapatite. Studies [2] suggest that the overall magnitude of caries reduction afforded by fluoride averages 25% in both children and adults, whether delivered professionally in the form of a fluoride gel or foam, self-administered in toothpaste, or by community water fluoridation.

Although the caries process in the heavily mineralized enamel outer layer of the tooth is primarily a physicochemical process, the underlying dentin contains approximately 20% organic matrix, primarily type I collagen and a smaller component of non-collagenous proteins. Continued acid dissolution of the mineralized component of dentin results in exposure of the organic matrix to enzymatic degradation by both bacterial collagenases and host-derived matrix metalloproteinases [8]. The presence of tubules within the dentin, through which odontoblast cell processes extend from the dental pulp, results in the formation of a tightly integrated "dentin-pulp complex." Inflammation within the confined space of the pulp cavity, either as a result of direct extension of bacteria into the pulp tissue, or by secondary strangulation of venous blood flow, may lead to pulpal necrosis. Inflammatory mediators resulting from degradation products of bacteria and necrotic pulp tissue lead to the formation of a mass of chronically inflamed granulation tissue and associated bone destruction at the apex of the non-vital tooth root (a "periapical granuloma").

CYSTS AND TUMORS OF THE JAWS

Origin

Jaw lesions can be categorized as being of odontogenic origin, referring to those that involve or recapitulate structures involved in the development of the teeth, or of nonodontogenic origin. By definition, odontogenic cysts and tumors are unique to the oral and maxillofacial region.

During tooth development, a thin epithelial structure from which the individual teeth ultimately form, termed the "dental lamina," arises from an ingrowth of surface epithelium into the underlying connective tissue [9]. Remnants of these structures are believed to be the source of the epithelium involved in the formation of many of the developmental odontogenic cysts. The molecular events involved in the development of the odontogenic neoplasms remain poorly understood [10, 11].

Clinical and radiographic presentation

The vast majority of odontogenic cysts and tumors originate in the tooth-bearing areas of the jaws (e.g., above the inferior alveolar nerve canal in the mandible) and are characterized by replacement of bone by soft tissue or, less commonly, a mixture of soft and hard tissue. In the absence of secondary infection or significant expansion, odontogenic cysts and tumors typically cause no symptoms and are usually identified following routine radiographic examination of the jaws (Figs. 111.2(A) and (B)).

The radiographic and clinical presentations of these lesions, though often characteristic, are not pathognomonic. As with extragnathic bone lesions, correlation of the radiographic features with the histopathologic findings is often required in order to arrive at a definitive diagnosis.

Odontogenic cysts

Odontogenic cysts can be further subclassified into inflammatory cysts and those of developmental origin.

Inflammatory odontogenic lesions

Periapical granuloma and periapical cyst

Both the periapical granuloma and the periapical (radicular) cyst are common, slow-growing lesions that develop at the apex or mid-root area of teeth exhibiting pulpal necrosis, usually representing the end result of caries extending into the pulp or as a result of previous trauma to the dental pulp. Continued bone destruction can lead to cortical bone perforation [Fig. 111.3(A)] and the formation of a mass of acute and chronically inflamed granulation tissue in the oral cavity [a "parulis"; Fig. 111.3(B)]. The periapical granuloma, consisting of a localized

Fig. 111.2. The dentist's typical armamentarium of radiographic techniques includes intraoral dental radiographs supplemented with extraoral panoramic imaging. (A) Intraoral radiograph (periapical film) demonstrating the outline of the mandibular anterior teeth and surrounding alveolar bone. A unilocular radiolucent lesion with a well-defined corticated border is evident in the center of the radiograph at the apices of the incisors. The left lateral incisor (arrow) was non-vital. The differential diagnosis was periapical cyst versus granuloma. (B) Extraoral panoramic radiography provides a complete overview of the maxillary and mandibular bones and neighboring structures. This radiographic technique is widely used as a screening tool. This panoramic radiograph, taken on an 18-year-old patient, reveals the presence of unerupted third molars ("wisdom teeth"). A small well-defined radiolucent area with corticated borders is evident around the crown of the maxillary left third molar (arrow). As the width of the radiolucent area is less than 4 mm and the associated third molar has not completed its root development, this most likely represents a normal dental follicle surrounding the developing tooth.

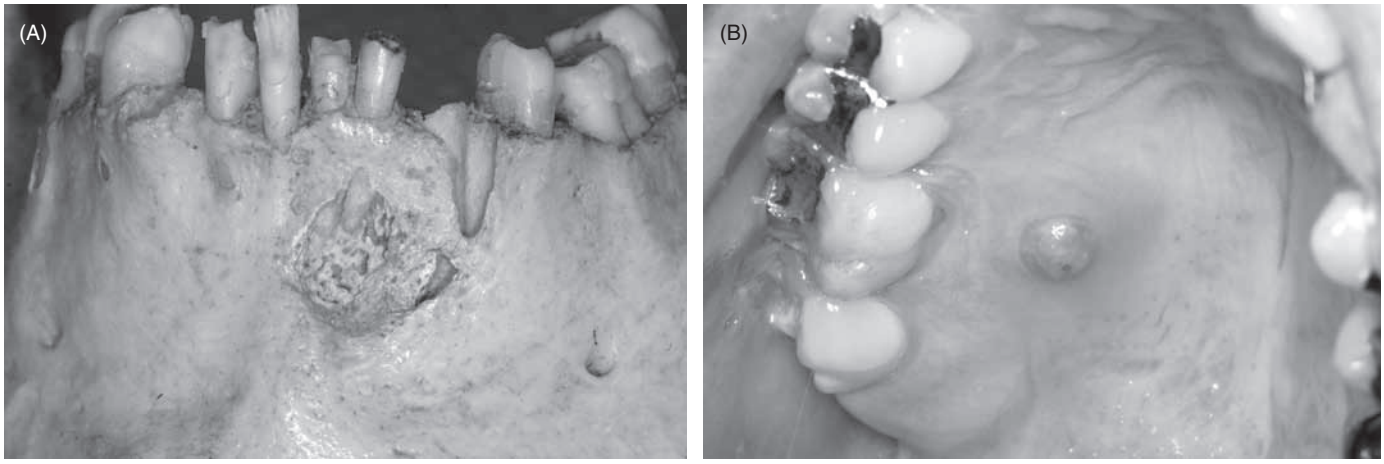

Fig. 111.3. (A) Cadaveric mandible with loss of buccal cortical plate. The crowns of the mandibular incisors are fractured, presumably resulting in pulpal necrosis and the subsequent development of a periapical granuloma or cyst. (B) 25-year-old male with a necrotic right maxillary first molar presented with a soft tissue nodule composed of acute and chronically inflamed epithelial-lined granulation tissue ("parulis") overlying the palatal root. The palate is an uncommon location for the development of a parulis, as these typically are noted on the buccal aspect of the alveolar process. In this case, the clinical differential diagnosis would also include a soft tissue neoplasm of salivary or connective tissue origin.

collection of chronically inflamed granulation tissue, is the precursor to the periapical cyst. In the presence of inflammatory mediators, cytokines, and growth factors released from mononuclear inflammatory cells and neighboring stromal cells as a result of the degradation of products from the necrotic pulp, residual epithelial cell rests involved in initial tooth formation are stimulated to proliferate [12]. Although the mechanism is poorly understood, the end result is the formation of a cystic lining (a "periapical cyst").

Non-vital teeth with periapical radiolucencies suggestive of a periapical granuloma or cyst are definitively treated by extraction of the causative tooth with conservative curettage of any lining from the cyst cavity. Failure to excise the cyst lining can lead to continued cyst expansion, termed a "residual cyst." When sufficient tooth structure remains to allow for restoration of the tooth, nonsurgical endodontic treatment, in which the degradation products are mechanically removed from the pulp chamber and canals, is usually the preferred treatment approach. If endodontic therapy is performed, the patient should be followed radiographically to confirm bone regeneration. In extremely rare cases, the epithelial lining of a periapical cyst or residual cyst can undergo malignant transformation [13].

Developmental odontogenic cysts

Dentigerous cyst

The dentigerous ("follicular") cyst, a slow-growing lesion capable of causing significant destruction of bone, is only seen in association with the crown of an unerupted ("impacted") tooth. The third molar and maxillary canine teeth are most commonly involved, since these teeth are the last to come into the mouth in the normal tooth eruption sequence, and consequently are the teeth most prone to being prevented from erupting as a result of crowding [14].

Treatment involves enucleation of the cyst lining, usually with extraction of the associated impacted tooth. Rarely, the cyst lining can undergo transformation into an odontogenic tumor, most commonly a cystic ameloblastoma [15], or, rarely, a squamous cell carcinoma [16].

Odontogenic keratocyst ("keratocystic odontogenic tumor")

The odontogenic keratocyst (OKC) demonstrates a preference for the posterior mandible and is characterized by a tendency to cause significant bone destruction if untreated and a high recurrence rate after conservative treatment [Figs. 111.4(A), (B)] [17]. OKCs range in size from small unilocular radiolucent lesions, sometimes associated with an impacted tooth, to destructive multilocular lesions involving large areas of the mandible or maxilla.

Approximately 5% of OKCs are associated with the nevoid basal cell carcinoma syndrome (NBCCS, Gorlin syndrome), an autosomal dominantly inherited condition. Additional stigmata include the development of multiple basal cell carcinomas of the skin at an early age, the presence of small pit-like developmental defects in the palms of the hands and plantar surfaces of the feet, and an increased incidence of neoplasms including medulloblastoma and meningioma [18]. NBCCS is associated with germline loss of function mutations in the *patched-1* (*PTCH1*) gene, a tumor suppressor gene that is a component of the sonic hedgehog pathway [19].

Similar *PTCH1* mutations have been documented in approximately 30% of sporadic, non-syndrome-associated OKCs [20, 21]. Recently, the World Health Organization has recommended that the OKC be renamed "keratocystic odontogenic tumor" to emphasize its aggressive, neoplastic-like behavior [22]. Additional findings supportive of a neoplastic nature include the demonstration of increased proliferative activity in the epithelial lining [23] and loss of heterozygosity at loci associated with the *p16* and *p53* tumor suppressor genes [24]. However, this proposed change in terminology has yet to be been universally accepted. Arguments offered against reclassifying the OKC as a "benign cystic neoplasm" is the documentation of *PTCH1* mutations in other developmental odontogenic cysts [25], the suggestion that molecular genetic criteria alone are not necessarily sufficient to define neoplasia, and, most significantly, that histologically, the OKC remains an epithelial-lined pathologic cavity of developmental origin.

Treatment options vary from marsupialization and decompression prior to definitive treatment, to surgical curettage with adjuvant cryotherapy or chemical fixation, to complete surgical resection [26]. Some surgeons choose to treat maxillary lesions more aggressively than mandibular lesions due to the greater risk of recurrent lesions spreading into neighboring vital structures. Recurrences have been documented up to 10 years after treatment [27].

Lateral periodontal cyst

The lateral periodontal cyst (LPC) is an uncommon lesion with limited growth potential that is often overlooked in the clinical differential diagnosis of a radiolucency occurring along the lateral root surface of an anterior tooth [28]. In contrast to the periapical cyst, there is no causal relationship to pulpal necrosis. Treatment involves conservative debridement of the lesion with preservation of the associated tooth. In order to avoid unnecessary endodontic therapy or tooth extraction, assessment of pulpal vitality of all teeth with associated radiolucent lesions is recommended.

Glandular odontogenic cyst

The recently described [29] glandular odontogenic cyst (GOC) is a rare lesion (one study [30] documented only 11 cases among 55,000+ oral cavity biopsies) with histologic features reminiscent of both the lateral periodontal cyst and mucoepidermoid carcinoma, a malignant salivary gland neoplasm rarely identified in the jaws. The

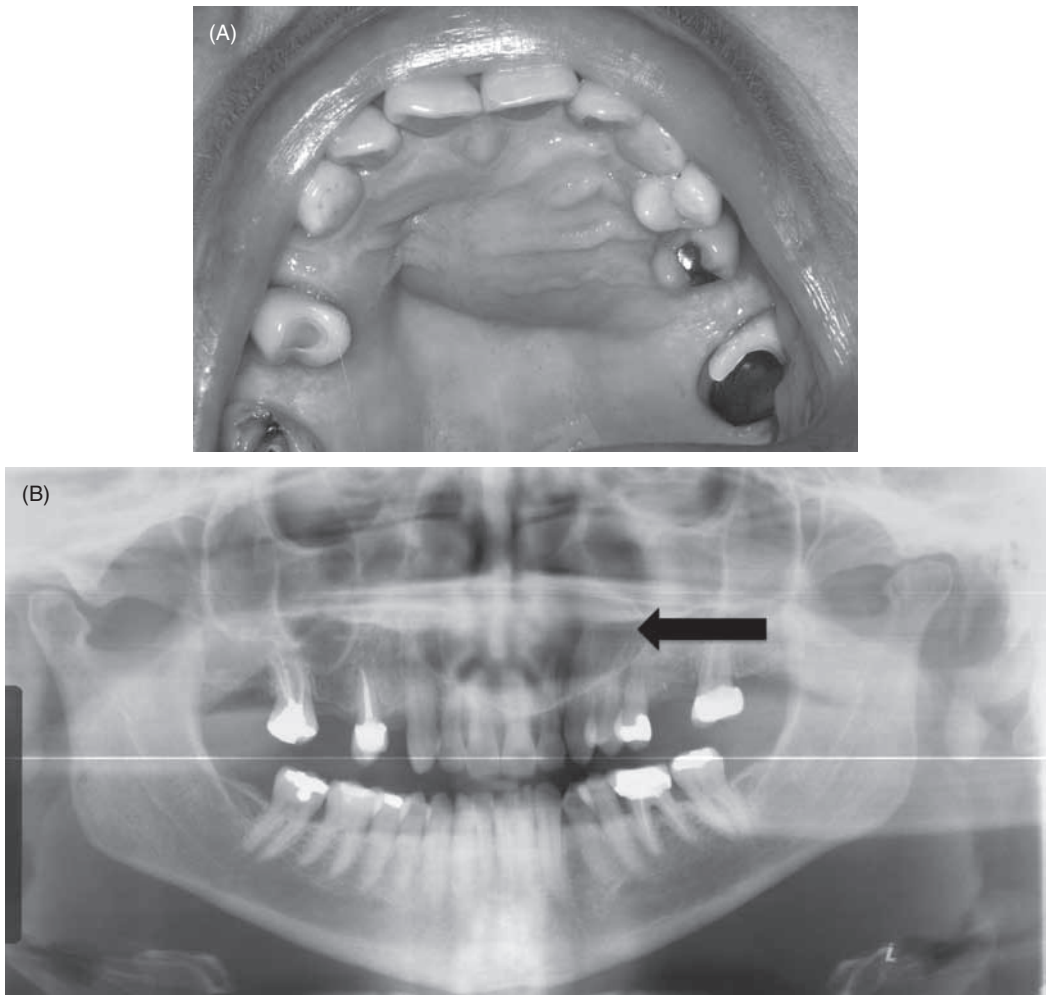

Fig. 111.4. (A) Fifty-six year old woman presents with a palatal expansion resulting from an odontogenic keratocyst ("keratocystic odontogenic tumor") that had been untreated over a 4-year period. (B) Panoramic radiography reveals a large well-defined corticated radiolucent lesion extending from the maxillary right canine to the left second premolar area [arrow; same patient as in (A)].

majority of GOCs occur in the anterior mandible, often crossing the midline [31]. The GOC exhibits a wide spectrum of clinical behavior, ranging from a benign process to a destructive lesion with features more suggestive of a malignant process.

Odontogenic tumors

Benign odontogenic tumors of the jaws

Ameloblastoma

The ameloblastoma is a locally destructive tumor with a propensity to cause significant cortical expansion, a marked predilection for the posterior mandible, and a high rate of recurrence [32]. Its incidence has been estimated at 0.3–2.3 new cases per million persons per year [33].

The unicystic ameloblastoma, seen predominantly in teenagers at an average 20 years earlier than the conventional ameloblastoma, represents a cystic version of the conventional ameloblastoma, possibly associated with a lower risk of recurrence [34]. Often associated with an impacted mandibular third molar, it is frequently mistaken radiographically for a dentigerous cyst.

Malignant odontogenic tumors

Malignant counterparts to the benign odontogenic tumors are extremely rare [35]. They commonly present as destructive lesions with irregular, poorly defined radiographic margins. Pain, paresthesia, and a tendency for early lymph node metastasis are characteristic. More commonly, malignancies involving the jaws originate by direct extension from neighboring soft tissue (e.g., oral squamous cell carcinoma), represent metastatic lesions from extraoral sites (especially breast, colon, and prostate carcinoma), or are of primary nonodontogenic origin. Rarely, maxillary sinus malignancies can mimic pain of dental origin [36].

Nonodontogenic tumors of the jaws

Central giant cell granuloma

A large number of nonodontogenic cysts, pseudocysts, and tumors also occur in the jaws. Among these is a lesion unique to the jaws: the central giant cell granuloma (CGCG). Interestingly, histologically identical lesions are seen in a number of other conditions including cherubism and hyperparathyroidism. Syndromes associated with an increased incidence of CGCG-like lesions include Noonan syndrome [37, 38] and neurofibromatosis type-1 [39, 40].

The classic CGCG is a variably aggressive non-neoplastic reactive lesion with an estimated incidence of 1.1 per million persons per year in the general population [41]. The CGCG is characterized histologically by the presence of multinucleated giant-cells (MGCs) in a background of spindle-shaped mesenchymal cells. The MGCs are usually concentrated in areas of hemorrhage and are believed to develop from the fusion of mononuclear phagocytes [42]. Although they share similarities with the osteoclast [43], phenotypic differences exist [44]. Intraosseous hemorrhage and abnormal repair of bone have been suggested as potential etiologic factors [45] in light of the observation that CGCGs are occasionally noted in association with other preexisting bone lesions such as fibrous dysplasia and ossifying fibroma [46].

Isolated lesions are commonly treated by surgical curettage. Treatment options for large or multiple lesions include intralesional corticosteroid injection [47], subcutaneous or intranasal administration of calcitonin [48], and therapy with interferon alpha-2a [49].

DEFINITION OF BISPHOSPHONATE-ASSOCIATED OSTEONECROSIS OF THE JAWS

Bisphosphonate-associated osteonecrosis of the jaws (BONJ) is a clinical entity that was first reported in the literature in several case series in 2003, although the earliest case reported to the U.S. Food and Drug Administration was in 1989 [1–4]. Of the over several thousand cases that have been reported in the literature, the vast majority are in patients with multiple myeloma and metastatic cancers (from the breast, prostate, and lung) to the skeletal system who were treated with intravenous bisphosphonates; however, this condition has been identified (albeit far less frequently) in patients with osteoporosis treated only with oral formulations [4–8]. All cases have affected either the maxilla or the mandible, except for several single case reports involving other bones including the external auditory canal, thumb, and middle ear/base of skull [9–11]. The strong association between bisphosphonate use and osteonecrosis of the jaws is now well accepted, and appropriately designed prospective research is ongoing.

The American Association of Oral and Maxillofacial Surgeons (AAOMS) has published a working definition for BONJ in which the following three characteristics must be fulfilled: (1) current or previous treatment with a bisphosphonate; (2) exposed, necrotic bone in the maxillofacial region that has been present for at least 8 weeks; and (3) no history of radiation therapy to the jaws [12]. Stage 0 BONJ is defined as cases without exposed necrotic bone with nonspecific symptoms or clinical and/or radiographic abnormalities that are highly suggestive of BONJ such as pain, sinus tracts, and other signs or symptoms that cannot be attributed to an odontogenic infection [13, 14]. The AAOMS definition excludes such conditions as poorly healing dental extraction sites (e.g., alveolar osteitis, or "dry socket"), benign sequestration of the lingual plate, necrotizing periodontitis, noma, and osteoradionecrosis [15–20]. The American Society for Bone and Mineral Research has the same definition for *confirmed* cases; *suspected* cases fulfill all the criteria of a *confirmed* case except that the exposed bone has been present for fewer than 8 weeks [21]. These definitions are a critical initial step toward promoting uniform reporting for research and epidemiological reporting purposes, and may need to be revised as new diagnostic parameters come to light. Application of such criteria in well-designed prospective studies will help to move research forward [22]. At the present time, we rely on a good patient history, clinical examination, and imaging studies for the diagnosis of BONJ.

ETIOLOGY

The etiopathogenesis has been attributed primarily to suppression of bone turnover (due to bisphosphonate-induced inhibition of osteoclast activity and apoptosis) coupled with conditions that are unique to the mandible and maxilla. First, the jaw bones are separated from the oral cavity and commensal microflora by only a very thin mucosal barrier that is readily breached during normal physiologic functions (e.g., chewing). Second, the jaws are involved frequently by infection either through the periodontium (i.e., periodontal disease) or endodontically, through the dental pulp (i.e., caries extending into the pulp chamber, through the roots, and into the bone). Third, dentoalveolar surgical procedures are common (e.g., tooth extractions and periodontal surgeries) during which bone is damaged and exposed to a bacteria-rich environment. Fourth, at least in certain animal models, the rate of turnover of the jawbones is higher than for the long bones, which, if true in humans, may result in greater uptake and higher local concentrations of bisphosphonates [23, 24]. With profound osteoclast inhibition, the hypodynamic bone may be unable to respond to repair processes associated with physiologic trauma or infection, although how this mechanistically translates into bone necrosis is still unclear. The fact that tooth sockets in patients who develop BONJ may be evident years after extraction is further evidence that bone turnover and remodeling in these areas are severely compromised [25]. Microdamage accumulation may play a role in the pathogenesis although the exact mechanism is unclear [26–28].

There is evidence that bisphosphonates have antiangiogenic properties that may also contribute to poor wound healing [29–31]. Bisphosphonates have long been known to cause direct epithelial toxicity in the digestive tract, and it has recently been proposed that bisphosphonate-induced soft tissue injury may also be a contributing factor in the development of BONJ [32–38].

Several BONJ animal models have been developed, and although none of these models mimic all aspects of BONJ in humans, they may help to better elucidate the underlying driving factors that lead to necrosis [34, 39–41].

RISK FACTORS AND PREVALENCE

Several risk factors for BONJ have been identified. One of the most consistently observed is the use of nitrogen-containing bisphosphonates and in particular zoledronic acid, which is the drug of choice for treating multiple myeloma and metastatic cancers in the U.S. due to its shorter infusion time and equivalent clinical efficacy compared to pamidronate. Patients with cancer on zoledronic acid alone have a 9.1 to 15 times the risk of developing BONJ as compared to a 1.6–4 times risk when pamidronate is followed by zoledronic acid [42–44]. The cumulative dose of bisphosphonates, particularly intravenous preparations, is probably the single most important factor, with the risk increasing over time; one study showed cumulative hazard of 1% in the first year of treatment with zoledronic acid, and 15% at 4 years [45]. The median time of treatment with zoledronic acid to development of BONJ in patients with cancer ranges from 9 to 30 months (although cases have been reported after only 3 months) and appears to be significantly shorter when compared with other agents [5, 44–46]. The route of administration is also important, but this is likely a surrogate factor for the use of pamidronate and zoledronic acid, both of which are administered intravenously, have high potency, and are used more frequently in the oncologic population.

Approximately 60% of cases have a preceding history of tooth extraction or other oral surgical procedures [47–49] but only 0.5% of extractions result in BONJ [50]. It is unclear to what extent preexisting infection (e.g., periodontal and dental disease), the most common indication for dentoalveolar surgery, may be a contributing factor [5, 47, 51, 52]. In some cases, it is likely that a preexisting, evolving BONJ lesion was what caused a tooth to become painful and mobile in the first place, necessitating extraction, so that the process of tooth removal exposes necrotic bone.

Additionally, nonsurgical trauma appears also to be a risk factor, as many cases occur on the mylohyoid ridge of the lingual mandible (where the mucosa is especially thin and susceptible to masticatory forces), on tori, and in patients wearing dentures, with no associated dental infection or history of oral surgical procedure [53]. Genetic markers and risk factors are being studied [54–56]. The role played by conditions associated with poor healing such as the presence of cancer, use of other immunosuppressive agents, concomitant use of thalidomide or bortezomib in patients with myeloma, vitamin D deficiency, and diabetes have yet to be clearly elucidated [57–59].

Prevalence estimates based on retrospective chart reviews range from 2–11% in the oncology population [42, 44, 60–63]. More recently reported prospectively collected data have suggested that the true incidence is closer to 2–3% [64]. The prevalence of BONJ in those taking oral bisphosphonates has been reported to be between 1 in 2,260 to 8,470, or 0.1–0.5% [65–67]. However, some of these figures do not differentiate between those taking oral and intravenous bisphosphonates. The median time of development of BONJ in patients with osteoporosis is 3.5 years [67]. The hazard ratio for jaw surgery and inflammatory jaw conditions/osteomyelitis after exposure to intravenous (IV) bisphosphonates versus non-exposure is 3.15 and 11.48, respectively [68]. The odds ratios for patients with osteoporosis treated with oral compared with IV bisphosphonates who developed BONJ was 0.65 and 4.01, respectively, and for those requiring jaw surgery, 0.86 and 7.80, respectively [69].

CLINICAL PRESENTATION

BONJ presents with exposed, yellowish-white necrotic bone that varies in size from a few millimeters to several centimeters. The exposed bone may have rough and sharp edges, or may be smooth. The mandible is more frequently affected than the maxilla (2:1) and lesions are more common in areas with very thin mucosa overlying bony prominences such as mandibular and maxillary tori, bony exostoses, and the mylohyoid ridge which are also typically considered sites with high trauma risk (Fig. 112.1) [4, 70]. In some cases, osteonecrosis is associated with bone expansion, in particular affecting tori, putatively attributed to excess bone deposition without accompanying remodeling (Fig. 112.2) [71]. Lesions often develop in sites of previous dental extractions (Fig. 112.3); however in many cases, there is no antecedent surgical procedure (Fig. 112.4). The bone may project outward, causing trauma to the adjacent soft tissue. Loose bone fragments in the process of sequestration may also cause pain due to soft tissue irritation. Teeth that are located within the necrotic bone often become progressively mobile and symptomatic and may spontaneously exfoliate. Pathologic fractures of the mandible may occur in severe cases with extensive involvement; however, this is an infrequent complication [4, 48]. Approximately 60% of cases report some pain at initial presentation; however, many cases may remain asymptomatic for weeks, months, or years [4, 47, 48, 63]. Not surprisingly,

Fig. 112.1. BONJ of the left mandibular torus with healthy-appearing surrounding soft tissue.

Fig. 112.3. BONJ in the area of a nonhealing mandibular premolar extraction site. The surrounding soft tissue is healthy appearing.

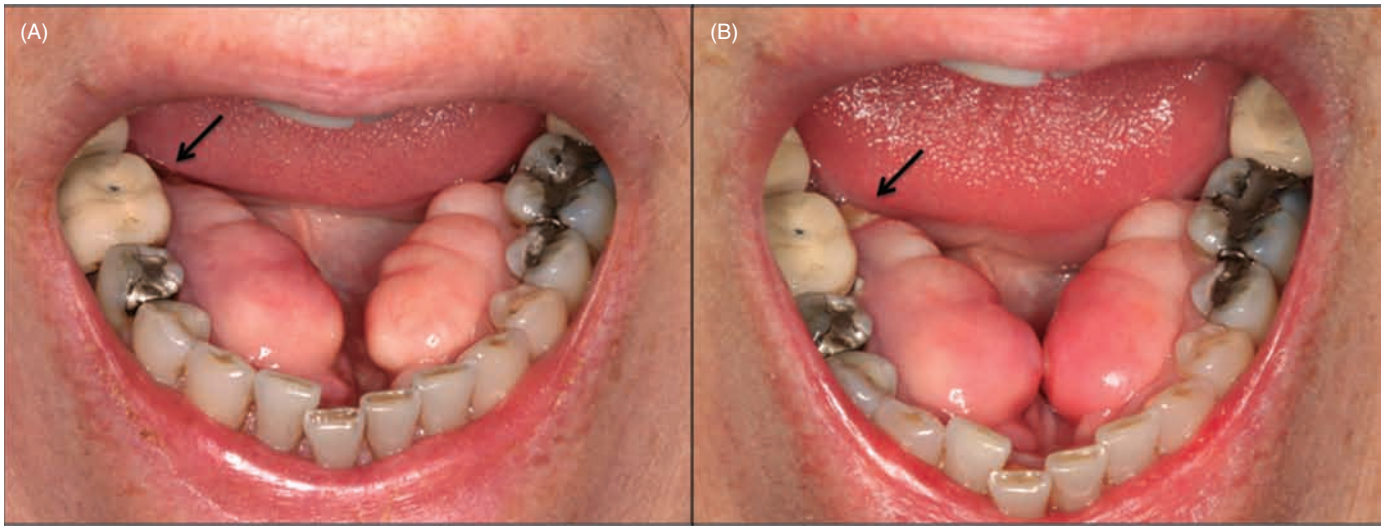

Fig. 112.2. (A) BONJ of the right mandibular torus at the time of diagnosis, and (B) 1 year later, demonstrating bony expansion bilaterally with a small area of exposed bone (arrows).

patients with BONJ have a diminished quality of life that is directly related to the severity of the condition [72].

The necrotic bone is more often than not superficially colonized by normal oral flora, similar to teeth being colonized by dental plaque, forming a biofilm [73]. The most common colonizing pathogens are Actinnomycetes and Eikenella [74, 75]. Infection of the bone leads to pain and suppuration, and osteomyelitis may ensue. The surrounding soft tissue may become erythematous and edematous, sometimes with an associated purulent discharge with intraoral or even extraoral sinus tract/fistula formation. Secondary maxillary sinusitis, with or without an oral-antral fistula, may be the initial presenting symptom in those with maxillary involvement (Fig. 112.5) [4, 70]. Symptoms of paresthesia and anesthesia may develop as the local neurovascular bundle (e.g., inferior alveolar nerve) becomes affected by inflammation or infection around the necrotic bone, in addition to nerve compression due to narrowing of canal/foramen by bone deposition [76].

Fig. 112.4. Spontaneous area of BONJ of the right posterior maxilla arising in an area of preexisting periodontal disease.

RADIOGRAPHIC AND HISTOLOGIC FINDINGS

A number of radiographic signs have been identified in BONJ from both plain films and more advanced imaging studies [e.g., computed tomography (CT) and magnetic resonance imaging (MRI)] [77–82]. These include osteosclerosis, osteolysis, mottling, thickening or loss of the lamina dura, widening of the periodontal ligament space, sequestrum formation, and persistent extraction sockets (Fig. 112.6) [25, 79, 80, 83]. Radiographic changes often mimic periapical pathology, severe periodontal infection, and banal osteomyelitis. In cancer patients, radiographic changes may raise the suspicion of myeloma or metastatic bone disease [84]. As a bone biopsy may induce BONJ, this is only indicated when there is a strong clinical suspicion of metastatic disease and/or if the diagnosis will alter clinical management.

Intraoral periapical radiographs and panoramic radiographs provide high resolution and readily demonstrate evidence of BONJ, especially when disease is advanced [79, 81]; however, they fail to detect many early changes or mild disease and are limited in their ability to evaluate extent of involvement due to their two-dimensional nature. While CT scans provide more accurate three-dimensional information regarding the extent of changes, these also have not proved useful for early detection in

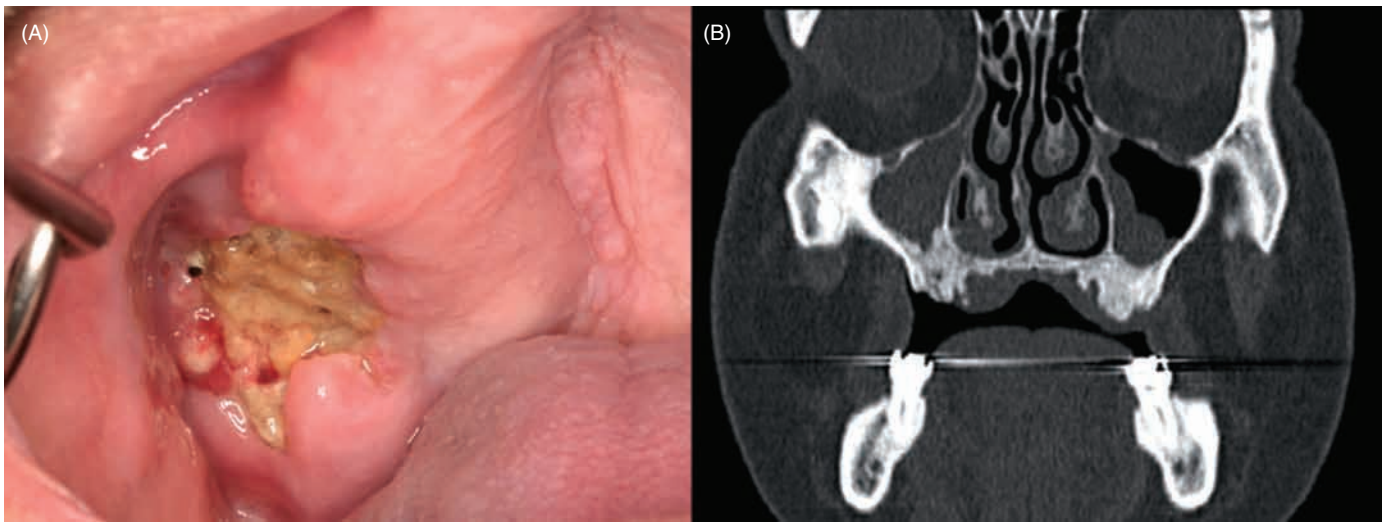

Fig. 112.5. (A) Extensive BONJ of the right posterior maxilla with associated soft tissue infection and purulence. (B) CT scan, with mottled right maxillary alveolar process and complete opacification of the right and partial opacification of the left maxillary sinuses.

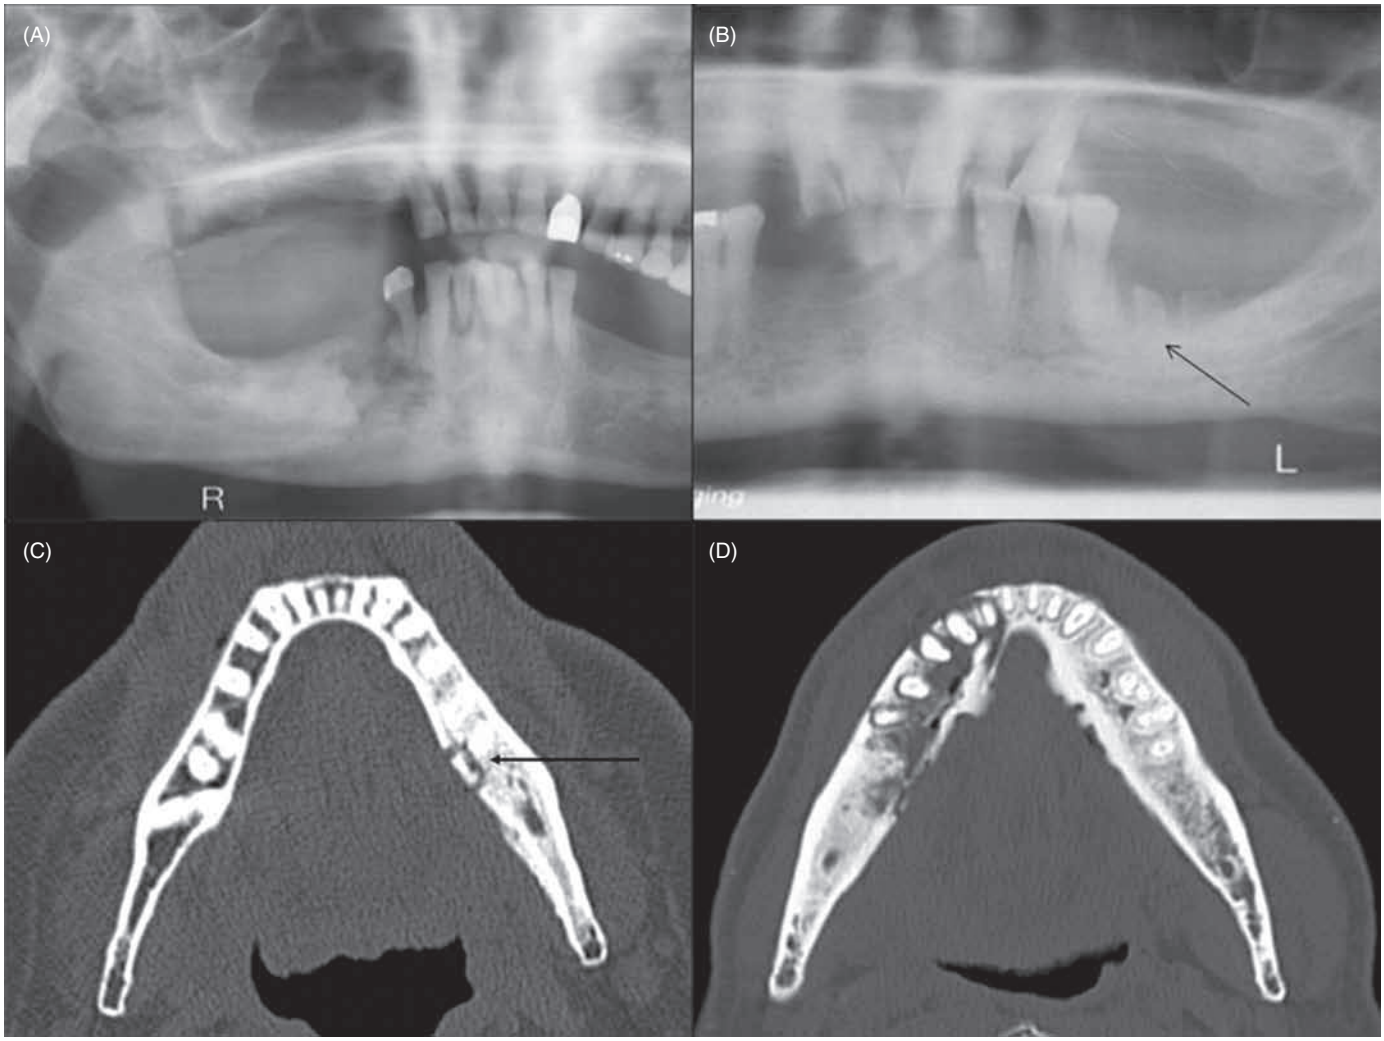

Fig. 112.6. Radiographic features of BONJ. (A) Panoramic radiograph demonstrating a mixed radiolucent and radiopaque lesion of the right mandible with a larger area of diffuse osteosclerosis. (B) Panoramic radiograph demonstrating a persistent extraction socket of the left mandible years after extraction. (C) Axial CT scan of the mandible demonstrating sclerosis with lingual sequestrum formation (arrow). (D) Axial CT scan of the mandible demonstrating extensive sclerosis and mottled changes.

asymptomatic individuals [74, 79, 82]. Head and neck cone beam CT is an imaging modality that uses approximately 10% of the radiation of conventional spiral CT and has acceptable resolution for diagnosis of BONJ [82]. MRI may be of some utility in evaluating the marrow and associated soft tissue changes but is not useful for interpreting bony pathology [79]. Nuclear medicine techniques have demonstrated that Tc-99m is not taken up in clinical areas of BONJ (although these may be positive in early or subclinical BONJ); however, ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) and NaF-PET scans integrated with CT may demonstrate focal uptake, indicating ongoing bone formation despite osteoclastic suppression [55, 79, 80]. The precise role for these imaging modalities in risk assessment, diagnosis, and clinical management remains to be determined.

Histopathologic examination of debrided bone fragments demonstrates necrotic bone often with extensive surface bacterial colonization, and granulation tissue, all nonspecific findings (Fig. 112.7) [85–87]. In spite of inhibition of osteoclastic activity, abnormal, giant osteoclasts are present in the vicinity of the necrotic bone [87, 88]. Bacterial cultures from the exposed surface or purulent discharge typically reveal normal oral flora [86, 89]. Actinomycetes are a normal component of the oral flora, and their identification, histopathologically or microbiologically, must be carefully interpreted. A diagnosis of actinomycosis should only be made if the culture was obtained from a sterile location (i.e., a nonexposed surface), if pain and suppuration/sinus tracts are present, and/or if sulfur granules are noted either clinically or histologically [90].

MANAGEMENT

Management of BONJ is focused primarily on preserving quality of life by controlling pain and discomfort, managing infection, avoiding procedures that may lead to the development of new areas of necrosis, and encouraging sequestration of the bone and reepithelialization of the mucosa. Published treatment algorithms/guidelines are principally based on expert opinion consensus and not prospective studies [12, 70, 83, 91]. A clinical staging system has been developed to categorize patients, guide treatment and collect data (Table 112.1) [12].

Patients on bisphosphonate therapy without BONJ

For those exposed to bisphosphonates, whether oral or IV, but without BONJ, management is directed toward optimizing dental health by educating patients regarding their risk for developing BONJ, evaluating for odontogenic infections (through clinical examination and full mouth intraoral and panoramic radiographs), and treating areas of active odontogenic infection.

For patients on IV therapy for oncologic indications, elective surgeries should be avoided if possible. When surgical procedures are necessary, patients should be followed closely postoperatively for any signs of infection or poor healing until the area is completely healed [92]. For patients on oral or IV bisphosphonates for nononcologic indications, the AAOMS guidelines suggest no alteration in planned surgery for patients who have had less than 3 years of exposure to oral bisphosphonates, unless there has also been concomitant therapy with corticosteroids [12].

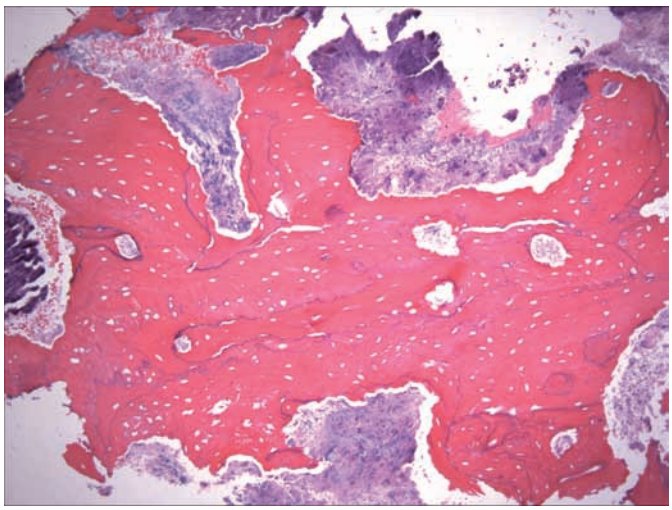

Fig. 112.7. Photomicrograph of necrotic bone with surface bacterial colonization (hematoxylin and eosin, magnification 100x).

Patients on bisphosphonates therapy with BONJ

When sharp edges of necrotic bone traumatize the adjacent soft tissue, or when fragments are mobile, conservative nonsurgical sequestrectomy and/or smoothing of the involved bone provides symptomatic relief. When signs and symptoms of infection are present (i.e., inflamed surrounding soft tissue, purulence, and sinus tracts), management with both systemic antibiotics (e.g., penicillin, amoxicillin/clavulanate, clindaymycin, or metronidazole) and topical antimicrobial agents (chlorhexidine gluconate) are effective in reducing or eliminating signs and symptoms. However, long-term daily antibiotic therapy for several months may be necessary to prevent recurrence of infection in patients prone to relapse, and a subgroup of patients may require IV antibiotic therapy.

Surgical intervention has typically been reserved for those cases that are refractory to medical management with significant associated morbidity [4, 12]. Surgical management includes localized debridement and in some cases more aggressive resection of involved necrotic bone, and recent reports have demonstrated successful outcomes, with 87–100% of cases showing complete soft

Table 112.1. The American Association of Oral and Maxillofacial Surgeons Clinical Staging System for Bisphosphonate-Associated Osteonecrosis of the Jaw

Stage 0	Stage 1	Stage 2	Stage 3
No clinical evidence of exposed necrotic bone; presence of nonspecific clinical findings, and symptoms including sinus tact, localized periodontal pocket, and jaw pain	Exposed, necrotic bone that is asymptomatic	Exposed, necrotic bone associated with pain and infection	Exposed, necrotic bone with pain, infection, and one or more of the following: • pathologic fracture • extraoral fistula • osteolysis extending to the inferior border

tissue healing with variable follow-up periods [93–96]. One study demonstrated no statistical difference in outcomes when comparing surgical debridement alone for cases that failed antimicrobial therapy compared with antimicrobial therapy alone [97]. In addition to surgery and antimicrobial therapy, a number of other ancillary treatments have been reported primarily as case reports and small uncontrolled case series. These include hyperbaric oxygen therapy [98, 99] topically applied autologous platelet derived growth factor with surgery, low-level laser therapy, ozone therapy, pentoxifylline and tocopherol therapy, and teriparatide therapy [100–108]. Further research is necessary to better evaluate the potential benefits of these therapies.

Complete resolution of BONJ occurs in 18–53% of cases with or without intervention [5, 6, 14, 49, 109, 110]. However, it should be borne in mind that even if there is epithelialization and normalization of the visible mucosa, in most cases, the defect in the underlying bone does not change for months or years so that the term "complete resolution" should be interpreted with care.

Drug holiday and bisphosphonate dose reduction

Long-term discontinuation of IV bisphosphonates may be beneficial in stabilizing established lesions although it is unclear whether it prevents the development of new lesions because of the approximately 10-year half-life of the drug [12, 109]. Two studies showed that patients who discontinued bisphosphonate therapy demonstrated stabilization or resolution of BONJ compared to those who did not when followed for at least 6 months [5, 98, 111, 112]. Furthermore, animal studies have shown that epithelial healing is improved if bisphosphonates are discontinued for 2 weeks [35, 113]. Regardless, due to the growing recognition of BONJ as a potentially serious clinical complication of bisphosphonate therapy, a number of institutions have modified treatment protocols and reduced the dose and/or frequency of infusions according to disease signs and symptoms [114–118].

At this time, monitoring of patients consists primarily of history and periodic examination. Radiographic evaluation may be of some utility in assessing progression over time. There have been no controlled studies of serologic markers for bone turnover such as bone specific alkaline phosphatase, N-telopeptide cross-linked (NTX) and C-telopeptide cross-linked (CTX) that show a statistically significant relationship with the development of BONJ [5, 50, 119]. Furthermore, such measurements reflect remodeling activity in the entire skeletal system and not the jaws alone, and there is wide variation within the population. Similar to treatments for BONJ, prospective controlled studies that demonstrate the usefulness and cost-effectiveness of using such markers are necessary before their clinical application can be justified [12].

OSTEONECROSIS OF THE JAW ASSOCIATED WITH NON-BISPHOSPHONATE MEDICATIONS

Recent reports indicate that osteonecrosis may also occur in association with novel agents used in the treatment of osteoporosis and malignancies such as denosumab and bevacizumab. Denosumab is a human monoclonal antibody to receptor activator of nuclear factor-κB ligand (RANKL) that was FDA approved for the management of osteoporosis and metastatic cancer [120]. In a phase 3 study of denosumab compared to zoledronic acid in prostate cancer patients, the reported cumulative incidence of osteonecrosis with denusumab was 1% compared to 2% with zoledronic acid, further suggesting a key role for osteoclast suppression in the pathogenesis of BONJ [121].

Antiangiogenic agents, including bevacizumab, sunitinib, and sorafenib, which have been used in management of cancer patients, have been linked to osteonecrosis of the jaw [122, 123], especially when combined with bisphosphonates [123–127]. Further investigation of the potential role of antiangiogenic agents in the pathobiology of osteonecrosis is needed.

INTRODUCTION

Periodontal diseases constitute a variety of inflammatory conditions affecting the health of the periodontium. The primary etiological component is bacterial-derived plaque accumulation around teeth. The two major categories of periodontal diseases are gingivitis and periodontitis, which are distinguished from one another based upon the extent of tissue loss that directly supports the teeth. Gingivitis is limited to the soft tissues surrounding the teeth where the extension has not caused any bone loss whereas periodontitis is characterized by soft tissue and alveolar bone loss resulting in decreased supporting structures for the teeth.

ETIOLOGY

Although more than 500 bacterial species have been identified within the oral cavity, plaque-associated periodontal diseases are associated with a relatively narrow subset of periodontal pathogens [1]. Susceptibility to these mixed infections is often highly variable host immune response to these pathogens. Both genetic and environmental factors can influence the immune response and modify susceptibility to infection (Fig. 113.1). Periodontal pathogens produce harmful products and enzymes (e.g., hyaluronidases, collagenases, proteases) that break down extracellular matrices such as collagen as well as host cell membranes in order to produce nutrients for their growth [2] and subsequent tissue invasion (see Fig. 113.2). Many of the microbial surface proteins and lipopolysaccharide (LPS) molecules are responsible for eliciting an immune response in the host resulting in local tissue inflammation [3]. *P. gingivalis*, *A. actinomycetemcomitans*, and other periodontal pathogens possess multiple virulence factors such as cytoplasmic membranes, peptidoglycans, outer membrane proteins, LPS, capsules, and cell surface fimbriae (with *P. gingivalis*) [4]. Once immune and inflammatory processes are initiated, various inflammatory molecules such as proteases, matrix metalloproteinases (MMPs), cytokines, prostaglandins, and host enzymes are released from leukocytes, gingival fibroblasts, osteoblasts, or other tissue-derived cells [5, 6]. Proteases can degrade the collagen, permitting leukocyte infiltration [7]. Although the production of collagenase from infiltrating neutrophils and other resident periodontal tissues is part of the natural host response to infection, in periodontal disease there is an imbalance between the level of activated tissue-destroying MMPs and their endogenous inhibitors [8, 9].

The inflammatory infiltrate from the gingival tissue can initiate tissue and alveolar bone destruction through the activation of several proinflammatory cytokines, including interleukin (IL)-1β, tumor necrosis factor-α (TNFα), and IL-6. Within the diseased periodontal tissues, activated osteoclasts are an integral component of bone destruction [10, 11]. Multiple inflammatory signals have

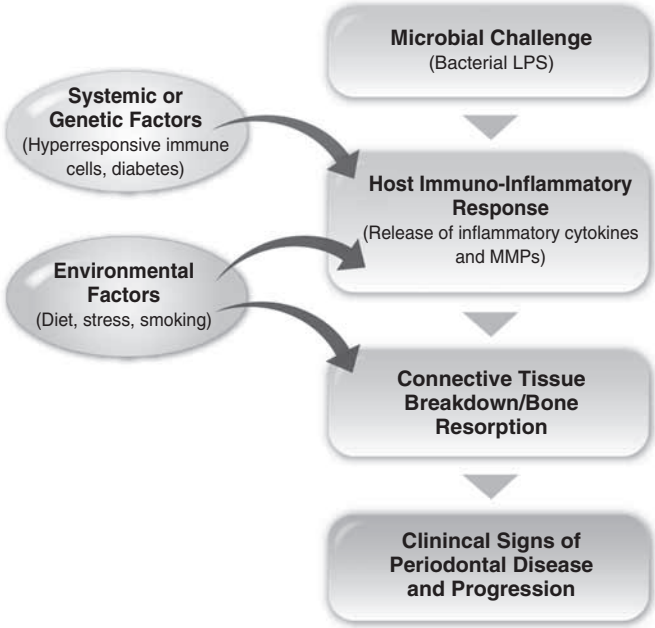

Fig. 113.1. Etiology of periodontal disease progression and factors that impact the disease progression. Periodontal diseases can occur when periodontal pathogenic bacteria is present in a susceptible host. Genetic and environmental factors modify the host immune response toward bacteria, initiating tissue and bone destruction manifested as periodontitis.

been shown to modulate the receptor activator of nuclear factor-κB ligand (RANKL), RANK, or osteoprotegerin (OPG) within periodontal tissues [12]. In the presence of periodontal pathogens (e.g., *A. actinomycetemcomitans*), $CD4^+$ T cells display increased expression of RANKL, triggering the activation of osteoclasts that leads to bone loss [13]. As long as the subgingival plaque persists, and this increase in microbial density propagates, the destructive periodontal lesion will remain. As the pocket deepens, the flora becomes more anaerobic, and the host response becomes more destructive and chronic. Periodontal tissue destruction can result in tooth loss if left unabated [14, 15].

DIAGNOSIS AND CLASSIFICATION OF PERIODONTAL DISEASES

Despite our current appreciation regarding the etiology and progression of periodontal diseases, the diagnosis and classification is still made from clinical assessments [16, 17]. Information routinely collected includes medical history and history of previous/current periodontal problems, along with a thorough clinical exam. Clinical parameters of inflammation (e.g., bleeding upon probing into the periodontal sulcus), pocket depth measurements, clinical attachment levels, evidence of plaque/calculus, and tooth mobility are used to arrive at a clinical diagnosis. Radiographic assessments of the extent of bone loss are primary criteria to determine if bone loss has occurred.

Plaque-induced gingival diseases have traditionally been divided into two general categories: gingivitis and periodontitis [16]. Gingivitis is characterized by inflammation without any loss of periodontal supporting structures (i.e., connective tissue and bone), whereas the hallmark of periodontitis is pathological detachment of connective tissue leading to the resorption of alveolar bone support around teeth. In 1999, the International Workshop of Periodontal Diseases and Conditions recognized a new classification system of seven different forms of plaque induced periodontal diseases [17]. See Table 113.1 for the classification and differences between the various types of periodontal diseases. Table 113.2 shows the diagnosis of periodontal diseases.

TREATMENT

In general, periodontal therapy is directed toward the reduction and elimination of inflammation, thereby allowing the gingival tissue to heal. Both personal and professional maintenance is critical in preventing the recurrence of inflammation. Since gingivitis is defined as a reversible condition where no bone loss has been documented, therapy for gingivitis is usually limited plaque removal and personal plaque control instructions.

Therapy for periodontitis varies considerably depending upon the severity of attachment loss, anatomical location variations, along with type of periodontitis and the therapeutic objectives [18]. Since periodontitis destroys the supporting alveolar bone and surrounding connective tissues, therapy is directed toward arresting the progression of ongoing disease and resolution of inflammation along with repair or regeneration of destroyed tissues. Therapeutic approaches for periodontitis fall into two main categories: (1) nonsurgical therapy and (2) surgical therapy (see Tables 113.3 and 113.4) [18].

The most effective nonsurgical intervention is scaling and root planing combined with personal plaque control. Clear benefits have been validated from scaling and root planning, including reduction of inflammation, decreased pocket depths, gain of clinical attachment, and decreased progression of disease [18].

Adjunctive pharmacological agents have been used to manage both gingivitis periodontitis. The benefit of topical antibacterial agents to help reduce bacterial plaque and prevent gingivitis has been documented in clinical trials. There are three agents currently accepted by the American Dental Association (ADA) approved as antigingival agents (either mouth rinses or dentifrices) [19]. One product lists essential oils (thymol, menthol, eucalyptol) and methyl salicylate as the active ingredients. The other two contain either chlorhexidine gluconate or triclosan. To carry the ADA seal, these agents must show plaque and inflammation reduction in 6-month trials

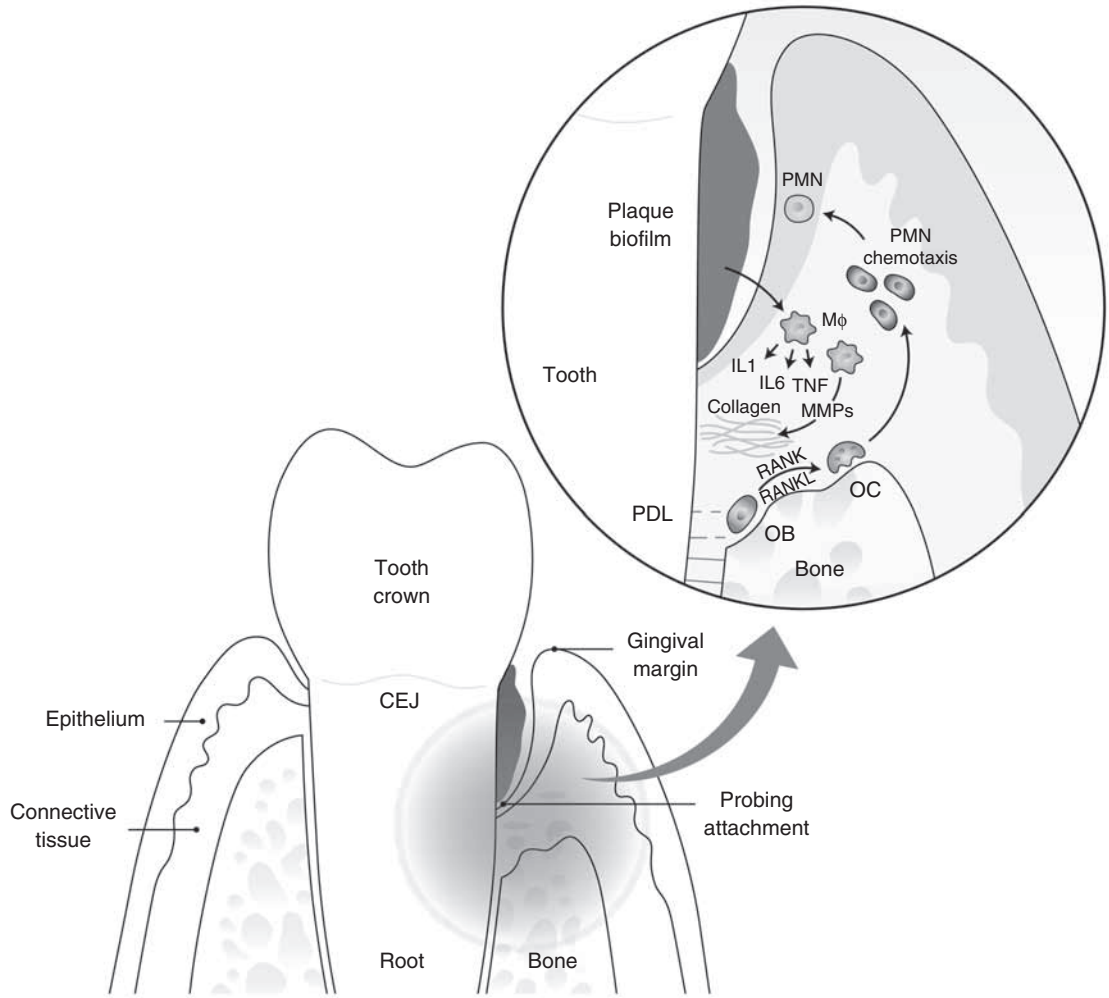

Fig. 113.2. Anatomy of periodontal tissues and cellular biology of inflammatory bone loss. The periodontal tissues surrounding the tooth include epithelium, connective tissue, periodontal ligament (PDL), and alveolar bone. The insert depicts cell responses to bacterial plaque biofilm on the root surface. Polymorphonuclear lymphocytes (PMNs) and macrophages (Mϕ) secrete inflammatory cytokines and matrix metalloproteinases (MMPs) to increase the immune response and degrade the connective tissue matrix. Osteoclastogenesis is induced to these stimuli to increase bone resorption through the RANKL/RANK system.

without any adverse effects. For periodontitis, both systemic and locally delivered chemotherapeutics have been used successfully for management of periodontal diseases. Systemically administered antibiotics have been used when mechanical therapy has not been sufficient (Table 113.3) [19]. However, judicious use of antibiotics is recommended to treat acute infections or management of periodontitis in immune-compromised patients to avoid emergence of drug-resistant organisms.

Other systemic therapies focus on modulation of host-immune responses. Considerable efforts have focused on non-steroidal anti-inflammatory drugs (NSAIDS) and the collagenase inhibitor subantimicrobial dose doxycycline. Both have shown to have beneficial effects, although long-term administration with any systemic agent may have potential negative side effects (Table 113.3). Controlled local delivery within periodontal pockets can change the pathogenic microflora and improve the clinical parameters of periodontitis. The FDA has approved several systems, including vinyl acetate fibers containing tetracycline, biodegradable chips containing chlorhexidine, and a minocycline-containing polymer for use as adjuncts to scaling and root planing [19]. In addition, a doxycycline bio-absorbable polymer gel has been approved as a monotherapy for reduction of periodontal disease clinical parameters.

Surgical therapy is primarily needed to access and facilitate mechanical instrumentation of the root surface debridement. The main objectives of periodontal surgery are to decrease bacterial etiological factors (e.g., subgingival calculus), reduce the pocket depth, and regenerate lost periodontal supporting tissues. Flap access surgeries increase the surgeon's ability to instrument deep pocket depth areas and areas between roots (furcations) for more

Table 113.1. General Classification of Periodontal Diseases and Conditions*

Disease Classification	Comments
Gingivitis	Generally plaque-induced but can be modified by endocrine factors, medications, and malnutrition. No alveolar bone loss.
Chronic periodontitis	Alveolar bone loss can be localized or generalized. Not based upon age. Slow onset/progression.
Aggressive periodontitis	Alveolar bone loss can be localized or generalized. Not based upon age. Rapid onset/progression.
Periodontitis as a manifestation of systemic diseases	Can be associated with hematological (e.g., netropenia), or genetic disorders (e.g., Papillon-Lefèvre syndrome)
Necrotizing periodontal diseases	Could be gingival or periodontal forms
Abscesses of the periodontium	Could be gingival or periodontal abscess
Periodontitis associated with endodontic lesions	Associated with infections within the tooth

*Adapted from Ref. 17. Used with permission from the American Academy of Periodontology.

Table 113.2. Diagnosis of Periodontal Diseases

Diagnostic Assessments	Specific Parameter	Comments
Clinical	Probing depth	Shallow pocket depths associated with less disease progression
	Bleeding upon Probing	Lack of bleeding associated with less inflammation
	Radiographs	Absence of bone loss associated with less disease progression
Microbiological	Culture for periodontal pathogens	May be useful to detect exact pathogens in patients refractory to conventional treatment
	DNA/biochemical probes	Identify non-cultivatable organisms
Biomarkers	Inflammatory cytokines	IL-1 genotype may identify susceptible patients
	Pyridinoline cross-linked carboxyterminal telopeptide of type I collagen	Correlates well with clinical parameters and presence of periodontal pathogens

Table 113.3. Nonsurgical Treatment of Periodontitis

	Treatment Category	Treatment or Agent	Comments
Mechanical	Mechanical debridement	Scaling and root planing—manual instrumentation and ultrasonics	Decrease inflammation Decrease probing depth Increase clinical attachment levels
Chemotherapy	Mouth rinses Dentifrices (toothpastes)	Chlorhexidine Triclosan Essential Oils	ADA approved for reduction of gingivitis
	Locally applied; sustained release	Tetracyclines (doxycycline and minocycline) Chlorhexidine	Can be used as adjunctive therapies with scaling and root planing
	Systemic antibiotics	Tetracyclines Clindamycin Metronidazole/amoxicillin	May be used in more aggressive periodontitis cases
Host Response	MMP inhibitors	Low dose doxycycline	May decrease progression of attachment loss
	NSAIDs	Flurbiprophen	May decrease progression of attachment loss

Table 113.4. Surgical Treatment of Periodontitis

	Treatment Category	Clinical Procedure	Comments
Pocket Reduction	Pocket reduction surgery	Mucoperiosteal flap for access to debride root surface	Dec. pocket depth. Inc. patient access for oral hygiene. Can enhance access for restorative dentistry.
Regeneration	Guided tissue regeneration	Mucoperiosteal flap to gain access and a barrier membrane placed to facilitate new periodontal ligament, cementum, and bone on previously diseased roots	Can use resorbable or non-resorbable membranes with or without bone grafts. Dec. pocket depths. Inc. clinical attachment. Fill osseous defects.
	Bone grafts (autogenous, allogenic, xenografts)		Can use resorbable or non-resorbable membranes with or without bone grafts. Dec. pocket depths. Inc. clinical attachment. Fill osseous defects. Autogenous graft is gold standard.
	Biologicals [enamel-derived matrix proteins, BMPs, platelet-derived growth factors (PDGFs)]		Fill osseous defects. Improved clinical attachment and dec. pocket depth. BMPs not FDA approved for intraoral use. PDGFs with absorbable carrier are FDA approved.
	Autologous growth factors (platelet-rich plasma, platelets rich in growth factors)	Whole blood drawn from the patient and centrifuged to separate and collect the platelet-rich layer	Enhance bone and soft tissue healing.
Replacement	Ridge augmentation (autogenous or allogenic block grafts, particulate grafts, sinus augmentations)	Mucoperiosteal flap for access to graft the insufficient alveolar ridge. Barrier membranes will be used to exclude the soft tissue and provide space maintenance for the graft	Grafting for height or width to provide adequate alveolar bone for implant placement. May be enhanced by using additional growth factors or biologicals.
	Titanium dental implants	Osteotomy prepared with irrigation and increasingly larger diameter drills into alveolar ridge	Replacement of missing teeth with surgically placed titanium dental implants followed by abutment and crown restorations.

complete calculus removal. Osseous resection has traditionally been performed to more effectively reduce pocket depths. However, the optimal goal is to restore lost periodontal tissues. Several different regenerative surgical strategies have been employed, including bone grafting (autogenous and allografts), along with guided tissue regeneration (GTR) with or without bone grafts [20]. A concentrated source of autologous growth factors can be obtained from the patient and used to enhance the regenerative procedures. In the past 10 years, several biological agents have been used to stimulate periodontal regeneration, including growth factors (e.g., platelet-derived growth factor), other proteins (e.g., enamel-derived growth factor), or synthetic peptides (e.g., a 15 amino acid type I collagen fragment) (see Table 113.4) [18, 20]. Recently, recombinant parathyroid hormone (PTH) administration was shown to improve clinical outcomes in the treatment of chronic periodontitis. Patients treated with PTH showed greater resolution of alveolar defects and accelerated osseous wound healing in the oral cavity [21].

The periodontal surgeon also addresses oral bone loss due to factors other than periodontal disease when treatment planning dental implants for missing teeth. Whether teeth were lost due to periodontal disease or decay, the remaining ridge may be inadequate for proper implant placement. Ridge augmentation to improve the maxillary or mandibular width and height of alveolar bone can be achieved with autograft, allograft blocks, or particulate bone. In addition to ridge augmentation, the maxillary sinus cavity causes insufficient height for implant placement in the posterior maxilla. A surgical procedure, termed "sinus augmentation" or "sinus lift" procedure can be performed to gain the necessary ridge height (See Table 113.4).

FUTURE PERSPECTIVES

Current basic research has focused on a newer field called "osteoimmunology," centered on the molecular mechanisms the immune system and the impact on inflammatory bone loss and the skeletal system. Clinical diagnostics that address novel salivary diagnostics measuring biomarkers that may be predictive of periodontal severity, susceptibility, or perhaps predict future disease are actively being pursued. In the clinical setting, tissue engineering and regeneration remain active areas of investigation and new biologicals undergo clinical trials to enhance predictability of grafting materials used for periodontal regeneration or dental implant therapy to replace missing teeth.

CHANGES IN ORAL BONE MASS AND STRUCTURE WITH AGING

As the structure of the mandibular and maxillary bones is similar to that of the rest of the skeleton, it is reasonable to expect that with aging these skeletal segments undergo a process of bone loss, with decreased trabeculation, cortical thinning, and increased porosity, similar to what occurs in the rest of the skeleton. Based on standard bone histology, it has been known since the 1960s that there is an age-dependent decrease in mandibular and maxillary bone mass. Thus, oral bone cortical porosity increases with age, and the severity of this process depends upon the area of oral bone studied [1]. The porosity of the buccal cortex of the mandible is dependent upon the presence or absence of teeth, and trabecular bone loss is observed with tooth extraction. As a corollary to the increased cortical porosity, an increase in endosteal trabeculation also occurs with age. Studies in cadavers also showed that bone mass decreases concordantly with age in the mandible and the radius, while cortical porosity increases. Furthermore, in females, femoral porosity is inversely associated with the height of the alveolar bone [2].

METHODS TO ASSESS ORAL BONE LOSS

Dentists typically use clinical measures to assess the loss of the tooth attachment apparatus, which is in part, though not entirely, due to loss of alveolar bone. The attachment consists of the tissues that support the tooth and includes the gingiva, periodontal ligament, alveolar bone, and tooth cementum. A periodontal probe is inserted into the gingival sulcus until it encounters firm resistance from the base of the sulcus (Fig. 114.1). On the probe, the distance from the base of the sulcus to the tooth's cementoenamel junction (CEJ) is measured and is termed "attachment loss" (AL). In many cases, AL is used as a surrogate measurement for bone loss. Probing depth, another clinical parameter used in dental medicine and clinical studies, is the distance from the depth of the sulcus to the crest of the gingiva, with depths less than 3 mm usually considered clinically acceptable.

Techniques that more directly assess oral bone loss typically involve the use of radiographic measurements. The most common include measures of alveolar crestal height (ACH) and assessment of alveolar crestal height (ACH). ACH is commonly assessed with dental radiographic images by measuring (adjacent to the tooth) the

Fig. 114.1. Clinical measurement of attachment loss. A periodontal probe (with mm markings) is inserted into the gingival sulcus until it encounters firm resistance from the base of the sulcus, and the distance from the base of the sulcus to the cementoenamel junction (CEJ) is measured as attachment loss. Probing depth is the distance from the depth of the sulcus to the crest of the gingiva.

distance from the CEJ to the top of the alveolar bone crest (Fig. 114.2). ACH is usually measured on the mesial (toward the front of the mouth) and distal (toward the back of the mouth) sides of teeth and is reported as the average loss of bone height for all teeth measured in the mouth (mean ACH). The larger the mean ACH, the worse the bone loss surrounding the teeth. After a tooth is lost, there is loss of the bone in that region. This is called residual ridge resorption (RRR). Most often, the extent of RRR is described in edentulous subjects, but RRR can be used in dentate subjects who have lost one or more teeth (partially edentulous). BMD of oral bone has been assessed using a variety of techniques including dual-energy X-ray absorptiometry (DXA), single photon absorptiometry (SPA), dual photon absorptiometry (DPA), quantitative computed tomography (QCT), and radiographic absorptiometry (RA). For clinical research, the most widely used images for oral bone assessment are digital radiographic images (periapical, bitewing, and panoramic). This is because these images are commonly available and relatively inexpensive. These images can be obtained by digitizing plain films or images on phosphor plates, or by using images captured by charge-coupled devices (CCDs), complementary metal oxide semiconductors (CMOSs), or charge induction devices (CIDs). All imaging techniques are limited by cost, accuracy, reliability, precision, and/or practicality. QCT provides a valuable assessment of oral BMD because it allows for assessment of density in regions that with other modalities would be obstructed by teeth. However, it is expensive, and there is high exposure to radiation. Cone beam computed tomography (CBCT) has become widely available in dentistry. Although linear measurements using this technology appear to be relatively accurate and reliable, and images of oral bone can be studied in three dimensions, there is a large amount of scattered radiation, which makes CBCT determinations of BMDs problematic. SPA has been used to assess the maxilla, and DPA and DXA can be used to assess the mandible; however, positioning, reproducibility, and obstruction of teeth in dentate subjects make BMD measurement difficult.

Our group uses a vacuum-coupled, positioning device and phosphor plates to obtain images that can be used to determine changes in oral bone (Fig 114.3). Using this repositioning device, two images taken at different times are registered by minimizing trabecular noise and subtracted (Fig. 114.4). With this approach, we are able to achieve a least significant change (threshold that represents real biological change with 95% confidence) of 0.06 mm for crest height change, compared to 0.49 mm least significant changes for cementoenamel junction–alveolar crestal (CEJ-AC) distance [3]. This dramatic improvement in precision of oral bone loss determination is due in large part to the fact that this image subtraction approach overcomes the inherent limitation of standard CEJ-AC measurements, which rely on two-dimensional radiographic representation of complex three-dimensional structures that are often not clearly visible in sequential images. A limitation of our method is that it is time intensive.

A number of other measurements of oral bone have been developed for use with panoramic radiographs. The gonial index (GI) was introduced first and represents the thickness of the inferior mandibular cortex at the gonion [4]. A similar index, the antegonial index (AI) is a measurement made in the area of the antegonial notch. The panoramic mandibular index (PMI) was proposed as the ratio of mandibular cortical thickness (at the mental foramen) to the distance from the mental foramen

Subsequent images are registered by minimizing trabecular noise. (B) Subtraction image. The arrow points to a discrepancy in crest ridge height between the two original images, showing as a dark area in this subtraction image, representing a change of –0.084 mm (adapted from Ref. 3).

(inferior or superior border) to the inferior border of the mandible [5]. Another panoramic radiograph image-based index, the mandibular cortical index (MCI), was later introduced. It is determined by visually assessing (on panoramic radiographs) the degree of erosion of the mandibular cortex posterior to the mental foramen [6]. Other indices such as the mental index (MI) or mandibular cortical width (MCW), which measure the cortical width below the mental foramen have also been proposed [6, 7]. Several of these indices are illustrated in a recent article [8]. In addition, an automated, computer-aided system was developed to measure cortical width on panoramic radiographs (see below) [9]. Limitations of panoramic radiographs are that they are not as widely used as are periapical and bitewing radiographs, and measurements vary with subject positioning.

RELATIONSHIP BETWEEN ORAL AND POSTCRANIAL BONE MASS

Earlier studies using bone mineral density (BMD) measurements from dental radiographs or absorptiometric

methods established that oral BMD is significantly associated with total body calcium (determined by neutron activation analysis) and forearm and vertebral BMD, and that loss of alveolar bone or residual ridge is part of the osteoporotic syndrome [10–13]. Postmenopausal women with radiographic evidence of vertebral fractures had decreased mandibular bone mass, fewer teeth, and a lower GI (thinner gonial mandibular cortexes) than age-matched subjects with no evidence of vertebral fractures [14]. Furthermore, in women over 50 years of age who had no radiographic indications of vertebral fractures, mandibular bone mass measures were correlated with lumbar spine and forearm BMD [15].

Direct assessment of bone mineral content (BMC) of the mandible using a DXA device demonstrated that mandibular bone mass decreases 1.5%/year in old women and 0.9%/year in old men, and it is correlated with BMD at the forearm [16, 17]. Good correlations between appendicular (forearm) or central (vertebral, proximal femur) BMD measured by DXA and oral bone measurements derived from dental radiographs have been consistently reported [18, 19]. Similarly, computed tomography (CT) methods have confirmed a significant correlation between mandible and lumbar vertebrae bone mass [20], and longitudinal studies have shown that ACH and alveolar radiodensitometric parameters were correlated with changes in femoral and lumbar BMD [21–23].

Significant correlations were found between the PMI index and femoral and lumbar BMD in 355 postmenopausal women (ages 48–56) [6, 24] and with self-reported osteoporosis, though the association was weak [25]. Simple visual inspection of the mandibular cortex on panoramic radiographs produced similar results for predicting femoral and lumbar BMD.[26] Using the latest automated methods for measurement of mandibular cortical thickness, a decrease in mandibular cortical thickness of similar magnitude as for bone loss in the proximal femur was detected in women aged 42.5 years or older [27]. In a small cohort of men, measures of cortical bone in panoramic radiographs revealed higher oral bone loss in men with osteoporosis [8]. Several studies have also reported significant correlations between the MCI index and biochemical markers of bone turnover (serum total alkaline phosphatase and urinary N-teleopeptide cross-links of type I collagen) in women and men [28, 29]. Such correlation is important in that bone turnover fluctuates widely with age, menopausal status, and within a day, yet the correlation indicates that oral bone loss is associated with active bone remodeling.

OSTEOPOROSIS AND TOOTH LOSS

Because teeth can be lost from decay and trauma and clinicians use various thresholds for determining when teeth should be extracted, it is difficult to determine whether there is an association between tooth loss and osteoporosis. Nonetheless, most published studies indicate that a lower BMD corresponds to a lower number of teeth. A cross-sectional study of mandibular bone mass determined on dental radiographs found that tooth loss and edentulism were significantly more common in osteoporotic subjects relative to a control group [15]. Subsequent studies confirmed the correlation between decreased mandibular cortical bone width and tooth loss, particularly in women older than 70 years of age [30]. Likewise, tooth loss was found to be highly correlated with low alveolar and vertebral bone mass and with vertebral fractures [31, 32].

An inverse correlation between postcranial bone mass and self-reported tooth loss was found to be significant in men, though it was not significant in women after correction for BMI, age, and smoking [33]. In another study of lumbar-spine and forearm BMD in postmenopausal women, it was concluded that systemic bone loss may contribute to tooth loss [34]. The same group of investigators later reported that women using estrogen replacement after menopause had a higher number of teeth relative to nonusers, and duration of estrogen use independently predicted the number of remaining teeth; estrogen users (1–4 years) had on average 1.1 more teeth than nonusers [35]. A 3-year, prospective Swedish study of 14,375 older men and women also found that women with the fewest teeth at baseline (lowest tertile) had a risk of hip fracture that was twice that of the women in the highest two tertiles, with the risk of fracture being threefold higher in men [36]. In a cross-sectional study of 70 dentate Caucasian women (51–78 years of age), it was found that interproximal alveolar bone loss was related to hip BMD [37]. More recently as part of the OSTEODENT collaboration, it was found that after controlling for age and smoking, tooth loss was significantly associated with osteoporosis [38].

However, in a group of Finnish women no correlation between postcranial BMD and tooth loss was found, although dental practices in Finland may have led to extractions for preventative purposes rather than as a result of underlying disease, as 25% of women had all their mandibular teeth extracted before the age of 30 [39]. Data from our own group are also not supportive of a clear relationship between spine or femur BMD and number of remaining teeth among subjects enrolled in a hormone replacement study trial [21, 40]. However, subjects were relatively young postmenopausal women who had 10 or more teeth and were generally periodontally healthy, limiting the ability to detect an association between BMD and tooth loss. Likewise, no relationship was found between BMD and tooth number in white women between the ages of 45 and 59 who were within 12 years of menopause, after adjustment for age, years since menopause, and hormone replacement [41]. Finally, a prospective study of a subgroup of participants from the Study of Osteoporotic Fractures found absolute BMD and percentage change in BMD to be similar in dentate women and edentulous at baseline examination [42]. Therefore, the issue as to whether systemic bone loss in osteoporosis contributes to tooth loss is not yet settled. The available

data would, nevertheless, suggest that at least in elderly people, low BMD is often associated with a lower number of teeth, even though this may not be the case in younger people and in early postmenopausal women.

A common concern in the dental treatment of patients with osteoporosis is whether or not osseointegration and osseous regeneration is compromised. Recent reviews suggest rates (especially in the maxilla) may be lowered in patients with osteoporosis [43, 44]; however, the diagnosis of osteoporosis is not a contraindication for implant therapies. Studies of this area are complicated by the frequent lack of information and standardization of therapies (primarily, bisphosphonates) that are used by patients.

MECHANISMS OF ORAL BONE LOSS

In principle, the same systemic processes that cause age-dependent bone loss in the postcranial skeleton are active in oral bone, where the reduced alveolar bone may be particularly susceptible to destruction by periodontal disease, with concomitant reduction in alveolar crest height and loosening of the tooth attachment apparatus [37, 45]. Genetic factors that predispose a person to systemic bone loss also predispose an individual to alveolar bone loss. Likewise, certain lifestyle factors, such as cigarette smoking and suboptimal calcium and vitamin D intakes, as well as pathologic conditions that facilitate local infections (such as diabetes) may increase the risk for systemic bone loss and deterioration of the alveolar bone. In addition to these systemic factors, a key contributor to alveolar bone loss is periodontal disease, during which resorption of the alveolar bone occurs by recruitment and activation of osteoclasts, by secretion of inflammatory cytokines (during the local inflammatory process) in particular interleukin 1 (IL-1), IL-6, and tumor necrosis factor α (TNFα)—all potent osteoclastogenic factors—in response to bacterial infection [46]. The fundamental pathogenetic mechanism of alveolar bone resorption in periodontal disease is, therefore, activation of a normal biologic process (osteoclast formation and activity) by an abnormal local condition (infection driven inflammation).

ASSESSMENT OF ORAL BONE AS A SCREENING TOOL FOR OSTEOPOROSIS

The idea of using parameters of dental health to estimate the risk of systemic bone loss and/or fractures has been extensively studied in light of the correlations between oral and postcranial bone mass. However, as discussed earlier, such correlations are not always very good, and there is no consensus on which method or parameter should be used to assess oral bone in this regard. Radiometric parameters determined in panoramic radiographs, such as the MCI and PMI, and other measures of cortical bone have been proposed. Initial studies revealed poor repeatability for these measures, probably because of the need of a manual calculation of the mandibular bone parameters from standard radiographs by general practitioners [47, 48]. Specific training for dental practitioners marginally improved the predictive value of the oral measures [49]. Nonetheless, when these measures have good repeatability, sensitivities greater than 80% for predicting osteoporosis from mandibular radiometric measurements have been reported [50, 51].

A semiautomated, computer-aided system has been developed to measure MCI on panoramic radiographs. Although these methods do not seem to significantly improve the predictive value for estimating postcranial bone mass relative to manual measurements, they do offer in principle improved practical applicability to routine clinical settings [9, 52]. Using a combination of computer-aided measurements of cortical width and the MCI, it might be possible to improve specificity [9]. Data from the OSTEODENT consortium indicate that the diagnostic value of panoramic, mandibular cortical thickness measures at the mental foramen was only modestly lower in predicting osteoporosis than algorithms based upon clinical risk factors [53]. Combining the two methods increases specificity but lowers sensitivity. Different radiometric parameters have been studied in the OSTEODENT project, and overall, measurement of cortical thickness appears to perform better than MCI for screening patients who would be recommended to undergo DXA testing for osteoporosis [54]. Again, inclusion of clinical data might improve the diagnostic performance of these measurements [55].

Trabecular patterns have also been used to assess oral bone. Endosteal mandibular trabeculation increases with age [56], and trabecular coarseness on periapical radiographs was found to be highly correlated with DXA measures of the forearm [57]. With periapical radiographs, morphologic features of trabecular oral bone had an accuracy of 92% in classifying osteoporosis and control patients [58]. In an expanded study of 598 women (mean age = 77 years), trabecular features had an accuracy for predicting hip fractures that was similar to that obtained with risk assessment tools [59]. These methods were not as successful when used with panoramic radiographs. An OSTEODENT-based collaboration also found that trabecular patterns were accurate in indentifying osteoporotic women, with success being slightly better with panoramic radiographs than with periapical radiographs [60]. In a subsequent study, trabecular features plus age had a sensitivity of 0.75 and a specificity of 0.78 in predicting osteoporosis status [61]. Similar high classification rates were found in other studies [62, 63].

More recently, automated determinations of cortical width were combined with other clinical risk factors in an OSTEODENT index that was tested in 339 women against the World Health Organization (WHO) fracture risk assessment tool (FRAX®) [64]. The OSTEODENT index had the same predictive value for identifying sub-

jects who should be treated for osteoporosis as had FRAX without inclusion of DXA data [65]. It is possible that with further refinements in the OSTEODENT automated measurement of mandibular cortical parameters the predictive value may increase, thus offering a new platform for osteoporosis screening in dental clinics. Because two-thirds of the U.S. population visits dentists each year [66], and dentists regularly perform dental radiographic examinations, it may become reasonable for dentists to use dental radiographs to screen for osteoporosis and refer for further evaluation patients who appear to be at risk—just as they screen for oral cancers when they perform oral examinations [7].

ORAL BONE LOSS AS A PREDICTOR OF FRACTURES

As association between oral bone mass and low-trauma (osteoporotic) fractures has been consistently reported using different methods for assessing oral health. Earlier studies using DPA showed that women with fractures had lower forearm and mandibular BMC than did women without fractures [67]. In a small cohort of women with osteoporosis, cortical thickness at the gonial angle was determined on digitized panoramic radiographs. The best predictor of vertebral compression fractures were pixel gray-scale values, although fractal dimensions and microdensitometry measurements were also effective [68]. Furthermore, in a study of 501 subjects (91 of whom had self-reported osteoporotic fractures), the thickness of the mandibular cortex below the mental foramen (MI) and the MCI were found to be associated with osteoporotic fractures [69]. However, another study on relatively healthy subjects who were followed for 5 years did not confirm such findings, as neither panoramic cortical width nor MCI was predictive of those who had fractures [70]. A limitation of this study was that fracture events were self-reported and were not confirmed radiologically. Overall, there is evidence of an association between oral health and fracture risk, but routine screening through dental examinations cannot yet be recommended, primarily because of the limitations of the methodologies to assess oral bone health and their applicability to routine clinical settings.

Another clinically important question is whether tooth loss is correlated with fractures. As noted earlier, alveolar bone loss occurs with age and weakens the tooth attachment apparatus. Teeth are lost when there is not enough remaining alveolar bone to retain them. In a 3-year prospective study of 14,375 subjects, tooth loss and fracture risk were found to be significantly associated [36], suggesting that edentulous people or individuals with fewer teeth are more likely to be at risk of fractures than people with teeth. However, considering the multiple causes of tooth loss, and periodontal disease in particular, the predictive value of tooth loss for fracture risk is likely to be low.

IMPACT OF OSTEOPOROSIS THERAPY ON ORAL BONE HEALTH

One important, modifiable factor contributing to age-dependent bone loss is inadequate intake of vitamin D. Although no randomized clinical trial exists as of yet, a number of small-scale, noncontrolled studies point to beneficial effects of vitamin D on periodontal health (reviewed in Ref. 71). Results of a recent pilot study from our group corroborates this notion, revealing that subjects taking oral calcium (1,000 mg or more daily) and vitamin D (400 IU or less daily) supplementation had better clinical parameters of periodontal health and less ACH loss relative to individuals who did not take supplements [72]. Such differences were maintained after 1 year, although consistent periodontal care (scaling and root planing) minimizes such differences [73]. Thus, vitamin D supplementation may positively impact periodontal health.

Clinical studies have shown that estrogen deficiency decreases alveolar bone density [74], and a recent study in ovariectomized monkeys has revealed eroded endosteal surfaces and decreased cortical bone density in histologic sections of mandibular bone, associated with enlarged Haversian canals [75]. Accordingly, estrogen replacement therapy is beneficial to oral bone health. In the Leisure World Cohort and the Nurses' Health Study, estrogen use was found to reduce tooth loss [76, 77], and data from the Third United States National Health and Nutrition Examination Survey (NHANES III) demonstrated that women who had taken estrogen had less attachment loss relative to nonusers [78]. Furthermore, in a double-blind, randomized, 3-year controlled trial hormone/estrogen replacement therapy improved alveolar bone mass as well as femoral and vertebral bone density [21, 79].

Bisphosphonates, potent inhibitors of bone resorption, should in theory protect from alveolar as well as systemic bone loss, since the two processes are fundamentally similar. A few placebo-controlled, randomized trials have been conducted to test this hypothesis. Patients with periodontal disease who received periodontal maintenance therapy and were randomized to take a placebo or either oral alendronate (10 mg daily) or risedronate (5 mg daily) for 1 year experienced significantly greater improvements in AL, probing depth, and gingival bleeding relative to a placebo group [80]. However, in another randomized trial, alendronate (70 mg once weekly) did not significantly improve alveolar bone loss in subjects of both genders (71% had periodontal disease) who also received periodontal care, although there was a detectable positive effect in a subgroup of subjects with low alveolar bone mass at baseline [81]. Intriguingly, a more recent trial reported that alendronate delivered locally as a 1% gel to patients with aggressive, chronic periodontal disease significantly improved clinical parameters of periodontal health (probing depth, plaque index, and AL) relative to placebo, as an adjunct therapy to scaling and root planing [82, 83]. However, the use of bisphosphonates for alveolar bone loss is at present overshadowed by the concerns

engendered by the reported association between bisphosphonate use and osteonecrosis of the jaw, a topic discussed in another chapter. Such a severe side effect seems to be linked primarily to the use of very high doses of bisphosphonates in cancer patients, while the incidence of this event in patients treated with bisphosphonates for osteoporosis is quite low. A balanced assessment of risks and benefits of this class of drugs for alveolar bone health is complicated because standardized principles for the diagnosis of osteonecrosis of the jaw are seldom applied, leading to overestimation of the risk, and the widespread use of bisphosphonates increases the likelihood of random association with osteonecrosis of the jaw. There is also concern that bisphosphonates increase the risk of implant failure; however, studies indicate that the risk appears to be low [84, 85].

PAGET'S BONE DISEASE

Up to 17% of patients with Paget's bone disease have manifestations in the oral cavity [86]. The lesions in the oral cavity are more commonly found in the maxilla than in the mandible [87]. Alveolar ridge enlargement is observed and can lead to spreading of the teeth and an abnormal occlusal pattern. Because of alveolar ridge enlargement, edentulous patients with Paget's disease may require new dentures more frequently to compensate for the enlargement. Enlargement of the middle third of the face can also be observed [88, 89]. Another complication of Paget's disease is hypercementosis (excessive deposition of the mineralized cementum structure of the tooth root), which may result in tooth ankylosis. Conversely, Paget's disease may lead to loosening of the teeth during its osteolytic phase [87]. Because the majority of affected patients have no symptoms until bone deformities emerge, the diagnosis is primarily attained by incidental biochemical testing or radiologic examination [90]. Radiographically, in the beginning stage, the bone exhibits reduced radiodensity and may resemble cemento-osseous dysplasia. At a more advanced stage, numerous irregular radiopaque areas become evident, taking on the typical "cotton wool" appearance of Paget's bone disease [86]. Histologically, there are increased numbers of osteoclasts; however, osteoblastic activity is also observed with evidence of a continuous process of abnormal deposition and resorption of bone [91]. There is little information on the effect of systemic therapy for Paget's disease with oral localization. One case report suggested that a 6-month course with alendronate in a patient with Paget's bone disease had no obvious negative effects on placement of dental implants [92].

PRIMARY HYPERPARATHYROIDISM

Several manifestations of hyperparathyroidism occur in the oral cavity. These include partial or complete loss of the lamina dura, increased periodontal ligament width, decreased alveolar bone density, and at more advanced stages, brown tumor formation [93, 94]. Loss of the lamina dura is not a pathognomonic sign of the disease because this is also seen in other diseases such as Cushing's syndrome and osteomalacia. With hyperparathyroidism, there is subperiosteal bone resorption, which is typical of parathyroid bone disorders occurring at other skeletal sites (acroosteolysis). Brown tumor is a chronic osseous lesion with abundant hemorrhage, is normally well demarcated, and can be unilocular or multilocular. Brown tumors are now rarely observed because primary hyperparathyroidism is typically diagnosed at early stages, before any long-term consequence of parathyroid hormone excess becomes manifest. A recent study found reduced cortical density in the mandible but in non-tooth-associated bone [95]. Parameters of periodontal health such as AL, probing depth, and bleeding on probing were unchanged in primary hyperparathyroidism patients, but there was a correlation between increased widening of the periodontal ligament and serum parathyroid hormone levels. Decreased cortical bone density and an increased presence of tori (which may reflect an anabolic-like action of primary hyperparathyroidism in the oral cavity) have also been reported [95].

RENAL OSTEODYSTROPHY

The oral manifestations of renal osteodystrophy are primarily the consequence of secondary hyperparathyroidism and share many features of primary hyperparathyroidism including loss of the lamina dura, "ground glass" appearance of the bone, loss of trabeculation, and brown tumor formation [96]. Probably as a consequence of the stimulatory effect of PTH on periosteal bone formation, an enlargement of the jaws may occur in renal osteodystrophy, associated with cementum resorption [97]. However, renal osteodystrophy does not lead to widening of the periodontal ligament, and indices of periodontal disease are unchanged in patients with secondary hyperparathyroidism from chronic renal failure [98].

SUMMARY

Several important questions remain regarding the correlation between systemic and oral bone mass. A better understanding of the rate of bone loss in the mandible compared with other skeletal regions with age, and the effect of menopause is still needed. Longitudinal progression of mandibular bone loss and the effects of different therapies on mandibular density compared with other skeletal sites also remain to be determined. In particular, establishing the potential benefits of calcium and vitamin D supplementation on oral bone health is an issue of high clinical relevance, considering the widespread use of

these supplements in elderly populations and their relatively modest costs. Randomized clinical trials in large cohorts are needed, and a positive outcome could have a high impact on public health.

Methodologies to assess oral density and alveolar bone loss need to be further refined and improved, especially those based on radiodensitometric approaches. Application of relatively simple and reliable methods to assess oral bone status in routine clinical settings could also be helpful in identifying subjects with or at risk of osteoporosis. Additional studies on this potential application of oral bone mass assessment are of potential high impact. Metabolic bone diseases and periodontal disease are major health concerns in the United States, especially in older populations. Studies that improve our understanding of the mechanisms by which metabolic bone diseases are associated with oral bone are needed and will be increasingly important, as will quality of life issues related to these very prevalent disorders in older Americans.

INTRODUCTION

All homeostatic functions, including those in bone, are controlled by the brain. Indeed, clinical evidence that traumatic brain injury (TBI) accelerates the healing of fractures suggests that there is a link between the central nervous system and bone remodeling [1]. The discovery that leptin regulates bone formation through the central nervous system initiated a new research field: neuronal control of bone remodeling [2]. Since then, other neuropeptides and neurotransmitters, such as neuropeptide Y (NPY) [3], cocaine- and amphetamine-regulated transcript (CART) [4], neuromedin U [5], and, more recently, serotonin [6, 7], have been demonstrated to possess bone-regulating activities.

LEPTIN AND THE SYMPATHETIC NERVOUS SYSTEM

Leptin is a 16 kDa peptide hormone that is synthesized by adipocytes [8]. Leptin affects appetite and energy metabolism through the pro-opiomelanocortin (POMC) pathway, which increases food intake and energy expenditure, and the agouti-related protein (AgRP)/NPY pathway, which decreases food intake and energy expenditure [8]; both pathways are active in the arcuate nucleus. *Ob/ob* mice that lack functional leptin are obese and sterile [8]. In spite of their hypogonadism, the most common cause of osteoporosis, *ob/ob* mice and *db/db* mice that lack a functional leptin receptor exhibit high bone mass [9]. Intracerebroventricular (ICV) infusion of leptin to *ob/ob* mice or wild-type mice at a minimal dose, without any detectable leakage into general circulation, results in reduced bone mass [9]. This observation was subsequently verified in both rats and sheep [10, 11]. Moreover, mice lacking leptin receptors specifically in the central nervous system demonstrate an identical bone phenotype to mice lacking leptin receptors in the entire body (*ob/ob* mice), whereas mice lacking leptin receptors only in osteoblasts have normal bone metabolism [12]. Thus, leptin relies on the central nervous system to regulate bone mass.

Leptin stimulates activity of the sympathetic nervous system, causing a decrease in bone mass mainly through adrenergic α2 receptor (adrb2), the most strongly expressed adrenergic receptor in osteoblasts [13]: The treatment of wild-type mice with the nonselective beta-agonist, isoproterenol, or the adrb2-selective agonist, clenbuterol or salbutamol, decreases bone mass [13, 14]. In contrast, mice with decreased sympathetic activity (*dopamine-beta-hydroxylase*-/- mice [13], *adrb2*-/- mice [4], and mice treated with nonselective beta blockers [13]) demonstrate high bone mass due to an increase in bone formation and a decrease in bone resorption. In addition, these mice are resistant to the effects of leptin in decreasing bone mass,

demonstrating that the main downstream pathway of leptin in bone metabolism is the sympathetic nervous system. Moreover, osteoblast-specific *adrb2*-/- mice recapitulate the bone abnormality of *adrb2*-/- mice [15], indicating that adrb2 in osteoblasts, not in other tissues, is responsible for the effect of the sympathetic nervous system on bone.

Sympathetic signaling in osteoblasts involves two different pathways to control bone formation and bone resorption. The former is via cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) and v-Myc myelocytomatosis viral oncogene homolog (c-myc) transcription factors [15, 16]. Upon stimulation of the sympathetic nervous system–adrb2 pathway in osteoblasts, CREB phosphorylation is inhibited by an unidentified mechanism[15] that results in the inhibition of further downstream effectors, i.e., molecular clocks, such as Per, Cry, and AP-1 transcription factors [16]. Molecular experiments revealed that Per1 and Per2 negatively regulate the expression of c-myc and G1 cyclins, and thus osteoblast proliferation, and that the absence of Per1 and Per2 or Cry1 and Cry2 favors bone mass accrual [16]. In contrast, AP-1 stimulates the expression of c-myc and G1 cyclins [16]. As a combined effect of these antagonistic proteins, the sympathetic nervous system (SNS) decreases bone formation [16]. The latter pathway, which regulates bone resorption, is also mediated through osteoblasts [4]. Upon stimulation of the SNS–adrb2 pathway, osteoblastic ATF4 is phosphorylated, inducing *Rankl* expression [4]. As the bone resorption abnormality in *adrb2*-/- mice cannot be corrected by leptin ICV infusion, it has been suggested that leptin signaling is dependent on the SNS to regulate bone resorption; however, given that osteoclasts do exist in *adrb2*-/- mice, SNS signaling is not essential for osteoclast differentiation.

Various mouse models of osteoporosis, such as ovariectomy-induced [13], unloading-induced [17], or depression-induced bone loss [18] are all ameliorated by the concomitant treatment with beta-blockers, though there are some conflicting reports. These discrepancies may be related to the amount of beta-blocker used in the study: a low dose of propranolol that does not affect any cardiovascular functions was sufficient to increase bone formation parameters, and increasing the doses of propranolol progressively decreases its beneficial effect on bone [19].

Recently, it was shown that the norepinephrine content in bone was decreased by TBI via cannabinoid receptor 1 signaling and that the TBI-induced stimulation of osteogenesis was restrained by a beta agonist [20]. Many epidemiological studies also confirmed the effect of a beta-blocker on bone mass or fracture [21, 22]. Though there are some conflicting results showing either beneficial or indifferent effects of beta-blockers in the prevention of osteoporotic fractures, a meta-analysis of eight studies demonstrated that the use of beta-blockers is associated with the reduction of hip fracture risk and the risk of any fracture [22]. Considering the widespread usage of beta-blockers in clinical medicine, beta-blockers can also be easily applied to the treatment of osteoporosis. However, because most of the studies addressing the relationship of beta-blockers and osteoporotic fracture are observational studies, randomized clinical trials are strongly needed.

Other adrenergic receptors and muscarinic receptor are also involved in bone remodeling. *M3 muscarinic receptor*-/- mice and neuron-specific *M3 muscarinic receptor*-/- mice, both of which show increases in sympathetic nervous activity, demonstrate a low bone mass phenotype due to a decrease in bone formation and an increase in bone resorption [23], whereas osteoblast-specific *M3 muscarinic receptor*-/- mice have no bone abnormality [23]. These results demonstrate that the parasympathetic nervous system affects bone mass by targeting neurons and that the balance between the autonomic nervous systems defines bone mass. Moreover, *α2A/α2C adrenergic receptor*-/- mice demonstrate high bone mass despite an increase in sympathetic nervous system activity and selective α2AR agonists increase osteoclast formation [24], indicating that α-adrenergic receptors are also involved in bone remodeling. Whether these observations may be applied to human beings remains unknown.

SEROTONIN

Serotonin is a monoamine compound that is produced exclusively by the action of Tph2 in the central nervous system [25]. *Tph2*-/- mice develop an osteoporotic phenotype due to an increase in SNS activity, and *ob/ob* mice demonstrate an increase in the concentration of serotonin in the brain [6]. The antiosteogenic and anorexigenic actions of leptin were hampered in mice lacking leptin receptors exclusively in serotonergic neurons located in the brainstem [6], whereas mice lacking leptin receptors specifically in the arcuate nucleus or ventromedial hypothalamus, which are known to be indispensable for the anorexigenic action of leptin [8], have normal bone mass [6], demonstrating a pivotal role of serotonin for the action of leptin. Thus, brainstem-derived serotonin favors bone mass accrual by its binding to the 5-HT2c receptor [6]. However, contradictory observations using identical mouse models is also reported [26]: serotonergic neurons do not express leptin receptors and hence serotonergic neuron-specific leptin receptor-/- mice have normal bone mass and normal body weight. Currently, the cause of discrepancy is not known, although it has been proposed that serotonergic neuron-specific leptin receptor-/- mice by Yadav et al. might have been globally leptin receptor-/- mice. Moreover, selective serotonin reuptake inhibitors (SSRIs), which inhibit serotonin uptake and are believed to stimulate the serotonin signaling pathway, increase the risk of fracture [27]. Thus, further study is needed to thoroughly address the role of serotonin in the brain for the control of bone metabolism.

In the periphery, serotonin is mostly produced by the action of Tph1 by enterochromaffin cells in the gastroin-

testinal tract [25]. *Tph1*-/- mice whose serum concentration of serotonin is markedly decreased present high bone mass [7]. Peripheral serotonin acts on HTr1b and inhibits CREB phosphorylation and osteoblast proliferation [7]. Unexpectedly, gut-derived serotonin is shown to be a downstream mediator of the skeletal effect of LRP5: the gut-specific inactivation of LRP5 or the activation of LRP5 signaling only in the gut fully recapitulates the low bone mass in *LRP5*-/- mice or high bone mass in mice carrying an LRP5-activating mutation in the entire body [7]. Moreover, a low tryptophan diet normalizes the high serum serotonin concentration and low bone mass in *LRP5*-/- mice.[7]

A negative association between bone mineral density and serum serotonin levels is also reported in human [28], and, importantly, an inhibitor of Tph1, which does not affect Tph2, favors bone mass accrual in rodents to a similar extent as parathyroid hormone (PTH) injection [29]. Thus, serotonin and Tph1 is an attractive target for a novel bone anabolic therapy for osteoporosis. However, contradictory observations using identical mouse models are reported [30]: Osteocyte-specifc *LRP5*-/- mice have a decrease in bone mass that is identical to what was observed in global *LRP5*-/- mice, whereas gut-specific *LRP5*-/- mice and *Tph1*-/- mice have a normal bone mass. Moreover, LRP5 does not affect *Tph1* expression or serum serotonin concentration in mice, treatment with a different Tph1 inhibitor does not affect bone mass in mice, and hence LRP5 regulates bone metabolism exclusively acting in bone. Currently, the cause of discrepancy is unknown and requires further corroboration.

NEUROMEDIN U

Neuromedin U (NMU) is a neuropeptide produced in the gastrointestinal tract and in the brain, and NMU inhibits food intake by a leptin-independent mechanism [31]. *Nmu*-/- mice present a high bone mass phenotype with an isolated increase in bone formation [5], similar to *ob*/*ob* mice. This phenotype is not cell autonomous, as *Nmu*-/- osteoblasts are indistinguishable from wild-type osteoblasts *in vitro* [5]. In contrast, ICV infusion of NMU to *Nmu*-/- mice and wild-type mice decreases their bone formation and bone mass [5]. Importantly, leptin ICV infusion or isoproterenol treatment does not decrease bone mass in *Nmu*-/- mice, demonstrating that NMU mediates the action of leptin and SNS in the regulation of bone formation [5]. Further analysis reveals that NMU in the hypothalamus affects only the negative regulator of osteoblast proliferation, namely, the molecular clock [5, 16].

THE NEUROPEPTIDE Y SYSTEM

The neuropeptide Y (NPY) system comprises three ligands; NPY, peptide YY (PYY), and pancreatic polypeptide (PP), mediating their actions through five Y receptor subtypes: NPY1R, NPY2R, NPY4R, NPY5R, and Npy6R [32, 33]. NPY is predominantly neural, produced by central and peripheral neurons and is often co-secreted with noradrenaline [34]. NPY-ergic neurons are abundant in the brain, with high levels in several hypothalamic nuclei (the arcuate nucleus and ventromedial hypothalamus) [35–37]. Early studies identified NPY-immunoreactive fibers in bone, associated with blood vessels [38–41], but also cells in the periosteum and bone lining cells [38, 39]. Central NPY treatment was associated with a reduction in bone mass [9], while NPY treatment in osteoblastic cell lines inhibited the cAMP response to PTH and norepinephrine [42, 43], suggesting the presence of functional Y receptors and a possible regulatory role for NPY in bone forming cells.

A recent publication has confirmed the role of NPY in skeletal metabolism. NPY null mice demonstrated a generalized bone anabolic phenotype [44], without significant changes in body weight. Despite early reports of no effect [45], the negative relationship between hypothalamic NPY and bone formation is consistent with previous reports of reduced bone formation following overexpression of NPY in hypothalamic neurons [46] or cerebrospinal fluid [9] of wild-type mice, as well increased bone mass following loss of NPY receptors (discussed below). Interestingly, central NPY overexpression represents a model of forced central starvation, similar to that evident in leptin deficient *ob*/*ob* mice [47]. Importantly, elevation of central NPY (mimicking the conditions encountered in the hypothalamus during starvation [48]), decreased bone mass despite marked increases in body weight, as evident in *ob*/*ob* [47]. In this manner, weight may be matched to bone mass: Calorie restriction reduces body weight and increases central NPY [49], which inhibits bone formation, as a component of the whole body energy-conservative response. Conversely, excessive calorie intake increases body weight but reduces NPY expression, which stimulates bone formation, thereby matching bone mass to increases in body mass. Thus, the central perception of body weight, i.e., as evident by alterations in central NPY may act to pair bone mass to changes in body weight [44]; a process occurring in addition to the well-described mechanical responses to altered body weight. Interestingly, NPY is also expressed in osteoblasts and osteocytes, and expression is reduced *in vitro* by mechanical loading [44, 50]. Thus, NPY signaling may regulate multiple processes as part of a system to coordinate bone and energy homeostasis.

HYPOTHALAMIC NPY2 RECEPTOR EFFECTS ON BONE

Two NPY receptors have been connected with skeletal homeostasis: NPY1R and NPY2R. Both receptors are expressed in the hypothalamus as well as in peripheral nerves [51–53]. Analysis of the distal femur of germline

NPY2r-/- mice revealed a greater cancellous bone volume associated with a greater rate of bone formation, due to increased osteoblast activity, without an increase in mineralizing surface [3, 54]. Parameters of bone resorption were unchanged. Critically, the bone phenotype of germline *NPY2r*-/- mice was recapitulated in adult mice following selective deletion of NPY2R solely from the hypothalamus, demonstrating a role for central NPY2R in this pathway. Moreover, the skeletal changes observed in germline and conditional *NPY2r*-/- mice occurred in the absence of measurable changes in bone active endocrine factors. Thus, these findings indicated that the anabolism resulting from NPY2R deletion was mediated through a neural mechanism originating within the hypothalamus.

Importantly, a recent study demonstrated that ablation of hypothalamic NPY2R specifically from NPY-ergic neurons produced only moderate increases in cancellous bone volume, and no effect on cortical bone mass [55]. This result indicates that within the hypothalamus the NPY2R-mediated regulation of bone mass is mediated through neuronal populations other than NPY neurons. Preliminary indications suggest that sympathetic neurons emanating from the paraventricular nucleus, the target region for arcuate NPY, may be responsible for the efferent pathway (unpublished observation).

OSTEOBLASTIC NPY1 RECEPTOR EFFECTS ON BONE

The NPY1 receptor has recently been confirmed as a second Y receptor active in the regulation of bone. Similar to NPY2R-deficient mice, loss of NPY1R expression resulted in a generalized anabolic phenotype, with greater bone mass and formation [56] although with an additional increase in bone resorption. The bone phenotype, however, differed from *NPY2r*-/- mice in several critical aspects. Most importantly, conditional deletion of hypothalamic NPY1R receptors had no effect on bone homeostasis, indicating a noncentral mechanism for NPY1R action in bone. The existence of a direct NPY1R-mediated effect on anabolism was suggested following identification of NPY1R expression in osteoblastic cells *in vivo* [56]. Deletion of NPY1R from osteoblastic cells *in vitro* recapitulated the bone anabolic changes evident in germline *NPY1r*-/- mice, although bone resorption was not different from the wild type [57]. Moreover, treatment of wild-type osteoblast-like cultures with NPY resulted in a decrease in cell number, a response that was completely absent in *NPY1r*-/- cultures, which indicates functional osteoblastic NPY1R.

Moreover, this osteoblastic NPY1R expression may be directly involved in the *NPY2r*-/- phenotype. *NPY1r*-/-*NPY2r*-/- mice do not display an additive phenotype in bone, and NPY1R expression is substantially reduced in osteoblast-like cultures from *NPY2r*-/- mice. Although their role in the control of bone homeostasis is yet to be fully elucidated, these studies indicate that NPY1R signaling may be a critical downstream component of the neural regulation of bone mass.

THE CANNABINOID RECEPTORS

The endocannabinoid system mediates its actions via two cannabinoid receptors, CB1-R and CB2-R, which couple to inhibitory G proteins [58]. CB1-R is primarily found within the central nervous system [59], while CB2-R is predominantly expressed in peripheral tissues [20]. Cannabinoid receptors are also expressed in osteoblasts and osteoclasts, and play a role in the control of bone homeostasis by a centrally mediated and direct mechanism. Figure 115.1 is a schematic diagram of the central neuronal control of bone remodeling.

The CB1 receptor plays a significant role in regulating bone mineral density (BMD) [60]. It has been demonstrated that mice with inactivation of CB1-R, have increased BMD and, additionally, are protected against ovariectomy-induced bone loss [60]. Furthermore, the synthetic cannabinoid receptor antagonists inhibit osteoclast formation and bone resorption *in vitro* and protect against ovariectomy-induced bone loss *in vivo* [60].

There is limited evidence concerning CB2-R action in bone mass in humans. Karsak et al. provide evidence that the CNR2 gene, encoding the CB2-R, returned a significant association of a single polymorphism and haplotypes encompassing the CNR2 gene on human chromosome 1p36, associated with low BMD [61].

CB2-R-deficient mice display accelerated age-related cancellous bone loss and cortical expansion, albeit with unaltered cortical thickness [62]. Despite the loss of bone, *CB2r*-/- mice exhibit increased mineral appositional rate and bone formation rate. This low bone mass, associated with high bone turnover, is another phenotypic parallel with postmenopausal osteoporosis [62]. Functional CB2-R has been demonstrated in both the osteoblast and osteoclast lineages [62]. Combined, these studies indicate that CB2-R signaling contributes to the maintenance of bone mass by two mechanisms: (1) stimulating stromal cells/osteoblasts directly, and (2) inhibiting monocytes/osteoclasts, both directly and inhibiting osteoblast/stromal cell receptor activator of nuclear factor-κB ligand (RANKL) expression. Jointly, these data suggest that the cannabinoid system plays an important role in the regulation and maintenance of bone mass through the signaling of both the CB1-R and CB2-R.

THE MELANOCORTIN SYSTEM

Melanocortins are a complex family comprising a number of endogenous agonists that are all derived from a single precursor, pro-opiomelanocortin (POMC), of which α-, β- and γ-MSH (melanocyte-stimulating hormone) and

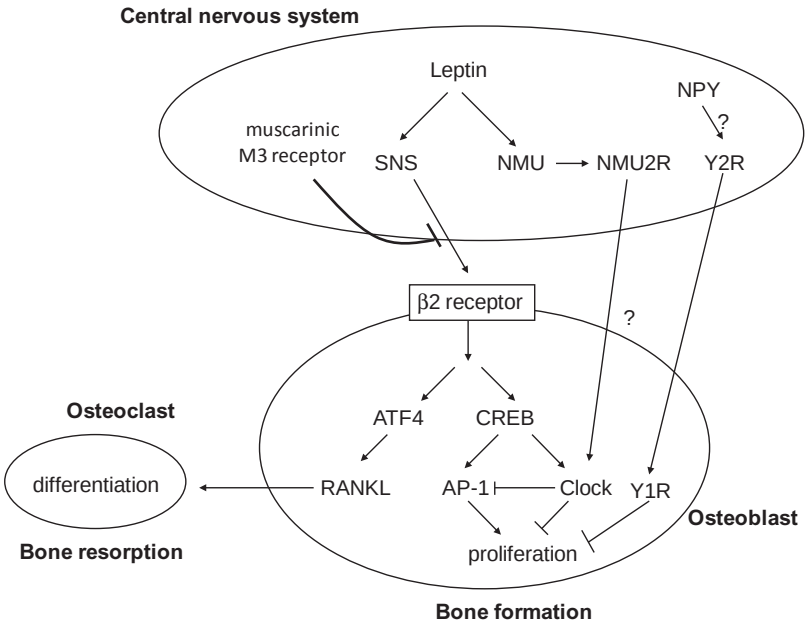

Fig. 115.1. A schematic diagram of central neuronal control of bone remodeling.

adrenocorticotropic hormone (ACTH) elicit their action by interacting with five melanocortin receptors (MCRs), identified as G-protein coupled receptors MCR1–5 [63, 64]. In addition to the melanocortin agonists, agouti-related protein (AgRP) has been identified as a high-affinity antagonist [65].

The regulation of bone homeostasis by this system centers around the action of the melanocortin 4 receptor (MC4R) expressed in hypothalamic neurons. Patients deficient in MC4R are known to exhibit high BMD, resulting from a decrease in bone resorption [66]. Importantly, the greater BMD is still evident following correction of the obesity that is characteristic of MC4R deficiency [66]. Mechanistic studies in mice have enabled dissection of this pathway to bone and interestingly, have implicated another hypothalamic neuropeptide, cocaine and amphetamine-regulated transcript (CART). Hypothalamic CART expression is increased in *MC4R*-/- mice, which display a high bone mass phenotype due to decreased osteoclast number and function [4, 67], as evident in human studies. Additionally, MC4R mutant mice lacking one or two copies of Cart exhibited a significantly lower bone mass [4, 67], demonstrating increased CART signaling, is critical to the low-bone-resorption/high-bone mass phenotype observed in MC4R-deficient mice.

INTRODUCTION

Traditionally, a specific, limited function has been ascribed to each anterior and posterior pituitary hormone. However, the recent use of mouse genetics has led to the realization that these hormones and their receptors have more ubiquitous functions in integrative physiology, particularly in organs such as the skeleton that are regulated by, and respond to, both local factors and systemic signals related to central metabolism and reproduction. While the skeleton expresses steroid-family receptors, which play major roles in regulation, the major pituitary hormones also have critical direct actions in skeletal homeostasis.

The skeletal expression of pituitary glycoprotein receptors further reflects that the function of these signals in endocrine control is evolutionarily more recent [1]. Thus, growth hormone (GH), follicle stimulating hormone (FSH), thyroid stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), and oxytocin all affect bone, and in mice, the haploinsufficiency of either the ligand and/or receptor often yields a skeletal phenotype with the primary target organ remaining untouched. Recognition and in-depth analysis of the mechanism of action of each pituitary hormone have improved our understanding of bone pathophysiology and opened new avenues for therapy. In this chapter, we discuss the interaction of each pituitary hormone with bone and the potential it holds in understanding and treating osteoporosis.

PITUITARY HORMONES AS DIVERSE AND EVOLUTIONARILY CONSERVED SIGNALS

ACTH is the clearest example of a pituitary hormone being part of a widely distributed G-protein coupled receptor (GPCR) system that is known to participate in local cell differentiation in several contexts. Yet, this distributed function is overshadowed by its pituitary–adrenal signaling function. There are five melanocortin receptors, including the ACTH receptor (MC2R), which regulate various physiological activities such as pigment production, appetite, and sexual function. All are controlled by ligands processed from a single large prohormone, pro-opiomelanocorticin (POMC). Hormone production occurs by tissue-specific regulated proteolysis, with ACTH being the predominant product in the anterior pituitary. At other sites, POMC, three melanotropins, and β-endorphin are synthesized from the same precursor. There are reports of ACTH production by human macrophage/monocyte cells [2], making it possible that MC2Rs in bone may be activated by local, instead of pituitary-derived ACTH.

Such decentralized control is also exemplified by corticotropin releasing factor (CRF), which, in the adult, stimulates pituitary ACTH production [3]. In the fetus, it stimulates cortisol synthesis directly [3]. This fetal system shows that evolution for centralization of ACTH as the CRF second messenger has not yet completely supplanted an ancestral regulatory system.

TSH and FSH are two of a group of hormones, along with chorionic gonadotropin (hCG) and luteinizing hormone (LH), which are heterodimeric proteins that share a common α-chain. Their specificity, however, depends on their differing β-chains. These hormones are particularly interesting in that simpler phyla have distributed functions. In coelenterates, which have a primitive nervous system but no endocrine glands, a TSHR family gene is readily identifiable, widely expressed, and shows the intron–exon structure found in mammals [4]. In lower vertebrates, such as in bony fish, the TSHR is abundant in the thyroid, but is also detectable in ovaries, heart, muscle, and brain [5]. In fish, the gonadal expression of the receptors, LH receptor (LHR) and FSH receptor (FSHR), is established, and all higher orders retain this. In fact, multiple differently processed forms of the FSHR occur in fish [6]; this may reflect isoforms with differing functions (below). Further, in fish the FSHR binds both FSH and LH, whereas the LHR recognizes only LH [7]. While high-level FSHR expression is restricted to gonads, low-level expression is seen in the spleen [8], quite similarly to findings in human cells (below).

Low-level TSH production by bone marrow cells has likewise been reported [9]; in this case, a splice variant activates the TSHR, and may do so locally in bone. Lymphocytes also express TSH [10, 11], but such production is unlikely to affect circulating levels. There is no evidence, however, for bone or marrow cell production of FSH, although coproduction of TSHβ and FSH is noted in CD11β cells from mouse thyroid [12]. Overall, therefore, the presence of GPCRs in tissues other than traditional endocrine targets, such as the skeleton, and in cases, coexistence of their ligands, comes as no surprise. What does, however, come as a surprise, is that the skeleton appears to be more sensitive to GPCR stimulation than the primary target organs, at least in mouse genetic and limited human studies.

GROWTH HORMONE ACTION ON BONE OCCURS PRIMARILY *VIA* IGF-1

Growth hormone (GH), a single-chain polypeptide, plays a vital role in skeletal homeostasis. It directly affects bone through a GPCR, but its primary action occurs via its release of insulin-like growth factors (IGFs). The predominant IGF, IGF-1, is synthesized mainly in the liver and approximately 80% that circulates is bound to IGF binding protein-3 (IGFBP3) and the acid labile subunit (ALS).

The importance of IGF-1 over GH in skeletal homeostasis is borne out by the demonstration that growth retardation and osteoporosis in GHR-deficient mice are arrested by the overexpression of IGF-1 [13]. Furthermore, despite elevated GH levels, mice lacking both liver IGF-1 (LID) and ALS, with depleted serum IGF-1, show reduced bone growth and bone strength [14]. These results suggest that the skeletal effects of GH require IGF-1. In fact, the induction of osteoclastic activity by GH also appears to require IGF-1 made from bone marrow stromal cells, which then activates bone resorption by acting on osteoclastic receptors, as well as by altering receptor activator of nuclear factor-κB ligand (RANKL) expression [15–17]. However, there is limited evidence to suggest that GH can act independently of IGF. For example, GH replacement reverses the increased adiposity in hypophysectomized rats, while IGF-1 replacement does not [18]. Furthermore, in ovariectomized LID mice, GH reverses osteopenia [19]. While these findings point to a direct action of GH on bone and other tissues, selective deletion of this GPCR in osteoblasts and other cells should provide further clarity.

FSH CONTRIBUTES TO BONE LOSS

We discovered that FSH directly stimulates bone resorption by osteoclasts [20]. Several studies have now confirmed direct effects of FSH on the skeleton in rodents and humans. Amenorrheic women with a higher mean serum FSH (approximately 35 IU/L) have greater bone loss than those with lower levels (approximately 8 IU/L) in the face of near-equal estrogen levels [21]. Likewise, in a recent study, patients with functional hypothalamic amenorrhea, in whom both FSH and estrogen were low, showed slight to moderate skeletal defects [22]. Importantly, women harboring an activating FSHR polymorphism, rs6166, have lower bone mass and high resorption markers [23]; this attests to a role for FSHRs in human physiology. Consistent with these human studies, exogenous administration of FSH to rats augments ovariectomy-induced bone loss, and a FSH antagonist reduces bone loss after ovariectomy or FSH injection [24, 25].

Clinical correlations between bone loss and serum FSH levels have been documented extensively. Most impressive is the Study of Women's Health across the Nations (SWAN), a longitudinal cohort of 2,375 perimenopausal women. Not only was there a strong correlation between serum FSH levels and markers of bone resorption, a change in FSH levels over 4 years predicted decrements in bone mass [26]. Analyses of data from Chinese women showed similar trends: a significant association between bone loss and high serum FSH [27, 28]. In a group of southern Chinese women aged between 45 and 55 years, those in the highest quartile of serum FSH lost bone at a 1.3- to 2.3-fold higher rate than those in the lowest quartile [29]. Likewise, examination of a National Health and Nutrition Evaluation Survey III (NHANES III) cohort of women between the ages of 42 and 60 years showed a strong correlation between serum FSH and femoral neck

bone mineral density (BMD) [30]. A recent cross-sectional analysis of 92 postmenopausal women found that serum osteocalcin and C-telopeptide cross-linked (CTX) were both positively correlated with FSH, but not with estradiol [31]. The Bone Turnover Range of Normality (BONTURNO) Study group likewise showed that women with serum FSH levels of greater than 30 IU/mL had significantly higher serum bone turnover markers than age-matched women, despite having normal menses [32]. In contrast, Gourlay et al. failed to show a strong relationship between bone mass and FSH or, indeed, estrogen [33]. Interestingly, however, the same authors showed an independent correlation between FSH and lean mass [34]. This latter association makes biological sense inasmuch as FSHRs are present on mesenchymal stem cells [20], known to have the propensity for adipocytic differentiation. However, studies have yet to determine whether FSH inhibits adipogenesis. Nonetheless, the weight of the evidence prompts the use of FSH at least as a serum marker for identifying "fast bone losers" during the early phases of the menopausal transition [35].

Mechanistically, FSH increases osteoclast formation, function, and survival through a distinct FSHR isoform [20, 36–38]. Wu et al. further showed that the osteoclastogenic response to FSH was abolished in mice lacking immunoreceptor tyrosine-based activation motif (ITAM) adapter signaling molecules [38]. This suggests an interaction between FSH and immune receptor complexes, although the significance of this remains unclear. In a separate study, FSHR activation was shown to enhance RANK receptor expression [39]. In addition, FSH indirectly stimulates osteoclast formation by releasing osteoclastogenic cytokines, namely IL-1β, tumor necrosis factor-α (TNF-α), and IL-6 in proportion to the surface expression of FSHRs [40, 41]. In a study of 36 women between the ages of 20 and 50, serum FSH concentrations correlated with circulating cytokine concentrations [41, 42].

Two groups have, however, failed to identify FSHRs on osteoclasts, having likely used primers targeted to the ovarian isoform [43, 44]. We very consistently find FSHR in human $CD14^+$ cells and osteoclasts using nested primers and sequencing to verify the specificity of the reaction, and amplifying regions that contain an intron to avoid the pitfall of genomic DNA contamination [36].

It has been difficult to tease out the action of FSH from that of estrogen *in vivo*, as FSH releases estrogen, and the actions of FSH and estrogen on the osteoclast are opposed. The injection of FSH into mice with intact ovaries [44], or its transgenic overexpression [43], even in *hpg* mice, is unlikely to reveal pro-resorptive actions of FSH. This is because direct effects of FSH on the osteoclast will invariably be masked by the antiresorptive and anabolic actions of the ovarian estrogen so released in response to FSH.

Whether lowering FSH in a hypogonadal state to prevent bone loss can be leveraged therapeutically is unclear.. There is evidence that women with low FSH levels undergo less bone loss [21] and that the effectiveness of estrogen therapy is related to the degree of FSH suppression [45]. With that said, patients with pituitary hypogonadism lose bone. Luperide treatment, and hence the lowering of FSH, has not been shown to prevent hypogonadal hyper-resorption [46]. While this proves that low estrogen is a *cause of* acute hypogonadal bone loss, it does not exclude a role for FSH in human skeletal homeostasis [46]. Rather than blocking FSH in acute hypogonadism, where the effect of low estrogen is likely to be overwhelming, FSH inhibition during the late perimenopause, particularly when estrogen levels are normal and FSH is high, could potentially be of therapeutic significance. A highly selective approach, such as the use of a blocking antibody, is thus envisaged [47].

TSH UNCOUPLES BONE REMODELING

TSH is a direct inhibitor of osteoclasts [48]. The haploinsufficiency of TSHRs in heterozygotic $TSHR^{+/-}$ mice results in osteoporosis, while thyroid hormone levels remain unaffected [48]. Furthermore, $TSHR^{-/-}$ mice are osteoporotic, a phenotype that cannot be explained by the known pro-osteoclastic action of thyroid hormones, particularly as $TSHR^{-/-}$ mice are hypothyroid [49]. Furthermore, skeletal runting, but not the osteoporotic phenotype, is reversed upon rendering $TSHR^{-/-}$ mice euthyroid by thyroid hormone replacement [48]. Thus, TSH acts on bone independently of thyroid hormones, and the osteoporosis of hyperthyroidism may, in part, be due to low TSH [50, 51].

The osteoporosis of TSHR deficiency is of the high-turnover variety. $TSHR^{-/-}$ mice show evidence of increased osteoclastic activity, similarly to hyt/hyt mice that have defective TSHR signaling [52, 53]. Studies show that recombinant TSH attenuates the genesis, function, and survival of osteoclasts *in vitro* in bone marrow [48] and murine ES cell cultures [54]. The latter suggests a role early in bone development [54]. In contrast, the overexpression of constitutively activated TSHR in osteoclast precursor cells [55], or transgenically, in mouse precursors [53], inhibits osteoclastogenesis. In postmenopausal women, a single subcutaneous injection of TSH drastically lowers serum C-telopeptide to premenopausal levels within 2 days, with recovery at day 7 [56]. In none of the studies with TSH replacement did thyroid hormones increase, exemplifying again that the pituitary–bone axis is more primitive than the pituitary–thyroid axis.

This anti-osteoclastogenic action of TSH is mediated by reduced NF-κB and Janus N-terminus kinase (JNK) signaling, and TNF-α production [48, 55]. The effect of TSH on TNF-α synthesis is mediated transcriptionally by binding of two high mobility group box proteins, HMGB1 and HMGB2, to a TNF-α gene promoter [57]. TNF-α production is expectedly upregulated in osteoporotic $TSHR^{-/-}$ mice [48], and the genetic deletion of TNF-α in these mice reverses the osteoporosis [55], proving that

the TSHR$^{-/-}$ phenotype is mediated by TNF-α, at least in part.

The role of TSH is osteoblast regulation is less defined. While it inhibits osteoblastogenesis in bone marrow-derived cell cultures, it stimulates differentiation and mineralization in murine cell cultures through a Wnt5a-dependent mechanism [58]. Likewise, *in vivo*, intermittently administered TSH is anabolic in both rats and mice [53, 59]. In rats, TSH, injected up to once every 2 weeks, inhibits ovariectomy-induced bone loss, 28 weeks following ovariectomy [53]. Calcein-labeling studies are consistent with a direct anabolic action of intermittent TSH [59]. Furthermore, in humans, Martini et al. [60] show an increase in N-terminal propeptide of human procollagen type I (PINP), a marker of bone formation, validating the conclusion that a bolus dose of TSH is anabolic.

Epidemiologically, a 4.5-fold increase in the risk of vertebral fractures and 3.2-fold increase in the risk of nonvertebral fractures is seen at TSH levels less than 0.1 IU/L [61]. There is also a strong negative correlation between low serum TSH and high C-telopeptide levels, without an association with thyroid hormone [62]. In patients on L-thyroxine, a significantly greater bone loss has been noted in those with a suppressed TSH than those without suppression [63–65]. The Tromso study supports this: participants with serum TSH below 2 SD had a significantly lower BMD, those with TSH above 2 SD had a significantly increased BMD, whereas there was no association between TSH and BMD at normal TSH levels [66]. In patients taking suppressive doses of thyroxine for thyroid cancer, the serum level of cathepsin K, a surrogate but yet unvalidated resorption marker, was elevated [67], and the HUNT 2 study found a positive correlation between TSH and BMD at the distal forearm [68].

Analysis of data from NHANES data has shown that the odds ratio for correlations between TSH and bone mass ranged between 2 and 3.4 [69]. Furthermore, euthyroid women with serum TSH in the lower tertile of normal have a higher incidence of vertebral fractures, independent of age, BMD, and thyroid hormones [70]. Importantly, patients harboring the TSHR-D727E polymorphism have high bone mass [71]; similar allelic associations have been reported from the United Kingdom and in the Rotterdam study [72, 73]. Another polymorphism, T+140974TC, seen in the Korean population, is also associated with increased BMD, moreso in patients with an elevated TSH, again substantiating the role of TSH in protecting against bone loss [72].

Physiologically, therefore, TSH uncouples bone remodeling by inhibiting osteoclastic bone resorption and stimulating osteoblastic bone formation, particularly when given intermittently. Furthermore, absent TSH, signaling stimulates bone remodeling directly, and through TNF-α production, causes net bone loss. Low TSH levels may thus contribute to the pathophysiology of osteoporosis of hyperthyroidism, which has traditionally been attributed to high thyroid hormone levels alone.

ACTH REGULATES VASCULAR SURVIVAL AND GROWTH IN BONE

Glucocorticoids, under natural regulation mainly by ACTH, are important coregulators of many processes including vascular tone, central metabolism, and immune response. At higher, pharmacological levels, they become anti-inflammatory and immunosuppressant drugs, with incident complications including diabetes, osteoporosis, and osteonecrosis. Osteonecrosis, in particular, is a painful debilitating condition that affects metabolically active bone, typically the femoral head [74], and invariably requires surgical treatment. The underlying mechanisms of glucocorticoid-induced osteonecrosis are poorly understood, although a key finding is that osteonecrosis occurs prior to macroscopic vascular changes [75].

Isales et al. [76] discovered that bone-forming units strongly express melacortin receptor 2 (MC2R). We showed that as with the adrenal cortex, ACTH induces vascular endothelial growth factor (VEGF) production in osteoblasts through its action on MC2Rs [77]. This likely translates into the protection by ACTH of glucocorticoid-induced osteonecrosis in a rabbit model [77]. An independent report with consistent findings was recently published [78]. We speculate that VEGF suppression secondary to ACTH suppression may contribute to bone damage with long-term glucocorticoid therapy. Much needs to be done to validate this idea to a therapeutic advantage, considering that ACTH analogs are already approved for human use.

CONTRASTING AGE-RELATED EFFECTS OF PROLACTIN ON BONE

Prolactin (PRL), a peptide hormone, is secreted by the anterior pituitary. It primarily acts to induce and maintain lactation and prevent another pregnancy by suppressing folliculogenesis and libido. During pregnancy, it increases the calcium bioavailability for milk production and fetal skeletalogenesis by promoting intestinal calcium absorption and skeletal mobilization [79]. Accelerated bone turnover and bone loss is noted in hyperprolactinemic adults [80]. Antagonism of PRL by bromocriptine, a dopamine agonist, reverses the bone loss [81].

This osteoclastic action of PRL is traditionally thought to arise from the accompanying hypoestrogenemia [82]. However, it has been shown that osteoblasts express PRL receptors (PRLRs) [83], suggesting a direct interaction between PRL and the osteoblast. In fact, the pattern of bone loss is distinct in PRL-exposed and ovariectomized rats [84].

Ex vivo, PRL decreases osteoblast differentiation markers [84], in part, through the PI3K signaling pathway [85]. *In vivo,* PRL accelerates bone resorption in adult mice [84] through an indirect action on osteoclasts, notably by increasing the RANK/OPG (osteoprotegerin)

ratio [84]. Osteoclasts, themselves, do not possess PRLRs [83]. In contrast, in infant rats, PRL causes net bone gain [86] and increased osteocalcin expression. Likewise, in human fetal osteoblast cells, PRL decreases the RANKL/OPG ratio [85]. It appears therefore that the net effect of PLR on bone depends on the biological maturity of the organism. In the fetal stage, it promotes bone growth and mineralization, while accelerating bone resorption in the mother to make nutrients available. Further, insight is needed to clarify the role of PRL in bone metabolism and determine the cellular pathways.

OXYTOCIN IS A BONE ANABOLIC HORMONE

Oxytocin (OT) is a nanopeptide synthesized in the hypothalamus and released into circulation via the posterior pituitary. Its primary function is to mediate the milk ejection reflex in nursing mammals. It also stimulates uterine contraction during parturition; however, OT is not a requirement for this function. Thus, OT-null mice can deliver normally but are unable to nurse. Subcutaneous OT injection completely rescues the milk ejection phenotype, attesting to this being a peripheral, as opposed to a central, action [87]. Central actions of OT include the regulation of social behavior, including sexual and maternal behavior, affiliation, social memory, as well as penile erection and ejaculation [88–91]. It also controls food, predominantly carbohydrate, intake centrally [92]. Thus, the social amnesia, aggressive behavior, and overfeeding observed in $OT^{-/-}$ and $OTR^{-/-}$ mice are reversed on intracerebroventricular OT injection [93].

OT acts on a GPCR, present in abundance on osteoblasts [94], osteoclasts, and their precursors [95]. In line with the ubiquitous distribution of OT receptors (OTRs), cells of bone marrow also synthesize OT, suggesting the existence of autocrine and paracrine interactions [96]. *In vitro*, OT stimulates osteoblast differentiation and bone formation. Thus, $OT^{-/-}$ and $OTR^{-/-}$ mice, including the haploinsufficient heterozygotes with normal lactation, display severe osteoporosis due to a bone-forming defect [97]. This not only indicates that the osteoblast is the target for OT, but also that bone is more sensitive to OT than the breast, hitherto considered its primary target. Once again, the finding emphasizes a relatively primitive pituitary–bone axis. Effects of OT on bone resorption *in vivo* appear minimal, as OT stimulates osteoclastogenesis but inhibits the activity of mature osteoclasts, with a net zero effect on resorption.

In vivo gain-of-function studies document a direct effect of OT on bone. Intraperitoneal OT injections result in increased BMD and *ex vivo* osteoblast formation [97]. In contrast, short-term intracerebroventricular OT does not affect bone turnover markers. OT injections in wild-type rats alter the RANKL/OPG ratio in favor on bone formation, again attesting to an anabolic action [98].

Although unproven, OT may have a critical role in bone anabolism during pregnancy and lactation. Both are characterized by excessive bone resorption in favor of fetal and postpartum bone growth, respectively [99]. This bone loss is, however, completely reversed upon weaning by a yet unidentified mechanism [100]. OT peaks in blood during late pregnancy and lactation, and while its pro-osteoclastogeneic action may contribute to intergenerational calcium transfer, its anabolic action could enable the restoration of the maternal skeleton. $OT^{-/-}$ pups show hypomineralized skeletons, and $OT^{-/-}$ moms display reduced bone formation markers. The question whether estrogen, via its positive regulation of osteoblastic OT production, can synergize this action through a local feed-forward loop, remains to be determined. These studies nonetheless pave the way for a greater understanding of pregnancy and lactation-associated osteoporosis, as well as new potential therapeutic options.

CONCLUSION

The discovery of glycoprotein hormones and their direct regulation of bone helps explain some of the inconsistencies of older models that assumed that pituitary signaling was mediated entirely via endocrine organs through steroid-family signals. Important direct responses include actions of TSH, FSH, ACTH, and OT in bone. It is important, in evaluating these new signaling mechanisms, to consider that the skeletal responses may or may not have similar mechanisms to the responses of the traditional endocrine targets, and that the signals may vary in importance due to secondary endocrine and paracrine control. The discovery of direct skeletal responses of pituitary hormones nevertheless offers a new set of therapeutic opportunities.

INTRODUCTION

A reduction in lean body mass and an increase in fat mass is one of the most striking and consistent changes associated with advancing age. Skeletal muscle [1] and bone mass are the principal (if not exclusive) components of lean body mass to decline with age. These changes in body composition occur throughout life and have important functional and metabolic consequences. The term "sarcopenia" refers to this age-associated loss of skeletal muscle mass and strength. It is a term was first used by Irv Rosenberg [2] and originally described by Evans and Campbell [3] and further defined [4]. The loss of skeletal muscle with advancing age is universal and contributes to a number of conditions that are common in elderly people. Much as bone density is associated with the risk of a bone fracture, it was thought that sarcopenia would predict the risk of disability and loss of independence in elderly people. Skeletal muscle has an important role in the development of a number of geriatric syndromes besides its vital role in movement and in the etiology of mobility disability. It is the primary site of glucose disposal, and muscle insulin resistance is a key feature in the etiology of type 2 diabetes. Sarcopenia is the primary reason for the age-associated decrease in basal metabolic rate and a declining energy requirement [1]. A number of authors have defined sarcopenia more specifically as a subgroup of older persons with muscle mass depletion, usually defined as being 2 standard deviations below the mean muscle mass of younger persons (usually age 35 years of age) [5]. More recently, there has emerged a consensus that skeletal muscle mass alone is not a strong predictor of outcomes related to risk of disability, and a definition of who is sarcopenic must include a functional measurement (habitual gait speed, for example) along with a measure of skeletal muscle mass. Sarcopenia has become recognized as an important geriatric condition and a key precursor to the development of frailty [6, 7]. Much like osteopenia (bone density) predicts risk of a bone fracture, sarcopenia is a powerful predictor of late-life disability.

Sarcopenia very likely begins in early adulthood [8] with atrophy and loss of type II muscle fibers [9, 10], and continues throughout life as a result of the complex interaction of environmental and genetic causes. Longitudinal studies have shown a clear decline in muscle mass, strength, and power beginning at approximately 35 years of age [11]. Strength and power decline to a greater extent than does muscle mass [12]. In addition to sarcopenia, intramusculater lipid, termed "myosteatosis" [13], increases with age and increasing body fatness. Janssen et al. [14] estimated that sarcopenia results in an excess cost to the health-care system of the United States of $18.4 billion a year (year 2001), due to associated disability. In the New Mexico Study, the prevalence of sarcopenia was originally determined to be over 50% in persons older than 80 years of age [5]. Subsequent studies in this population using more direct estimates found a prevalence of 12% for persons 60 to 70 years old and nearly 30% for persons over 80 [5, 15]. Janssen et al. #Longitudinal analysis with sarcopenia defined as a loss of appendicular muscle mass of >3% in 3 years.

tion Evaluation Survey III (NHANES III), found the prevalence of sarcopenia (–2 SD) in persons 60 years of age and older was 7% to 10%. Women were more likely to be sarcopenic than men in this study, but others have reported the opposite [17–21]. Table 117.1 compares a number of different studies on the prevalence of sarcopenia. A common finding of all of these studies is that sarcopenia is highly prevalent in older people and that it increases with advancing age.

SARCOPENIA AND BONE

The loss of skeletal muscle and bone mass with advancing age is closely related [22]. Doyle et al. [23] examined the ash weight of the third lumbar vertebrate and compared it to the weight of the left psoas muscle in male and female cadavers and reported a strong relationship ($r = 0.722$, $p < 0.001$, Fig. 117.1). They proposed that the weight of the psoas was a reflection of the forces the muscle exerts on the bone, resulting in increased or decreased bone. Using neutron activation to determine total body Ca (TBCa) and measurement of total body ^{40}K (TBK) as an indication of active cell mass (skeletal muscle), Cohn and coworkers [24] measured 79 men and

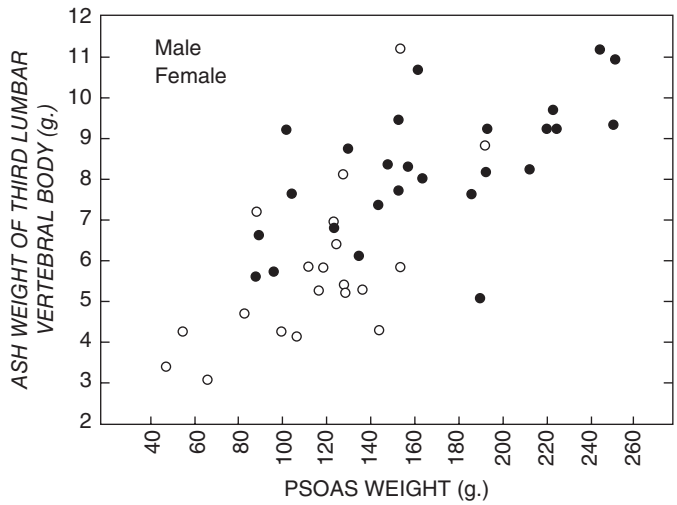

Fig. 117.1. Relationship ($r = 0.722$, $p < 0.001$) of ash weight of L3 vertebral body and psoas weight in 26 male and 20 female cadavers (age range 26–83). From Doyle et al. (Ref. 23).

women between the ages of 30 and 90. They found that at each decade of life, the TBK/TBCa ratio remained constant with advancing age, concluding that "the mechanism responsible for loss of bone with age, whether nutritional deficiency or decreased gonadal function and physical activity may also be responsible for the loss of muscle mass with age." Ellis and Cohn [25] observed a TBK/TBCa ratio of 0.122 ± 0.008 for men and 0.100 ± 0.007 for women, indicating greater muscle mass per unit skeletal mass that remained constant with advancing age. Capozza and coworkers [26] evaluated the relationship between bone mineral content and lean body mass (BMC/LM) in a cohort of 3,205 pre- and postmenopausal women. In addition, they examined pre- and postmenopausal women who had experienced a recent fracture. They found no differences in this ratio between premenopausal women with and without fractures. However, in postmenopausal women, both LM and BMC showed similar changes with age, and women experiencing a fracture had significantly lower BMC/LM, particularly in women with a hip fracture.

Because skeletal muscle mass is an important determiner of bone density and functional status, loss of skeletal muscle also results in loss of bone density. Disuse is discussed below. Weight loss through dietary restriction results in a loss of body fat, lean mass, and bone density. Langlois et al. [27] examined the association between weight change and risk of hip fracture in a cohort of 2,413 community-dwelling white men aged 67 years or older during an 8-year follow-up period. Extreme weight loss (10% or more) beginning at age 50 years was associated in a proportional hazards model with increased risk of hip fracture (relative risk, 1.8; 95% confidence interval, 1.04–3.3). Weight loss of 10% or more was associated with several indicators of poor health, including physical disability, low mental status score, and low physical activity ($P < 0.05$). Weight gain of 10% or more beginning at age 50 years provided borderline protection against the risk of hip fracture (relative risk, 0.4; 95% confidence interval, 0.1–1.00). Despite differences between older men and women in the incidence of, and risk factors for, hip fracture, weight history is also an important determinant of the risk of hip fracture among older men. Weight loss of 10% or more beginning at age 50 years increases the risk of hip fracture in older white men; weight gain of 10% or more decreases the risk of hip fracture. The relationship between extreme weight loss and poor health suggests that weight loss is a marker of frailty that may increase the risk of hip fracture in older men. Physicians should include weight history in their assessment of the risk of hip fracture among older men. Ensrud et al. [28] examined effects of changes in body weight on bone density in a group of 6,785 women over 65 years over a period of 5.7 years. They demonstrated that the greatest loss of bone occurred in women who lost weight (compared to those who were weight stable or gained weight) and this weight loss doubled the risk for a hip fracture irrespective of current weight or intention to lose weight. They concluded, "These findings indicate that even voluntary weight loss in overweight elderly women increases hip fracture risk." Villareal et al. [29] also demonstrated that weight loss is associated with a substantial loss of bone density. A 1-year program of calorie restriction and weight loss resulted in approximately 2% loss of bone mineral density (BMD) from the total hip and intertrochanter. Women who participated in a regular exercise program and lost a similar amount of weight and demonstrated no change in BMD.

There are a number of factors associated with the risk of a bone fracture; bone density and skeletal strength are the primary ones. Skeletal muscle strength and functional capacity are strongly associated with risk of a fall in elderly people [30]. The skeleton adapts to stress and mechanical loads and skeletal muscle exerts powerful loading forces on bone. The increased muscle mass/unit bone demonstrated by the greater TBK/TBCa ratio in men compared to women, observed by Ellis and Cohn, helps to explain the greater bone density and lower fracture risk in men. Using the measurement of TBK, Aloia et al. [31] reported that muscle mass declines during menopause and TBCa and bone density were associated with this loss. They also found that measures of TBK, bone density, and TBCa were positively related to body mass index (BMI) but not body fatness. Indeed, a high percentage of older women who experience a fracture of the hip are sarcopenic [32]. In this group of 313 women with a hip fracture, dual energy X-ray absorptiometry (DXA) assessment of lean mass and bone density showed a significant relationship between the prevalence of sarcopenia and osteopenia ($p = 0.026$) (Table 117.2).

However important bone density is in risk for a fracture, risk of a fall is equally as important, as at least 90% of hip fractures result from a fall. Gunter et al. [33] found that functional capacity was powerful predictor of those who were classified as fallers or non-fallers. They concluded that "given that the 'get up and go' discriminates between fallers and non-fallers and is associated with lower extremity strength and power, fall prevention

Table 117.2. Count and Expected Count of Women with Sarcopenia and Osteoporosis*

Total	230	83	313

*From Di Monaco et al. (Ref. 32). In 313 older women who have experienced a hip fracture, the actual number of women with sarcopenia (defined as LBM > 2 SD less than young adult) and osteoporosis, from DXA estimates. This population has a higher prevalence of both conditions than age-matched Caucasian women with no history of fracture.

strategies should focus on improving both functional mobility and lower extremity strength and power." In very old (89 ± 7 years old) and frail residents of a long-term care facility, Greenspan et al. [34] demonstrated that a fall to the side, low femoral bone density, and impaired mobility were independent risk factors for a hip fracture. In this population of frail elderly men and women, strategies for improving muscle function may significantly decrease the risk of an injurious fall and should be considered as a first-line prevention of an initial fall or recurrent fall. This may be particularly important as prevention or treatment of very low bone density in this population may take a long time to be effective or may not improve bone strength sufficiently to prevent a fracture. The responses of very old and frail long-term care residents to a progressive resistance training program are both substantial and rapid [35, 36]. The positive effects of this exercise training includes greatly improved strength, increased stair climbing power, improved balance, and increased level of spontaneous activity, each of which may decrease the risk of an injurious fall.

Orwell et al. [37] examined 2,587 community-based men between the ages of 65 and 99 years of age. Incident falls were ascertained every 4 months during 4 years of follow-up. Men in the lowest quartile for testosterone had a 40% greater risk for falling than men in the highest quartile. The men with the low testosterone also had a lower score for physical function but had a higher risk of falling even after controlling for functional capacity. These data suggest that muscle mass may play a strong role in preventing falls and subsequent bone fracture.

Disuse and physical activity

The positive effects of physical activity on bone density are well described. Regular, weight-bearing, aerobic exercise such as walking slows the age-associated rate of loss of bone density [38, 39]. In 96 healthy, Caucasian women, a positive relationship was seen between measures of muscle strength, physical activity, and bone density [40]. While regular physical activity helps to preserve LM [41], progressive resistance training (PRT) has also been shown to have a dramatic effect on both muscle mass, strength, and bone density. Nelson et al. [42] examined the effects of a twice-a-week, year-long PRT (80% of one repetition maximum) program in postmenopausal women who were randomly assigned PRT or to a sedentary control group. Femoral neck BMD and lumbar spine BMD increased by 0.005 ± 0.039 g/cm^2 (0.9% ± 4.5%) (mean ± SD) and 0.009 ± 0.033 g/cm^2 (1.0% ± 3.6%), respectively, in the strength-trained women, and decreased by –0.022 ± 0.035 g/cm^2 (–2.5% ± 3.8%) and –0.019 ± 0.035 g/cm^2 (–1.8% ± 3.5%), respectively, in the controls (P = 0.02 and 0.04). In addition, the women in the exercise group also increased muscle mass, strength, and balance when compared to the control group. These results demonstrate that a twice-a-week exercise program positively affects not just bone density, but other important causes of a fall and fracture in older women.

Walsh et al. [43] examined the relationship between sarcopenia and osteopenia and found that in premenopausal osteopenic women the prevalence of sarcopenia was 12.5%. In postmenopausal women it was 25% for those with osteopenia and 50% for those with osteoporosis. Physical activity was independently related to skeletal muscle mass (beta = 0.222, p = 0.0001), but diet and hormone replacement therapy (HRT) were not. They found that after adjusting for physical activity, muscle mass was not significantly related to BMD. These data strongly suggest that, while muscle mass may be linked to bone health, it is the forces that muscle exerts on the skeleton that may be the most important in maintaining bone density with advancing age.

Muscle strength is a predictor of a number of outcomes including risk of disability and bone fracture. Muscle strength is generally a reflection of skeletal muscle mass; however, strength shows a greater decrease with advancing age than does muscle mass. In 89 frail, very old nursing home residents, muscle mass was significantly associated with leg strength [44]. However, after controlling for gender, r2 = 0.0625, indicating that that muscle mass explained only a very small amount of the variability in muscle strength. Reduction in muscle strength may result from a number of factors, including decreased level of physical activity, while in subjects who undertake progressive resistance exercise training, increased strength is seen before any changes in muscle size. One important factor affecting muscle strength in elderly people is intramyocellular fat. Goodpaster and coworkers [45] have demonstrated that aging is associated with increased lipid infiltration of muscle, which results in decreased force production even after controlling for muscle cross-sectional area. Fat infiltration increases the risk of a bone fracture in older people. Schafer et al. [46] examined 2,762 older subjects in longitudinal health and reported that increased intramyocellular fat was associated with a 19% increased risk of a fracture. They also showed that when compared with subjects with normal glucose tolerance, those with type 2 diabetes had increased rate of fracture.

Inactivity has a powerful effect on skeletal muscle strength, size, and bone density. A large number of studies using bed rest as a model for exposure to a microgravity environment have demonstrated losses of muscle, exercise capacity, cardiovascular function, and bone density. However, elderly people with reduced exercise reserve, low muscle mass, and low bone density are most often hospitalized and placed on complete bed rest for long periods of time as therapy. The consequences of prolonged bed rest on body composition and functional capacity in elderly people has not received a great deal of attention. Covinsky et al. [47] showed that activities of daily living (ADL) function were often significantly reduced as a result of hospitalization. Kortebein et al. [48] examined the effects of 10 days of bed rest in healthy elderly men and women. These subjects experienced a

reduction in LM of 3.2% ($p = 0.004$) and a decrease in leg lean mass of 0.95 kg (–6.3%, $p = 0.003$). This reduction of leg muscle mass was associated with a 30% decrease in the fractional synthetic rate of muscle protein. They also experienced a decrease in physical activity, strength (–15.6%), and VO_{2peak} (–15.0%). The reduction in VO_{2peak} was equivalent to the effects of 15 years of aging [49, 50]. Younger men and women undergoing 28 days bed rest as a model for microgravity have been shown to lose about 400 g of muscle tissue [51]. These data demonstrated that healthy older people lose more than twice the amount of muscle compared to young subjects in one-third the amount of time during periods of bed rest.

There are few studies that have examined the recovery from bed-rest-induced changes in muscle and bone. Manske et al. examined the role of muscle force production in triggering bone adaptations in mice. By using a Botox muscle injection to immobilize muscle, they discovered that, as expected, muscle and bone losses were similar during immobilization. However, contrary to their hypothesis that recovery of muscle size and strength would precede increased bone density, they found that muscle and bone properties recovered at similar rates.

Muscle–bone interactions

The skeleton adapts to changes in physical activity, and these adaptations are manifested through loading forces produced by skeletal muscle. This may be one important reason why strengthening exercises that produce high amount of force for a short period of time appear to have a more powerful effect than lower intensity endurance exercise. Nelson et al. [42] examined the effects of a 1-year-long resistance exercise training program on bone density, muscle mass and strength, and functional status. After 1 year of a twice-weekly exercise program, the strength-trained women experienced an average 0.9% ± 4.5% increase in lumbar spine BMD and a 1.0% ± 3.6% increase in femoral neck BMD, while the non-exercise control group showed a –2.5% ± 3.8% and –1.8% ± 3.5% decrease, respectively. In addition, the women in the exercise group (and not in the control group) increased muscle mass, strength, balance, and overall level of physical activity, each of which have been demonstrated to be risk factors for an injurious fall. Increased mechanical loading of bone [52] by skeletal muscle may be an important reason that resistance exercise, during which muscles generate a far greater amount of force than during endurance-type exercise, has a more powerful effect on bone density than does lower intensity exercise. Bassey and coworkers [53–55] have examined the effects of high impact exercises. In one study [53], premenopausal women performed 50 heel-drop exercises (standing on toes with hip and knee extended and dropping on to the heel) each day for 6 months. The women performing the exercises showed a 3–4% increase in trochanteric density compared to controls. However, a similar study in postmenopausal women [54] failed to show an effect of a similar exercise program. In a direct comparison of high-impact, jumping exercise in pre- and postmenopausal women [55], positive effects on bone density were observed in the younger compared to older subjects.

Skeletal muscle expresses growth factors that may also exert an anabolic effect on the skeleton. Indeed, Hamrick et al. [56] demonstrated that bone is rich in receptor proteins for growth factors secreted by skeletal muscle, particularly in the muscle–bone interface. Muscle growth and hypertrophy are associated with secretion of insulin-like growth factor-1 (IGF-1) and mechano-growth factor (MGF), which stimulates bone formation by oseoprogenitor cells in the periosteum that express IGF-1 receptor (IGF-1R). Muscle injury promotes release of fibroblast growth factor-2 (FGF-2), which induces bone formation and stimulates fracture healing by perioseal osteoprogenitor cells expressing FGF-R2. Hamrick [57] points out that a number of osteogenic factors are secreted by skeletal muscle including IGF-1, insulin-like growth factor binding protein, basic fibroblast growth factor, osteonectin, transforming growth factor-α1, matrix metalloproteinase 2, and leukemia inhibitory factor. These hormone-like "myokines" are increased during times of muscle hypertrophy, such as that seen with resistance exercise training. They also point out that myostatin, a negative regulator of muscle growth, has a direct effect on bone and periods of muscle atrophy due to disuse also result in loss of bone.

CACHEXIA AND BONE

Cachexia [58] has been defined as:

> a complex metabolic syndrome associated with underlying illness and characterized by loss of muscle with or without loss of fat mass. The prominent clinical feature of cachexia is weight loss in adults (corrected for fluid retention) or growth failure in children (excluding endocrine disorders). Anorexia, inflammation, insulin resistance and increased muscle protein breakdown are frequently associated with cachexia. Cachexia is distinct from starvation, age-related loss of muscle mass, primary depression, malabsorption and hyperthyroidism and is associated with increased morbidity.

While cachexia is defined as a muscle-wasting syndrome, little attention has been paid to the concomitant loss of bone density. Prostate and breast cancer have been associated with low bone density and increased fracture risk, which has been described as the consequences of adjuvant therapy [59]. Heart failure is also associated with low bone density [60]. Men with HIV infection have a high prevalence of sarcopenia and low bone density [61]. Patients with chronic obstructive pulmonary disease (COPD) have been demonstrated have low bone density. They also have poor functional capacity, suffer from cachexia (muscle wasting) and frequently use corticosteroids. However, an additional factor that may cause an accelerated loss of muscle and bone in these patients is

inflammation. Bone et al. [62] examined 40 COPD patients awaiting lung transplantation. They demonstrated that 95% of these patients had low bone density and also showed that biomarkers of bone formation and resorption were related to tumor necrosis factor-α (TNF-α) and interleukin 2. A strong relationship was seen between airway obstruction and BMD in patients with emphysema [63].

SUMMARY

The strong relationship between skeletal muscle mass and bone density has been described in a number of studies. This relationship is seen in children, adults, men, and women. Indeed, conditions that result in loss (weight loss, disuse, cachexia) or gain (resistance exercise, androgen therapy) in skeletal muscle also cause a gain in bone density. This coordinated loss of muscle and bone should be considered and treated, particularly in elderly people. When elderly people undergo hospitalization, they are often discharged with considerably lower muscle mass and bone density as well as orthostatic intolerance and poor functional capacity. Although increased body fat can increase the risk of type 2 diabetes and disability in older people, traditional weight loss regimens using energy restriction result in losses of bone and muscle and an increase in risk of a fracture. Use of exercise can be of great benefit. However, pharmacological tools to preserve skeletal muscle and the skeleton should be strongly considered. As new muscle anabolic therapies such as selective androgen receptor modulators or anti-myostatin compounds are discovered, the promise of a single medication that enhances muscle mass and quality as well as improves bone health is great.

INTRODUCTION

The cross-talk between the regulation of bone mass accrual and energy metabolism has two major tenets. The first one is represented by the various influences exerted by multiple organs involved in the control of energy intake and metabolism on bone mass accrual. This regulation includes, but is not limited to, an influence of the gastrointestinal tract via the inhibitory effect of gut-derived serotonin on bone formation and the role of stomach acidity on bone extracellular matrix mineralization, and the opposite influences on bone formation and bone resorption of leptin, and through it of brain-derived serotonin and the sympathetic nervous system on bone mass accrual [1–7]. The second tenet arose from a question raised by the existence of this broad, complex, and multifaceted regulation of bone mass by energy metabolism: could bone, as an endocrine organ, exert a feedback regulation on some aspects of energy metabolism? It turned out that this is indeed the case, and this chapter will review the main aspects of this recently discovered regulation.

OSTEOCALCIN-MEDIATED BONE REGULATION OF GLUCOSE METABOLISM

As is not so infrequent in biological research, the stepping-stone of this novel endocrine function of bone came out of an unrelated study that appeared to be a failure. *Osteocalcin* is an osteoblast-specific gene that encodes a secreted protein present in the bone extracellular matrix (ECM) and the general circulation [8, 9]. Upon synthesis by osteoblasts, osteocalcin is carboxylated on three glutamic residues, which are then called GLA residues (hence the other name given to osteocalcin: bone GLA protein). This post-translational modification confers to proteins high affinity to mineral ions and thereby allows gamma-carboxylated osteocalcin (GLA-Ocn) to bind to the hydroxyapatite mineral present in mineralized bone. Not surprisingly, this mineral-binding property, along with the great abundance of osteocalcin in the bone ECM, led to the very logical assumption that osteocalcin may be involved in controlling the mineralization of the bone ECM. The reality, however, turned out to be different. Indeed, neither loss- nor gain-of-function mutations of *Osteocalcin* nor its ectopic expression in other ECMs had any consequences on ECM mineralization in bone or in other tissues [10, 11]. This failure contrasted strikingly with the fact that a related GLA protein present in the cartilaginous ECM, matrix gla protein, is indeed a powerful inhibitor of ECM mineralization [12].

This negative result left unanswered the question that had motivated the original study: What is/are the functions of osteocalcin and how does it achieve them? A peculiarity of the *Osteocalcin*-deficient mice became informative in that regard; although this did not affect their overall body weight, these mice were abnormally fatty. This phenotype, along with the fact that osteocalcin is present in the general circulation, raised the

hypothesis that it may act as a hormone regulating some aspects of energy metabolism. That it was the case was first established through co-culture assays. Indeed, co-culture of wild-type osteoblasts with pancreatic islets or adipocytes increased the expression of *insulin* in these islets and of *Adiponectin* in adipocytes [13]. In contrast, *Osteocalcin*-null osteoblasts failed to increase gene expression in either case. These *in vitro* data found support in the analysis of the *Osteocalcin*-deficient mice [13]. Both insulin expression and secretion were decreased in *Osteocalcin*–/– mice, as was the proliferation of the insulin-producing β cells of the pancreas. Likewise, adiponectin expression and secretion were also decreased in absence of *Osteocalcin*, although expression of other markers of the adipocyte function, such as leptin and resistin, were not changed. There were two other phenotypes of interest in the *osteocalcin*–/– mice. The first one was a decrease in insulin sensitivity in muscle, liver, and white adipose tissue (WAT). This phenotype was established molecularly by studying gene expression in liver, muscle, and WAT, and physiologically by performing insulin tolerance tests and hyperinsulinemic euglycemic clamps [13]. The second additional phenotype observed in the *Osteocalcin*–/– mice was a decrease in energy expenditure [13]. As a result of all these abnormalities, *Osteocalcin*–/– mice were glucose intolerant, abnormally fat, and insulin resistant, all features of metabolic syndrome. These observations indicate that osteocalcin is a hormone that, in the sphere of energy metabolism, has four main functions: it favors β-cell proliferation, insulin expression and secretion, insulin sensitivity, and energy expenditure (Fig. 118.1). In contrast, osteocalcin does not affect appetite, a trait consistent with the normal level of leptin observed in the *Osteocalcin*-deficient mice [13].

The next question was to determine which form of osteocalcin is active: the carboxylated one, the uncarboxylated one, or both? This question was first addressed in cell culture systems. *In vitro* assays provided a quite clear answer by showing that it is the uncarboxylated form of osteocalcin that could enhance *Insulin* and *Adiponectin* expression in isolated islets or cultured β cells and in adipocytes, respectively, while the carboxylated form could not [13]. Likewise, recombinant uncarboxylated osteocalcin could induce the secretion of insulin in islets perifusion assays [14]. Using a transgenic approach to confirm this finding *in vivo* was not a valid option since the gamma-carboxylase, the enzyme responsible for osteocalcin carboxylation, is ubiquitously expressed and therefore overexpression or ectopic expression of an *Osteocalcin* transgene would mostly lead to increased levels of carboxylated, i.e., inactive, osteocalcin. Pharmacologic strategies, though, could demonstrate that uncarboxylated osteocalcin is metabolically active. Indeed, both long-term subcutaneous infusion and once-daily injections of recombinant uncarboxylated osteocalcin were shown to increase glucose tolerance and insulin sensitivity in wild-type mice [15, 16]. Furthermore, these treatments could partially restore insulin sensitivity and glucose tolerance in mice fed a high-fat diet as well as decrease weight gain by stimulating energy expenditure. Altogether, these studies established that uncarboxylated osteocalcin is a metabolically active form or this hormone.

That osteoblasts regulate glucose metabolism is surprising, but what is even more surprising is that there is a second gene expressed in osteoblasts that exerts an influence exactly opposite to the one of osteocalcin on this physiological process. This gene, *Esp*, encodes a little-known protein tyrosine phosphatase (ESP, also termed "OST-PTP") that is present in only three cell types: the embryonic stem cell, the Sertoli cell of the testes, and the osteoblast [17, 18]. This restricted pattern of expression justified the study, in the context of the entire animal, of the function of ESP; this was done in two different laboratories and in two different ways. One group generated mice lacking *Esp* in all cells while a second group generated mice lacking it only in osteoblasts [13, 17]. Remarkably, both animal models develop the same phenotype indicating that ESP's main, if not only, function occurs in osteoblasts [13].

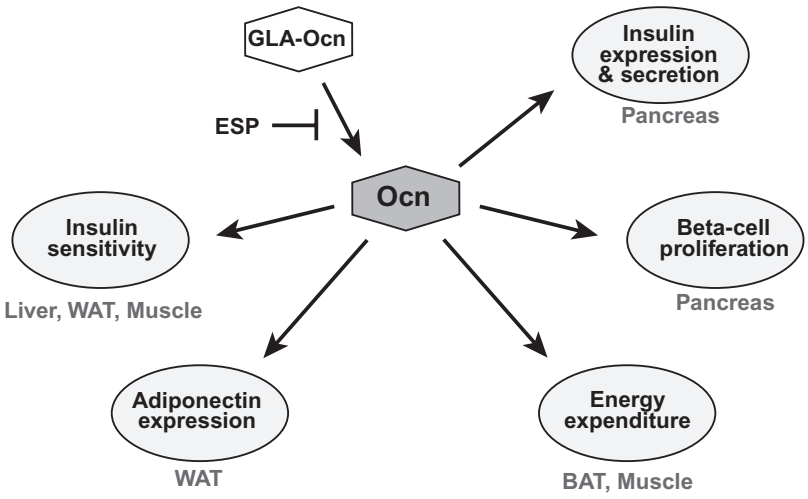

Fig. 118.1. Target tissues of the metabolic function of osteocalcin. Osteocalcin regulates glucose and energy homeostasis by acting on beta cell proliferation, insulin production, insulin sensitivity, and energy expenditure. To achieve these functions, it acts on multiple organs such as the pancreas, liver, white adipose tissue (WAT), brown adipose tissue (BAT), and muscle. Reducing the level of ESP, a tyrosine phosphatase expressed in osteoblasts, negatively regulates these effects.

The phenotype of the *Esp*-deficient mice was in all points the mirror image of the one seen in *Osteocalcin*-deficient mice. Indeed, *Esp*–/– mice are hypoglycemic because they are hyperinsulinemic; they are lean, hypersensitive to insulin, and display an increase in energy expenditure [13]. Consequently, when put on a high-fat diet, *Esp*–/– mice do not develop type 2 diabetes and become less obese than wild-type mice. That *Osteocalcin*–/– and *Esp*–/– mice have opposite phenotypes suggested that they act in the same genetic, if not biochemical, pathway and that, in fact, the *Esp*–/– mice are a model of a gain-of-function of osteocalcin. This assumption was verified genetically through the generation of *Esp*–/– mice lacking one allele of *Osteocalcin*. These latter mutant mice had normal insulin secretion, insulin sensitivity, and normal energy expenditure, thus establishing that *Esp* is indeed genetically upstream of *Osteocalcin* [13] (Fig. 118.1). Biochemically, however, the link was less obvious as ESP is a tyrosine phosphatase and osteocalcin is not a phosphorylated molecule, nor is gamma-carboxylase, the enzyme responsible for its carboxylation [19]. The solution of this puzzle came by approaching it through another angle.

BONE AS AN INSULIN TARGET TISSUE

The insulin receptor is a receptor tyrosine kinase; it is, therefore, conceivable that it could serve as a substrate for the phosphatase moiety of ESP and, through such functional interaction, would impact osteocalcin biology. That *Insulin* expression is regulated by osteocalcin is also a reason to study whether, in a feedback or feed-forward loop, insulin was affecting *Osteocalcin* expression, secretion, or activity. A third reason to study this question stems from an important aspect of insulin biology. Traditionally, liver, muscle, and WAT are seen as the main target tissues of insulin signaling, yet inactivation of the insulin receptor in myoblasts or in white adipocytes does not result in glucose intolerance [20, 21]. This observation implies that insulin should signal in additional cell types and tissues to achieve glucose homeostasis. The regulation of its secretion by osteocalcin made it conceivable that this tissue was bone. This hypothesis was tested by two laboratories that essentially reached the same conclusions.

A first line of experiments demonstrated through a classical substrate trapping assay that the insulin receptor is indeed a substrate for the tyrosine phosphatase moiety of ESP in osteoblasts [19]. This observation provided a biochemical basis to the notion that insulin signaling in osteoblasts could be a regulator of osteocalcin biology. As mentioned above, the specific deletion of the insulin receptor in osteoblasts in the mouse was engineered by two laboratories [19, 22], each using a different mouse Cre driver active in osteoblasts only [23, 24]. Both mouse models, thereafter named $InsR_{osb}$–/– mice, were hyperglycemic, and glucose tolerance tests (GTTs) showed that they were glucose intolerant. Glucose-stimulated insulin secretion tests showed that insulin secretion is also hampered in the absence of insulin signaling in osteoblasts. Lastly, insulin sensitivity in peripheral tissues was decreased in either $InsR_{osb}$–/– model. Hence, the ablation of insulin signaling in osteoblasts could do what its ablation in myoblasts could not: It created a glucose intolerance phenotype resembling type 2 diabetes [19, 22]. Two aspects of these experiments further highlight their biological relevance. First, it is important to note that those results were obtained in mice fed a normal diet, i.e., challenged only by the genetic manipulation they harbor. This indicates that the role of insulin signaling in osteoblasts is important in normal physiology. Second, since those two $InsR_{osb}$–/– mouse strains were cell-specific gene inactivation models in which deletion of the gene encoding the insulin receptor in osteoblasts was, in both cases, only partial, they are only hypomorphic models of its absence. That decreasing only its potency could lead to a significant metabolic phenotype highlights how important this regulatory pathway is for whole body glucose homeostasis.

The phenotype of the $InsR_{osb}$–/– mice is the mirror image of the one displayed by *Esp*–/– mice, an expected result given that the insulin receptor is a substrate of ESP and that its dephosphorylation hampers its activity [25]. A more remarkable finding was that there was more carboxylated osteocalcin and less active, undercarboxylated, osteocalcin in the serum of the $InsR_{osb}$–/– mice than in wild-type mice as quantified by a sensitive enzyme-linked immunosorbent assay (ELISA) specifically developed to detect these different forms of osteocalcin in the mouse [19, 26]. Although these findings provided an explanation for the fact that the phenotype of the $InsR_{osb}$–/– mice was a phenocopy of the one of *Osteocalcin*–/– mice, they raised another question: How could insulin signaling in osteoblasts be regulating osteocalcin levels and carboxylation, i.e., bioactivity?

Analysis of the bone phenotype of the $InsR_{osb}$–/– mice provided two answers to this question. First, gene expression studies revealed that expression the *Twist 1* and *Twist 2* genes, which encode nuclear factors inhibiting the transcriptional activity the osteoblast-specific factor Runx2 [27, 28], is enhanced in these mutant mice [22]. As a result, expression of the *Osteocalcin* genes is hampered, and less osteocalcin is produced (Fig. 118.2). In agreement with these data, infusing recombinant uncarboxylated osteocalcin in the $InsR_{osb}$–/– can rescue their metabolic phenotype [22]. Second, there is an increase in bone resorption parameters in the $InsR_{osb}$–/– mice, which is due to a decrease in expression of *Osteoprotegerin* (*Opg*) in osteoblasts [19]. One regulator of *Opg* expression is FoxO1, and insulin signaling in osteoblasts inactivates FoxO1 through phosphorylation just as it does in other cell types (Fig. 118.2) [19, 29]. This observation is consistent with the fact that inactivation of FoxO1 specifically in osteoblasts improves glucose tolerance and insulin sensitivity, at least in part, by promoting osteocalcin decarboxylation [30, 31]. A further analysis showed that two key genes are overexpressed in the osteoclasts of $InsR_{osb}$–/– mice: *Tcirg1,* a component of the proton pump

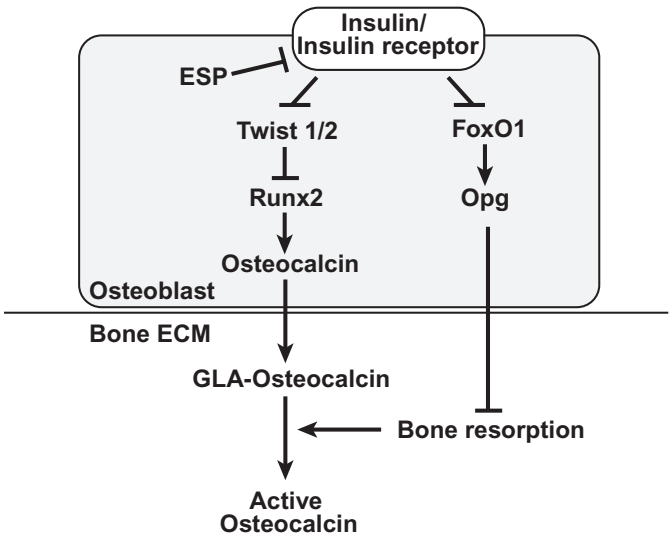

Fig. 118.2. Downstream effects of insulin/insulin receptor signaling in osteoblasts. On the one hand, insulin receptor signaling inhibits the expression of the Twist genes, releasing their negative effect on the transcriptional activity of Runx2, thereby promoting osteocalcin production. On the other hand, insulin receptor signaling inhibits the FoxO1-mediated induction of Opg expression, leading to an increase in bone resorption. This in turn promotes the release from the bone matrix and activation (via Glu13 decarboxylation) of osteocalcin. Through its ability to dephosphorylate, the insulin receptor ESP inhibits this process.

that is necessary for acidification of the resorption lacuna, and *CathepsinK*, which encodes a protein found in lysosomes that has an optimal enzymatic activity in acidic conditions [19, 32, 33]. In other words, through its negative regulation of *Opg* expression, insulin signaling in osteoblasts indirectly favors acidification within the resorption lacuna, a process that is mandatory for bone resorption to occur [32]. This aspect of insulin biology, which apparently has no relation to its regulation of glucose homeostasis, is, in fact, intimately intertwined with it.

WHEN BONE REMODELING MEETS GLUCOSE HOMEOSTASIS

It has been known for more than 20 years that the only means to decarboxylate a protein outside the cell is through an acid pH [34]. Accordingly, fully carboxylated osteocalcin incubated at pH 4.5 for a week becomes undercarboxylated on residue Glu 13 and is then able to enhance insulin secretion from isolated β cells. In contrast, when it is incubated at pH 7.4 for the same amount of time, carboxylated osteocalcin remains fully carboxylated and is unable to stimulate insulin secretion by β cells [19]. This set of observations implies that bone resorption, through the acid pH it requires, could enhance osteocalcin undercarboxylation, i.e., activation. The demonstration that *oc/oc* mice, which harbor a loss-of-function mutation in *Tcirg1* and therefore cannot properly generate the acidic milieu necessary for bone resorption, have less active osteocalcin and display glucose intolerance, insulin resistance, and a decrease in insulin secretion is in full agreement with this contention [19].

That insulin signaling in osteoblasts favors bone resorption and more specifically acidification of the bone ECM suggests that insulin uses the interplay between osteoblasts and osteoclasts to favor its own secretion via activation of osteocalcin. This hypothesis was demonstrated using several mouse models. Analyses of wild-type mice fed a high-fat diet and treated with receptor activator of nuclear factor-κB ligand (RANKL), of *Esp*–/– mice (a gain-of-function model of insulin signaling in osteoblasts) treated with alendronate, and of heterozygous compound *oc*/+; $InsR_{osb}$+/– mice all concur to demonstrate that insulin signaling in osteoblasts activates osteocalcin through its positive regulation of bone resorption and thereby, in a feed-forward manner, favors insulin secretion by pancreatic β cells [19].

OSTEOCALCIN AND ENERGY METABOLISM IN HUMANS

There is no example yet of a molecule identified as a hormone in mice that has abruptly lost this characteristic in humans. Nevertheless, as with all findings primarily made using animal models that investigate whether osteocalcin plays the same role in humans and mice, this has been an important question.

Following the original paper describing osteocalcin's endocrine function, a continuous flow of clinical studies have shown that the blood level of this new hormone is a reliable marker of glucose intolerance and more generally of a metabolic dysregulation in humans. For instance, levels of circulating osteocalcin have been inversely correlated with body mass index (BMI), fat mass, plasma glucose, fasting insulin, and insulin resistance in adult men and women, diabetic or not [35–44]. More generally, lower osteocalcin levels were observed in obese or type 2 diabetic subjects compared to nonobese or nondiabetic control individuals [35, 36, 45]. Likewise, decreased levels of osteocalcin have been associated with premature myocardial infarction in young patients and coronary heart disease in older individuals, in which it could be associated with the progression of atherosclerosis [43, 46, 47]. On the other hand, a lower odds ratio of developing metabolic syndrome was associated with higher levels of osteocalcin in black as well as white non-Hispanic individuals [38, 48]. Lastly, two recent interventional studies have correlated osteocalcin levels with glucose homeostasis even more directly. In the first one, weight loss and a decrease in homeostatic model assessment (HOMA) was associated with an increase in osteocalcin levels in obese children [45]. In the second one, an increase in blood glucose levels was observed in patients

upon resection of an osteoid osteoma, a begnin osteoblastic tumor that produces high levels of osteocalcin [49]. Altogether, this now quite large body of clinical studies has established that osteocalcin, in humans as in mice, is associated with the regulation of glucose homeostasis and energy metabolism.

A second point that needed to be addressed is whether osteocalcin's osteoclast-dependent mode of activation also occurs in humans. This question was more so important because ESP is a pseudogene in humans [50]. A combination of molecular biology and human genetic efforts showed that PTP-1B, a well-characterized protein tyrosine phosphatase that has been previously shown to dephosphorylate the insulin receptor in other cell types [51, 52], could play the same role instead of ESP in regulating osteocalcin activation in humans. Indeed, PTP-1B is highly expressed in human osteoblasts, can interact with the insulin receptor in these cells, and can regulate expression of *OPG* [19]. At the genetic levels it was shown that patients with osteopetrosis due to a defect in ECM acidification have abnormally high circulating levels of the fully carboxylated, i.e., inactive, form of osteocalcin and are hypoinsulinemic [19]. These results provide strong evidence that, as one would expect, osteocalcin is activated through the same mechanisms in mice and in humans.

Altogether, these clinical findings establish the importance of proper levels of osteocalcin for the good of energy homeostasis. They also identify a need for targeted investigations that will specifically evaluate the impact of the bone–osteocalcin–metabolism connection in the pathogenesis of human diseases and their treatments. Among such studies, one question to address is testing whether antiresorptive treatments, which are the main therapeutic approach to osteoporosis at the present time, might, in some rare circumstances, have a worsening effect on an already compromised glucose tolerance or insulin sensitivity. We do not believe, however, that this will be a major concern for the general population. Likewise, anticoagulating agents that affect the function of vitamin K, and therefore enhance osteocalcin gamma-carboxylation, could potentially have a mild and so far unrecognized effect on metabolism. It appears less likely, however, that increasing vitamin K levels would have such an effect since osteocalcin is already almost fully carboxylated in normal conditions. On the other hand, conditions and drugs usually associated with the control of glucose metabolism should also be reassessed for a potential effect on bone remodeling. Moreover, it could be possible that some glucose-lowering agents act, at least partly, by modifying the production or activation of osteocalcin.

In our view, a most important point is that the role of osteocalcin as a sole marker of bone formation needs to be reevaluated. Indeed, variations in its serum levels could be caused by variations in insulin levels or by a need for a transient metabolic adaptation rather than by changes in bone turnover. For instance, a negative association could be found between osteocalcin levels and prediabetes in overweight children but not with bone mineral content [53]. This observation is consistent with the growing number of clinical studies suggesting that osteocalcin, in addition of being a marker of bone formation, is a marker of insulin sensitivity.

INTRODUCTION

The number of persons who are overweight or obese in the United States has reached epidemic proportions at 69% [1]. Obesity is a national health problem and its prevalence is increasing in developing countries. Although obesity is associated with higher bone mineral density (BMD) and bone mineral content (BMC), it has been shown that bone quality may be compromised in adults [2] and in children [3–5] and that fracture risk is higher at certain bone sites. Also, for a given amount of bone in obesity, fracture risk is higher [6]. The etiology for a relationship between bone and adiposity is complex due to the multiple factors that are involved. Both osteoblasts and adipocytes are derived from a common mesenchymal stem cell (MSC), and factors that stimulate adipogenesis typically inhibit osteoblast differentiation [7, 8]. In addition, the hormonal profile and adipokines in obesity may contribute to bone quality. Furthermore, mechanical forces in obesity and during a fall may have specific effects on bone quality and fracture risk at certain bone sites compared to individuals with a lower body weight. Factors related to lifestyle in obesity such as poor dietary habits, sedentary activity, or repeated attempts to lose weight would also potentially influence fracture risk.

STROMAL CELL ADIPOCYTE/OSTEOBLAST

The pluripotent stromal cell is influenced by different factors that lead to the differentiation into their mature cell types that eventually constitute the balance between bone and adipose tissue, as well as cartilage and muscle mass. It was classically assumed that reduced bone mass and osteoblastogenesis that occurs with aging are associated with an increase in marrow adipogenesis [9]. However, the relationship between bone and fat formation within the bone marrow microenvironment is complex. There are a number of transgenic or gene-deficient (knockout) mice with phenotypes reflecting altered bone marrow adipogenesis and/or osteogenesis [7]. While Runt-related transcription factor 2 (RUNX2), which is also known as core-binding factor subunit alpha-1 (CBF-alpha-1) (Runx2/Cbfa1), and osterix are bone-specific transcription factors required for osteoblast differentiation [8], the peroxisome proliferator activated receptor δ (PPARδ) plays a central role in initiating adipogenesis and inhibiting osteoblastogenesis. Ligands for PPARδ include the thiazolidinedione class of antidiabetic drugs (i.e., rosiglitazone) that increase insulin sensitivity [10], has also been shown to increase adiposity, reduce bone mass, and increase fracture risk [11]. This

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

may occur due to regulation through increased PPARγ and fibroblast growth factor 21 (FGF21). For example, pharmacological doses of FGF21 induce severe bone loss by favoring the differentiation of bone marrow mesenchymal cells into adipocytes instead of osteoblasts in mice [12]. Glucocorticoids are another example of drugs that increase adiposity, especially visceral fat, at the expense of osteoblast differentiation. Both osteoporosis and aging-related bone loss increase marrow adiposity and suggest a switch in differentiation of stromal cells from the osteoblastic to the adipocytic lineage. It is possible that low-density lipoprotein oxidation products promote osteoporotic bone loss by directing progenitor marrow stromal cells to undergo adipogenic instead of osteogenic differentiation [13]. Also, skeletal unloading increases adipocyte differentiation and inhibits osteoblast differentiation, and both processes can be reversed by transforming growth factor–β or β2 [14]. Overall, the plasticity between adipose and osteoblast cells can help explain the relationship between different components of body composition. Continued study in this area could potentially result in drugs that could inhibit marrow adipogenesis and further our understanding of obesity and osteoporosis related to aging and to disease states.

OBESITY AND BONE MARROW FAT

Although the interaction between obesity and BMD has traditionally been considered a positive one, the relationship between fat and bone within the bone marrow differs. Previous studies have shown that an increase in bone marrow fat [also known as bone marrow adipose tissue (BMAT)] is associated with lower BMD [15, 16], which may have racial differences [17]. Bone marrow fat is also elevated after loss of BMD associated with caloric restriction (CR) [18]. Therefore, in contrast to the loss of subcutaneous or visceral adipose tissue depots, there is an increase in bone marrow fat after weight loss. It is possible that reduced concentrations of leptin, estrogen, and insulin-like growth factor-1 (IGF-1), and increased cortisol, which are known to be altered by CR, contribute to BMAT deposition. FGF21 also increases with CR [12, 19] and results in greater adipogenesis, growth hormone resistance, and lowers IGF-1 [20]. All of these actions could promote marrow adipocytes and BMAT [18, 21]. In obesity, the amount of BMAT may be influenced by hormones and adipokines related to visceral adiposity, since one study showed that vertebral bone marrow fat is positively associated with visceral fat [22]. This same study in obese women showed that BMAT is inversely associated with IGF-1 and BMD [22] but shows no association with body mass index (BMI), subcutaneous, or total abdominal adipose tissue. Hence, greater visceral fat associated with an altered metabolic profile and/or metabolic syndrome in obesity may be a marker of greater bone marrow fat and lower BMD. The specific role of marrow adipose tissue and its relationship with BMD in obesity remains unclear.

BONE MINERAL DENSITY IN OBESITY

It is well established that a higher body weight is associated with a higher BMD and indeed the fracture risk assessment tool (FRAX) model includes BMI along with other clinical risk factors to assess fracture risk [23]. More recently, it has become clear that while total BMD is higher in the obese, trabecular and cortical volumetric BMD (vBMD) show a different pattern compared to normal-weight individuals. In children, a higher body weight is associated with a higher trabecular bone, but not cortical vBMD, and may decrease bone strength [3, 5]. A lower bone strength in the forearm of overweight children may be attributed to the greater fat-to-muscle ratio as compared to normal-weight children [24]. In adults, obesity is also associated with higher trabecular and lower cortical vBMD [2]. Even when bone parameters were controlled for confounders such as lean mass, physical activity level, and macronutrient intake, the positive effect of higher body weight on the trabecular parameters still remained, but a higher BMI did not have a positive effect on cortical parameters such as BMC, area and thickness and strength indices, and it remained negatively associated with cortical vBMD [2]. Obesity is associated with an altered hormonal profile, and in particular the chronically elevated serum parathyroid hormone (PTH) [2, 25] may be affecting bone quality due to its known catabolic actions on trabecular and cortical bone [26]. Thus, a greater understanding of the etiology and implications for differences in the trabecular and cortical compartments of the bone in obesity is needed. Evidence points in the direction that bone quality is compromised, and it may explain newer findings [6, 27] of increased fracture risk in the obese.

Potential measurement errors in obesity

Excess adiposity may artificially decrease BMD, especially in axial sites [28]. Long-term precision of BMD using dual energy X-ray absorptiometry (DXA) with weight change may also be a concern, with lower precision in heavier persons [29, 30]. Also, the practicality of positioning an obese person within the scan area on the DXA bed can be challenging. Despite these concerns, the trends observed in clinical trials for higher BMD in obesity are consistent with findings in rodent studies [31]. Peripheral bone measurements may have an advantage since there is less surrounding fat thickness compared to axial sites. In addition, quantitative computed tomography (QCT) can be more accurate since it measures vBMD rather than two-dimensional areal BMD (g/cm^2) as measured by DXA. Furthermore, obesity in older patients increases the risk of spinal osteoarthritis, which can overestimate bone mass [32]. Careful examination of

the lumbar spine measurement for vertebral exclusion is important in the interpretation of BMD [33] and is a special consideration for the obese. Thus, clinical exams and research examining BMD in the obese individual requires additional effort to ensure accuracy and the T-score interpretation.

FRACTURE RISK

It is well established that lower weight individuals are at greatest risk of fracture compared to overweight and obese individuals. A low body weight or BMI (less than 20 kg/m^2) is associated with low BMD and higher fracture risk (approximately six times higher) compared to a BMI of approximately 30 kg/m^2 [34]. Higher fracture risk is exacerbated in the absence of physical activity [34]. On the other hand, De Laet et al. [35] found that risk of fracture increases again when BMI is greater than 35 kg/m^2. This is consistent with a reduction in the effective modulus in obese compared to nonobese rats [36]. The etiology of higher fracture risk in these two extremes in body weight may be related to differences in bone quality, biomechanical disadvantages, hormonal influences, or factors related to a poor diet and/or reduced physical activity. One or more of these factors may explain the higher risk of low trauma fractures in obese postmenopausal women who have a normal BMD [6]. Similarly, obese men have a higher risk of fracture, adjusted for BMD, compared to normal weight men [27]. The greater risk of falling and impact upon falling may increase fracture risk at certain sites in the obese. In a population-based longitudinal study in 10,902 women, those with high BMI had a significantly higher risk of proximal humerus and ankle fractures while they had a lower risk of forearm, vertebral, and hip fractures [37]. The higher risk of humerus fracture in obese women has also been found by others [38]. This finding of higher risk of non-vertebral fracture is consistent with higher forearm fracture risk in children with high body weight [39]. Similar to findings in normal-weight individuals, it can be expected that racial or ethnic differences will also affect fracture risk in the obese. There are a few reasons why fracture risk will differ at specific bone sites in the obese compared to normal-weight individuals, such as a different risk of falling due to altered gait [40], a different biomechanical impact upon falling, and/or greater padding due to excess soft tissue at certain sites, such as surrounding the axial sites. Overall, obesity is associated with lower hip fracture but a higher risk of proximal humerus fracture and possibly ankle and vertebral fracture in women (Fig. 119.1). Importantly, it has also been shown that once a fracture occurs in an obese individual, there are more complications along with a longer recovery time [41].

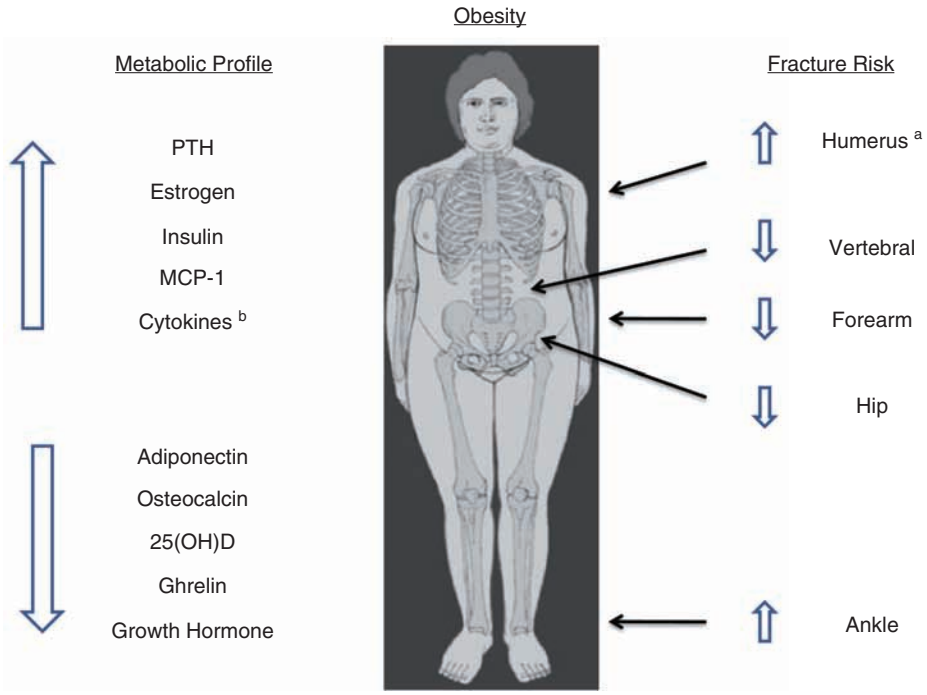

Fig. 119.1. Obesity: Metabolic profile and risk of fracture. The direction of fracture risk due to obesity at each site is similar in women and men, except the humerus (a), which is higher and lower with increasing BMI in women and men, respectively. (b) Pro-inflammatory cytokines.

BONE AND BODY COMPOSITION

Fat mass and fat-free soft tissue contribute to BMC and BMD [42, 43]. Fat-free soft tissue and strength are significant predictors of bone, and this positive effect may be due to exercise, lifestyle factors, estrogen sufficiency, or a combination of these factors. Low muscle mass is a risk factor for low BMD, whereas increased adiposity in adults is protective only when it is associated with substantial muscle mass. Total fat mass has shown to have both a positive and negative effect on BMD: the positive effect due to adipose-derived synthesis of estrogen and other hormones [42, 43] and the negative effect possibly due to release of other hormones and/or cytokines (Fig. 119.1). Fat mass accounts for approximately 15–30% of total body weight in normal-weight men and women, with much greater amounts in the obese. A fat threshold may exist whereby the higher adiposity may be detrimental due to increased release of adipokines and inflammatory cytokines, or reduced fat-free soft tissue may permit the threshold to be attained more readily. In addition, the distribution of adipose tissue in the body may be an important in the relationship with bone. In postmenopausal obese women it was found that the waist-to-hip ratio was a better predictor of bone at the radius than total fat mass [44]. In addition, abdominal fat has been found to be the most important positive predictor of BMD in women [45, 46], and low abdominal fat is associated with higher fracture risk [47], but the effect was not independent of body weight. In contrast, a greater visceral adiposity has been shown to be associated with reduced BMD in men [48] or young women [49, 50]. Others found an inverse relationship between BMD and visceral and subcutaneous fat corrected for lean tissue mass in adults across a wide age range [51]. Hence, studies do not show a consistent inverse relationship between visceral fat and bone, although these different relationships may depend on the specific bone site. Therefore, the site in which fat accumulates and the specific population of interest are important in understanding the link between adiposity and bone mass.

ADIPOKINES AND ENDOCRINE PROFILE IN OBESITY: ACTIONS ON BONE

Obesity may induce changes in bone due to several mechanisms, including an altered hormonal milieu because of factors secreted by adipose tissue, known as adipokines, which may be important mediators in the bone–fat relationship [8, 42, 43]. Adipose tissue is a highly metabolically active tissue containing a vast variety of cell types, and the more abundant cell types present are adipocytes, preadipocytes, immune cells, and endothelial cells. The adipocyte-derived factors have an effect on many organs in the body, including the bone. For example, excess adiposity has been shown to stimulate the osteoblast through increased production of the hormones insulin, estrogen, and leptin. Adipose tissue is a site of peripheral synthesis of estrogen from androstenedione resulting in higher serum levels of estrogen in obesity. Therefore, excess body fat is expected to be physiologically beneficial to bone health. In contrast, excess adipose tissue may hinder bone growth by enhancing the role of oxidized lipids in accelerating atherogenesis, thus calcifying vascular cells and inhibiting osteoblastic differentiation [52]. Other adipose-derived hormones include leptin, resistin, and adiponectin. Leptin is best known for its effect on suppressing appetite and increasing energy expenditure, but it has both a direct and central mediated effect on bone remodeling. The centrally mediated effect on bone occurs through sympathetic tone that inhibits bone formation and enhances bone resorption [53] yet *in vitro* has been shown to have direct effects on osteoblast differentiation [54]. Clinical trials have reported both positive and negative effects of leptin on bone [42, 43, 55, 56]. Serum levels of resistin are higher in obesity, and resistin is expressed in osteoblasts and osteoclasts. Resistin likely has a role in bone remodeling, but its overall effect is not established, and clinical trials do not consistently show an association with BMD [57]. The low levels of adiponectin in obesity may have a negative effect on bone since there are receptors expressed in human osteoblasts [58] but there are mixed findings in clinical studies [42, 59]. In addition, gut peptides [i.e., ghrelin, incretins, cholecystokinin (CCK), peptide YY–PYY, pancreatic polypeptide (PPY)] that regulate satiety are often altered in obesity and also regulate bone. For example, ghrelin is an appetite stimulant that is lower in obese subjects; a 1-year double-blind trial showed a positive effect of ghrelin treatment on bone [60]. However, a recent systematic review examining 59 studies concluded that there is a lack of convincing data to support an association between resistin, visfatin, or ghrelin with BMD or fractures [57].

Bone-regulating hormones that are altered in obesity include lower 25-hydroxyvitamin D [25(OH)D] [61] and higher levels of PTH [25]. The lower 25(OH)D is attributed to greater deposition into adipose tissue, or lower exposure in heavier individuals. Higher BMI and body fat are also associated with lower active 1,25(OH)D [62, 63]. Lower circulating 25(OH)D may explain the higher serum PTH in obesity; however, it is also possible that PTH has an independent effect to maintain higher adiposity. Greater adiposity due to hyperparathyroidism is associated with a decrease in fat oxidation [64]. However, it has been shown that correction of excess PTH following parathyroidectomy does not reduce body weight [65]. Thus, the cause and effect of the PTH and adiposity relationship is not entirely clear. Higher chronic levels of PTH reduce cortical bone but results in similar or higher trabecular bone [26, 66]. The overall effect of higher PTH on bone in obesity is not clear but has been shown to be associated with higher lumbar spine BMD and similar or lower bone mass at the femoral neck [67] and more cortical rich sites [2].

Obesity is also characterized by abnormal growth hormone (GH) secretion and insufficiency. Obese patients with no evidence of pituitary disease generally have normal or increased IGF-1 [68] that could be lower in the presence of central adiposity [69]. Hence, the effect of IGF-1 on bone in obesity is less well understood, yet the lower GH would be expected to have a negative effect on bone. Higher cortisol levels are associated with excess visceral adiposity, and excess endogenous cortisol may also lead to bone loss [70]. Osteocalcin, a bone formation marker secreted by the osteoblast, might also function as an important regulator of energy homeostasis [53] by regulating insulin sensitivity. Interestingly, serum osteocalcin levels are lower in obese individuals [71], and whether or not this has a direct effect on bone in this population is not known. Finally, higher circulating concentrations of inflammatory cytokines, including interleukin-6, monocyte chemoattractant protein-1 (MCP-1), and C-reactive protein, are found in obesity, and which, in general, have a negative effect on bone, but their specific effect on bone in obesity is not as clear [42]. For example, PTH upregulates serum MCP-1 levels in both normal-weight and obese subjects [72], and MCP-1 may mediate the anabolic effects associated with intermittent PTH on the osteoblast. Overall, the altered hormonal milieu and change in cytokines in obesity theoretically supports both positive and negative effects of higher body weight on BMD and the risk of fracture.

WEIGHT REDUCTION AND BONE

Loss of body weight in older men or women, whether voluntary or involuntary, is associated with reduced BMD and increased hip fracture risk [73, 74]. In addition, others have shown that only a 5% weight loss will increase fracture risk by 33% at the distal forearm [75]. Initial body weight is a strong predictor of the bone loss in response to weight reduction [43]. There may only be partial bone recovery with weight regain [76] so risk of fracture may be greater in individuals with a history of weight cycling. In overweight and obese older women who lose about 10% of their body weight, there is a 1–2% loss of bone at the trochanter, 1/3 radius, and lumbar spine [43, 77, 78]. The loss of bone can be attributed to a few factors including a decrease in micronutrient intake, calcium absorption, sex steroids, and/or mechanical loading [43]. Loss of bone due to moderate weight reduction is often not reported in younger women or men (younger than 50 years of age) [43, 79, 80], and this may be attributed to the well-maintained muscle mass and performance in men and young women. Weight reduction generally results in loss of highly trabecular rich regions [31, 78], but extreme loss of body weight (approximately 30% weight loss), proportionally increases bone loss [81], primarily from cortical regions [67, 82]. This suggests that moderate, compared to extreme, weight loss may differentially influence bone quality. Dietary interventions can attenuate bone loss such as with higher intakes of calcium and protein [78, 83]. Exercise may also attenuate bone loss with weight reduction [79, 84], and may also attenuate the risk of falling in older obese individuals due to an increased level of physical function [85]. There is strong evidence for bone loss and increased fracture risk due to weight reduction; the extent of loss is related to age, nutrient intake, exercise, as well as the amount and rate of weight loss.

SUMMARY

Obesity has a positive relationship with bone, but the quality of the bone differs compared to normal-weight individuals. Obesity is associated with lower cortical vBMD and higher risk of fracture for a given BMD or T-score. Hence, while the low- or normal-weight population remains at highest risk for fracture, new evidence shows that obesity also raises fracture risk. Many obese persons have a history of dieting, which may increase fracture risk. Also, adiposity-induced metabolic alterations, poor dietary intake, sarcopenia, and/or biomechanical disadvantages in obesity may contribute to the risk of fracture in obese children and adults. The benefits of weight reduction in the obese are multiple, and importantly, a higher protein intake, a multivitamin/mineral supplementation, and exercise should be encouraged to increase calcium and other micronutrients that are reduced during dieting to minimize bone loss. Due to the emerging data that obese patients are also at risk of fracture, this population should be included in osteoporosis screening and preventive measures should be encouraged.

INTRODUCTION

Studies published in the past decade report previously unexpected evidence on the control of bone metabolism by the central nervous system (CNS) and by neurotransmitters released in the skeleton by bone cells and their microenvironment. Bone is densely innervated by autonomic and sensory nerve fibers [1]. Bone cells, mainly osteoblasts, express receptors for neurotramitters and neuropeptides such as acetylcholine [2], norepinephrin (NE) [3], endocannabinoids (ECs) [4], neuropeptide Y [5], calcitonin gene related peptide, and substance P [1]. Central interleukin-1 (IL-1) signaling has been also implicated in the regulation of bone metabolism [6]. To date, the best experimentally characterized brain-to-bone pathway is the sympathetic nervous system (SNS) that mediates the skeletal effects of leptin and serotonin via a hypothalamic serotonergic relay [7]. Sympathetic nerve terminals form a synaptic-like junction with osteoblasts, which express β2-adrenergic receptors (β2AR). These receptors are activated by NE released from the sympathetic terminals, thus tonically restraining bone formation [8]. Activation of β2AR in osteoblasts also leads to stimulation of receptor activator of nuclear factor-κB ligand (RANKL) expression and their stromal cell progenitors, which in turn results in increased osteoclast number and activity [9]. The skeletal sympathetic tone is downregulated by brain-stem-derived serotonin and M3 acetylcholine muscarinic receptors expressed in the brain [7, 10]. NE discharge by skeletal sympathetic terminals is attenuated by the endocannabinoid 2-arachidonoylglycerole (2-AG) released into the sympatho-osteoblast junction by osteoblasts and activates CB1 cannabinoid receptors present in the prejunctional membrane.[3]

Neuropsychiatric diseases are mental disorders attributable to organic nervous system pathology, mainly brain pathology. The number of psychiatric diseases included in this category is still growing, as their organic etiology is being progressively established. In addition, clinical conditions involving cognition and/or behavior caused by brain injury or disease are sometimes included. Table 120.1 lists some of the major neuropsychiatric disorders and examples of related neural processes. It is now well established that some of these diseases, mainly major depressive disorder (MDD), anorexia nervosa (AN), and traumatic brain injury (TBI) are associated with changes in bone mass. Also, initial indications have been published suggesting that schizophrenia and Alzheimer's disease (AD) are accompanied by changes in bone density. Importantly, the skeletal status in these conditions is often complicated by psychiatric medication that affects bone directly and indirectly.

MAJOR DEPRESSIVE DISORDER

MDD is a mental disorder characterized by an all-encompassing low mood accompanied by loss of interest or pleasure in normally enjoyable activities, as well as

Table 120.1. Some Neuropsychiatric Conditions and Related Neural Processes

Major depressive disorder	Prefrontal-subcortical (limbic) dysregulation of monoamines, neurotrophins, hormonal systems, and neurogenesis
Bipolar disorder	Prefrontal cortex, anterior cingulate, hippocampus, and amygdala
Eating disorder	Atypical serotonergic system, right frontal, and temporal lobe damage
Schizophrenia	Structural alterations in frontal and temporal lobes, abnormal mesolimbic and mesocortical dopaminergic circuitry, changes in glutamatergic neurotransmission
Visual hallucination	Retino-geniculo-calcarine tract, ascending brainstem modulatory structures
Auditory hallucination	Frontotemporal functional connectivity
Obsessive compulsive disorder	Structural and functional alterations in the basal ganglia, particularly right caudate activity, changes in serotonergic neurotransmission
Post-traumatic stress disorder	Dysregulation of amygdala by ventromedial prefrontal cortex
Autism spectrum disorders	Genetic variations and mutations in single or multiple genes
Altzheimer's disease/dementia	Formation of plaques and tangles, neuronal death, neuroinflammation
Huntington's disease	Death of medium-sized neurons in striatum and cortex
Traumatic brain injury	Focal ischemia, neuroinflammation

alterations in appetite, body weight, sleep patterns, psychomotor activity, fatigue, worthlessness and low self-esteem, cognitive impairments, and suicidal ideation [11]. The term "depression" is ambiguous as it often refers to other mood disorders or to lower mood states lacking clinical significance. MDD is a disabling condition that adversely affects a person's family, work or school life, sleeping and eating habits, and general health. More than half of the individuals who commit suicide have MDD or another mood disorder [12]. It is generally believed that MDD is the consequence of a physiological vulnerability to stressful events. Although several central systems and processes have been implicated in depression, including alterations in serotonergic and adrenergic transmission, hormonal dysregulation, reduced neutrophines, and neurogenesis, as well as neuroinflammation and IL-1 secretion, the mechanisms involved are not well understood [13, 14].

Like osteoporosis, MDD is a prevalent disease, considered the second-leading cause of years of life lived with disability [15]. Both MDD and osteoporosis are substantially more common in women than men [11, 16]. Recently, data from the second Nord-Trondelag Health Study have demonstrated a cross-sectional association between depression and reduced bone mineral density (BMD) [17]. The relationship between MDD and low bone density has been established by several meta-analyses (reviewed in Ref. 18). The most comprehensive of these analyses includes 23 studies comparing a total of 2,327 depressed with 21,141 nondepressed subjects [19]. It shows that individuals with MDD have lower BMD and higher bone resorption markers than nondepressed subjects. The association of MDD with low BMD is significant in the spine, femoral neck, and distal radius, suggesting that the MDD-associated low BMD involves a multiplicity of trabecular bone sites throughout the skeleton. Consistent with the Nord-Trondelag Health Study [17], the overall effect size of depression on BMD for the entire population, comprising adult males and females, is rather small, with a moderate effect on serum and urine bone resorption markers.[19]

Women are significantly more vulnerable to depression-associated low BMD [19, 20]. This gender difference may be related to the greater sensitivity of females to stress in general, and to the greater responsiveness of depressed women to various stressors in particular (reviewed in Ref. 19). Still, the effect of MDD in men is more robust, i.e., it is not influenced by various moderating variables. In contrast, the association between MDD and BMD in women is heterogeneous, as it is significantly moderated by the menopausal status. Premenopausal women display a greater MDD-associated decrease in BMD compared to postmenopausal subjects [19], consistent with a decreased rate of bone mass accrual in teenager females with MDD [21], portraying reduced peak bone mass as one determinant leading to decreased BMD in depressed premenopausal women. The greater MDD-associated decrease in BMD in pre- as oppsed to postmenopausal subjects does not necessarily mean that MDD is not associated with low bone mass after menopause. However, in postmenopausal women this association may be masked by the multiplicity of factors contributing to the development of low bone mass, such as estrogen depletion, reduced physical activity, nutritional disturbances, and drug treatments (reviewed in Ref. 10).

Several studies report that the contribution of potential moderator variables to MDD-associated low BMD such as body weight and height, number of previous depressive episodes, total duration of disease, history of estrogen treatment, smoking, and race do not modulate the association between MDD and bone density. Low levels of physical activity, characteristic of depressed patients, were also suggested to be associated with low BMD (reviewed in Ref. 19). However, studies that assessed the levels of exercise found no evidence that it modulates the association between MDD and BMD [19]. In addition, in

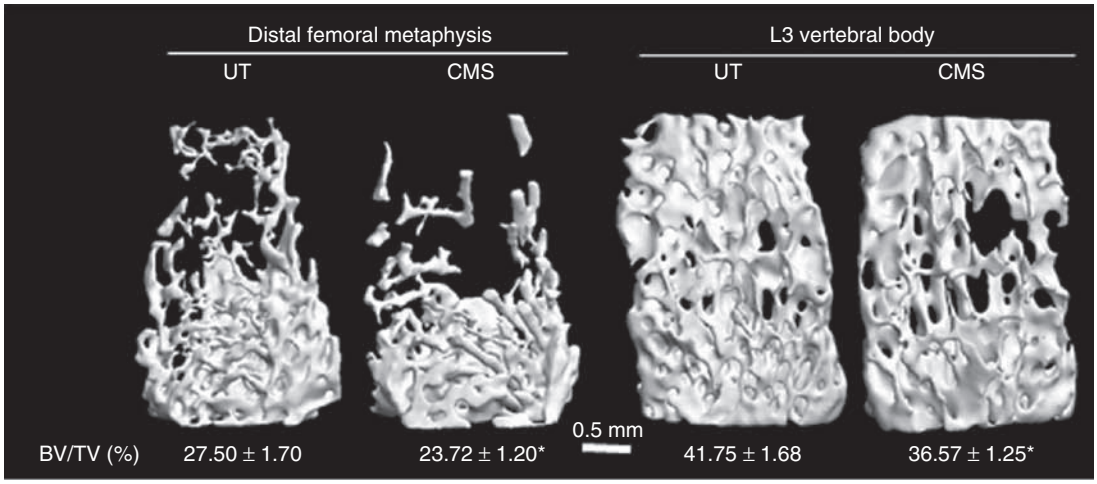

Fig. 120.1. Depression-induced structural impairment of the skeleton in mice exposed to chronic mild stress (CMS) for 4 weeks or left untreated (UT). μCT analysis. National Academy of Sciences, USA, copyright 2006 (Ref. 26).

several studies demonstrating depression-associated low BMD, the levels of endocrine factors believed to affect BMD do not differ between depressed and nondepressed subjects. These factors include serum 25-hydroxyvitamin D, parathyroid hormone, free T3, insulin-like growth factor I, and thyroid stimulating hormone (reviewed in Ref. 19). It is therefore unlikely that these variables are involved in the depression-associated low BMD.

Antidepressant therapy, especially by selective serotonin reuptake inhibitors (SSRIs), could be also a confounding variable affecting the above meta-analyses (discussed below). However, studies using antidepressant therapy as a covariate found no evidence to its effect on the association between MDD and BMD. It thus appears that the association between MDD and BMD is independent of the deleterious effects of antidepressants on the skeleton.

Taken together, these findings imply that all MDD patients are at risk for developing osteoporosis, with depressed women, particularly those who are premenopausal, showing the highest risk. These patients should be periodically evaluated for progression of bone loss and imbalances in bone remodeling and treated to prevent the progression of skeletal deterioration.

Causal relationship between depression and low bone mass

In the early 1980s, osteoporosis researchers suggested that depression was one of the major negative consequences of bone loss and osteoporotic fractures. They believed that osteoporosis occurred first, leading to a reactive depression. A similar, but distinct psychiatry literature reported that low BMD appeared to be an undesirable consequence of depression (reviewed in Ref. 22). The perspective that osteoporosis causes depression argues that the latter results from the pain and discomfort associated with osteoporotic fractures. The other approach, that depression is the causal process, claims that most studies demonstrate an association of depression with low BMD rather than with increased fracture rate. That depression is the causal attribute has been further proposed based on the well-established depression-induced increases in glucocorticoids and NE [23], agents also known to suppress bone formation and bone mass [24, 25]. In support of the latter concept, loss of bone mass and architecture has been demonstrated in mice with chronic mild stress (CMS), an established rodent model for depression (Fig. 120.1) [26]. The bone loss in this model results mainly from decreased bone formation. Both the reduced bone formation and the trabecular bone loss were apparently generalized as they were recorded in both the distal femoral metaphysis and lumber vertebral bodies. These skeletal deficits as well as the depressive symptoms (reduced sucrose preference and social exploration) could be prevented by the antidepressant drug imipramine [26]. The depressive-like state was associated with increased NE levels in bone and elevated serum corticosterone. Furthermore, the CMS-induced bone loss, but not the depressive-like state, could be prevented by the β-adrenergic antagonist, propranolol, portraying bone sympathetic innervation as a brain-to-bone pathway communicating depressive signals to the skeleton. In spite of the elevated serum corticosterone in mice subjected to CMS, the role of the hypothalamic–pituitary–adrenal (HPA) axis in CMS-induced bone loss is still unraveled, since it is unclear whether this elevation is sufficient to cause a negative bone remodeling balance and bone loss. Interestingly, although leptin has been implicated in both depression and the regulation of bone remodeling [27, 28], no relationship between leptin serum levels and CMS-induced bone loss could be established [26].

The adrenergic system and HPA axis are the most studied pathways mediating depressive signals from the CNS to the periphery. However, several other systems, implicated in both depression and low bone mass, could be involved in this process, such as the endocannabinoid system and inflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor-α (TNF-α) (reviewed in Ref. 18). In addition, dietary and behavioral patterns commonly observed in psychiatric patients may also contribute to the pathogenesis of low bone mass. Another contributing factor could be cigarette smoking, which is more common within psychiatric populations. It increases the risk for the onset of MDD and has repeatedly been shown to negatively influence bone mass in cross-sectional studies of both men and women. Likewise, depression and excessive alcohol consumption are common comorbidities, and alcohol abuse is a recognized risk factor for osteoporosis. Finally, although with a less well-defined cause–effect relationship, changes in food consumption are typically associated with depression, and certain nutrients reported to be deficient in patients with MDD are required for the maintenance of good bone health (reviewed in Ref. 18).

ANOREXIA NERVOSA

Anorexia nervosa (AN) is an eating disorder characterized by refusal to maintain a healthy body weight and an obsessive fear of gaining weight. It is often coupled with a distorted self-image and associated cognitive biases that modify the body self-perception [29, 30]. The average caloric intake in AN patients is 600–800 calories per day, but complete self-starvation is also known [31]. AN patients exhibit a high incidence of a spectrum of comorbidities such as prolonged amenorrhea, hair loss and/or thinning, and depression [11]. AN presents the highest mortality rate of any psychiatric disorder. It usually begins in adolescence with the number of female patients being tenfold higher compared to males [32]. AN can occur at any age. Noticeably, 0.2–4% of the affected individuals are adolescent girls and college-aged women [33].

AN is highly heritable with multiple polymorphisms in more than 40 genes involved in eating behavior, motivation and reward, personality traits, and emotion. Some of these polymorphisms have been identified in genes related to skeletal remodeling such as brain-derived neurotrophic factor and norepinephrine transporter. In addition, an abnormal brain response to the anorexic effects of estrogen and serotonin dysregulation has been reported [34, 35]. Also, autoantibodies for melanocortin, a neuropeptide implicated in personality traits associated with eating disorders and the control of bone mass, have been demonstrated in AN [36]. However, a causal relationship between these genetic and molecular changes and AN has not been established.

Low bone density is a serious complication in nearly all AN patients, with almost half of them presenting osteoporosis. It results from decelerated bone mass accrual as well as loss of established bone mass and is accompanied by structural changes such as reduced trabecular and cortical thicknesses, decreased trabecular number and greater trabecular separation (reviewed in Ref. 37). Measurement of serum bone remodeling markers suggests that lower rate of bone mass accrual occurs consequent to a low bone turnover, whereas adult AN patients present an absolute decrease in bone formation with increased bone resorption [38, 39]. Studies carried out so far do not point to impaired neuronal or neuroendocrine activity as the primary cause for the poor skeletal status in AN. Rather, their low BMD is a consequence of reduced muscle mass, hypogonadism, low insulin-like growth factor-1 (IGF-1), hypercortisolemia and profound alterations in energy metabolism. It is only partially reversible upon weight regain [37]. In the face of the vast neuroendocrine complications, the only remedy that can be currently offered to improve the skeletal status in AN is rescue of weight loss and menstrual function.

SCHIZOPHRENIA

Schizophrenia is a mental disorder characterized by disintegration of thinking and emotional responsiveness. It is commonly manifested as auditory hallucinations, paranoid or bizarre delusions, and/or disorganized speech and thinking, and is associated with significant social and occupational dysfunction. The onset of symptoms typically occurs in adolescence or young adulthood, with a global lifetime prevalence of about 0.5% [40]. Although impaired neurodevelopment and several neurodegenerative processes have been implicated in the etiology and pathogenesis of schizophrenia, its causes are poorly understood.

Most of the studies assessing the possible association of schizophrenia and osteoporosis report a positive relationship between schizophrenia, impaired bone metabolism, low BMD, and increased prevalence of osteoporotic fractures [41, 42]. In the absence of definitive organic pathogenic processes underlying schizophrenia, this relationship has been attributed to schizophrenia-associated factors such as hypogonadism, undernutrition, smoking, and polydipsia [41]. Of these factors, hyperprolactinemia, induced by neuroleptic medications (see below) and the resultant hypogonadism have received much attention. However, this approach has been recently challenged by studies from the Psychiatric Department of Yuli Veterans Hospital in Taiwan. These studies compared 965 adult schizophrenia patients and 405 nonschizophrenic community members living in the same district. They report that young male and female schizophrenia patients already have lower bone density than nonschizophrenics at the age of 20, consistent with impaired bone mass accrual prior to that age. However, the schizophrenia patients did not exhibit age-related bone loss, with female patients even showing some gain. The bone density in

schizophrenics older than 60 years was higher compared to the normal sample [43]. Interestingly, such a "protection" against age-related bone loss may result from mutations at the *Dgcr8* gene involved in the 22q11.2 microdeletions shown in schizophrenia patients [44], as silencing of *Dgcr8* leads to decreased osteoclastogenesis and a mild increase in bone mass [45]. Analyzing subsamples of schizophrenia patients with a low bone density (T-score equal to or lower than –2.5) and gender-matched patients with normal density, the Yuli study further reports no significant association between reduced bone density and serum prolactin or determinants involved in bone metabolism such as calcium, phosphate, osteocalcin, collagen type I N-terminal crosslinks (NTX), thyroid-stimulating hormone, and parathyroid hormone levels. In addition, there was no association between the bone density measurements and the type of antipsychotics or the menstruation status in the female patients [46]. Taken together, it appears that the changes in skeletal status reported in schizophrenia patients may be linked to comorbidities and behavioral patterns as well as schizophrenia-induced impairment of brain-to-bone communication.

TRAUMATIC BRAIN INJURY

Intracranial traumatic brain injury (TBI) occurs when an external force traumatically injures the brain. The trauma is caused by a direct impact or by acceleration alone and can involve damage to structures other than the brain, such as the scalp and skull. In addition to the damage caused at the time of injury, a sequence of events take place in the minutes-to-weeks following the injury. These pathological processes, which include alterations in cerebral blood flow and increased intracranial pressure, contribute substantially to the damage from the initial injury and often lead to an array of physical, cognitive, social, emotional, and behavioral effects. The outcome can range from complete recovery to permanent disability or death.

Many TBI patients show increased bone formation manifested mainly as heterotopic ossification (HO) and accelerated fracture healing. The reported incidence of TBI-induced HO is 15–40%, and it appears that the occurrence of symptomatic HO is correlated with the severity of TBI [47]. TBI-induced HO can cause pain and reduced range of motion of joints, which in 8–10% of cases results in severe functional limitation and even complete bony ankylosis of joints in 5% of cases [48].

There is clinical and experimental circumstantial evidence that the TBI-induced systemic increase in bone formation is associated with the release of osteogenic factors from the brain into the cerebrospinal fluid and blood circulation. These factors include fibroblast growth factor, growth hormone, IGF-1, parathyroid hormone, and bone morphogenetic proteins (reviewed in Ref. 47). However, so far a causal relationship between the serum levels of any of these factors and TBI stimulated bone formation has not been demonstrated.

There is also evidence that the TBI-generated central signals are communicated to the skeleton by the SNS, thus stimulating bone formation. Studies in mice have shown a decrease in the inhibitory sympathetic tone of bone formation within hours after TBI. It has been further demonstrated that the TBI-induced decrease of this sympathetic tone is mediated by increased bone ECs levels, leading to super activation of CB1 cannabinoid receptors expressed in the skeletal sympathetic nerve terminals, which in turn inhibits NE release [3]. Therefore, cannabinoid therapy could be effective for the prevention of TBI-induced HO.

ALZHEIMER'S DISEASE

Dementia syndromes affect 10% of the population aged over 65. Alzheimer's disease (AD) is the commonest cause of dementia. It accounts for 65% of the dementia cases either alone or in combination with vascular dementia [49]. Although the etiology of AD is essentially unknown, the disease presents progressive neuronal loss associated with a number of molecular changes in the brain, including reduced acetylcholine levels [50], mutations in the amyloid beta (Aβ) precursor protein (APP) gene, and the consequent accumulation of Aβ deposits as well as soluble Aβ oligomers. Also, hyperphosphorylation of tau protein leads to the formation of intracellular neurofibrillary tangles inside nerve cell bodies [51]. In addition, autophagy due to valosin-containing protein (VCP) gene mutations and interference to proteosomal degradation has been suggested to cause neuronal apoptosis leading to frontotemporal dementia, a major feature of AD [52].

Like other forms of dementia, AD is usually diagnosed in patients older than 65. Although osteoporosis can be observed by the age of 50, all its consequences become apparent from the seventh decade and onward [49]. Expectedly, this circumstantial relationship results in a significant correlation between the two conditions. This correlation may be also enhanced by common risk factors shared by the two diseases, such as low body mass, nutritional deficiencies (mainly vitamin K and vitamin D deficiencies), less exposure to sunlight, and reduced physical activity. That this relationship may not be merely circumstantial is suggested by (1) the higher incidence of osteoporosis in AD patients compared to subjects in the same age group without memory impairment (reviewed in Ref. 50) and (2) a similar incidence of osteoporotic fractures in women and men with AD as compared to several-fold higher incidence of fractures in females in the general population [53]. Importantly, the treatment and rehabilitation in postfracture AD patients are more difficult than in non-AD patients, with less than half of the AD patient regaining pre-fracture functional status. Also, patients with dementia fall more frequently, thus

displaying an increased incidence of femoral neck fractures [54].

Although only 5% of patients with AD have familial Alzheimer's disease (FAD) [6], the discovery of genes for FAD facilitated the generation of transgenic mice that express these genes, mainly mutated human APP. These transgenic mouse models reproduce many critical aspects of AD, mainly $A\beta_{1\text{-}40}$ and $A\beta_{1\text{-}42}$ plaque formation in the brain, including cerebrovascular Aβ deposition (reviewed in Refs. 55 and 56). Accumulating evidence from these mice suggests that intraneuronal $A\beta_{1\text{-}42}$ triggers early neuronal loss and synaptic deficits [57]. Alterations in synaptic integrity is one of the earliest events in AD pathogenesis, which precede neuronal loss.[58]

A couple of recent reports in mice expressing *APPswe*, the Swedish APP mutation, demonstrate a possible causal relationship between AD and bone loss. One of these studies demonstrated a biphasic effect on osteoclastogenesis with an increase in mice younger than 4 months old and a decrease in older animals. The increase in the young mice appears to be mediated by Aβ oligomers and receptors for advanced glycation end products (RAGE) in bone marrow macrophages (BMMs), whereas the decrease of osteoclast formation and activity in the older mice may be due to an increase in soluble RAGE, an inhibitor of RANKL-induced osteoclastogenesis [59]. The second study used animals coexpressing APPswe and PS1 (encoding a human presenilin 1 mutation). These mice showed an accelerated age-related bone loss [60]. While either study suggests that Aβ can stimulate bone loss, it is still unknown whether Aβ is produced in bone in AD patients (or otherwise) or dysregulates central mechanisms that control bone remodeling.

NEUROPSYCHIATRIC MEDICATIONS

A number of first-line agents used in the treatment of neuropsychiatric disorders are associated with low BMD and increased fracture risk, potentially amplifying the negative impact of these disorders on the skeleton. These drugs include mainly the SSRI family of antidepressants and tranquilizing psychiatric (or neuroleptic) medications.

SSRIs

Serotonin [5-hydroxytryptamine (5-HT)] is a biogenic monoamine neurotransmitter. Like many of these amines, its synaptic and extracellular concentrations are regulated by a transporter (5-HTT) acting by high-affinity 5-HT reuptake from the extracellular to the intracellular milieu. The transporter 5-HTT is a major target for a family of antidepressants that inhibit its activity, thereby potentiating the effect of 5-HT. The skeletal action of these drugs, called SSRIs, has attracted substantial interest because of its potential impact on osteoporosis and resultant fractures.

Serotonin (5-HT) is best known for its role in the CNS, gastrointestinal (GI) tract, and cardiovascular (CV) system. In the CNS, it is produced by presynaptic neurons and is released into the synaptic gap, leading to activation of pre- and postsynaptic 5-HT receptors, thus influencing a myriad of behavioral, physiological, and cognitive functions [61, 62]. In the GI tract, 5-HT is synthesized and secreted by enterochromaffin cells and diffuses to enteric nerve endings to stimulate peristalsis [63, 64]. In both the CNS and GI tract, the duration and intensity of the serotonergic activity is enhanced by the sodium chloride-dependent 5-HTT [65, 66]. In the CV system, 5-HT is taken up primarily by platelets via 5-HTT and stored in dense granules [67]. It is released by activated platelets and induces blood vessel constriction or dilation,[68] and smooth muscle cell hypertrophy and hyperplasia.[69]

Osteoblasts, osteocytes and osteoclasts express functional 5-HT receptors and 5-HTT (reviewed in Ref. 70). In osteoblasts, 5-HT receptor agonists influence cell proliferation, potentiate the parathyroid-hormone-induced increase in AP-1 activity and modulate the cellular response to mechanical stimulation. In osteocytes, 5-HT increases whole-cell cyclic adenosine monophosphate (cAMP) and PGE2 levels, which are also involved in the transduction of mechanical stimuli [71]. In osteoclasts, 5-HT and 5-HTT have been shown to affect differentiation but not activity [70].

What is the source of 5-HT in bone tissue? The CNS does not appear to be a likely source of 5-HT available to bone cells, as the blood–brain barrier is impermeable to 5-HT and serotonergic innervation has not yet been demonstrated in the skeleton. As in the case of other neurotransmitters, such as ECs [3], 5-HT could be synthesized and released by bone cells and act in an autocrine/paracrine manner. Indeed, mRNA transcripts for tryptophan hydroxylase-1 (Tph1), a rate-limiting enzyme in 5-HT synthesis, have been detected in osteoblast and osteocyte cell lines [72]. Most of an organism's 5-HT is produced in the GI tract and stored in dense granules in platelets. Because 5-HT from this source is released only upon platelet activation [67], it is an unlikely activator of bone cell 5-HT receptors. However, a small fraction of the GI-derived 5-HT remains in the serum and serum 5-HT has been suggested as a negative regulator of osteoblast proliferation, bone formation and bone mass.[73, 74]

What is the physiologic role of the skeletal serotonergic system? The diversity of actions of 5-HT results from the occurrence of multiple 5-HTRs, which are divided into seven classes based on their signaling pathways [75]. Of these, only $5\text{-}HT_{1A}R$, $5\text{-}HT_{2A}R$, $5\text{-}HT_{1B}R$, and $5\text{-}HT_{2B}R$ are expressed in osteoblasts, and only the expression of $5\text{-}HT_{2B}R$ is increased during osteoblast differentiation. Mice deficient in $5\text{-}HT_{2B}R$ have accelerated age-related, low turnover bone loss, secondary to impaired osteoblast recruitment and proliferation [76]. In line with these findings, rats treated with 5-HT have increased BMD [77]. In contrast, mice deficient in osteoblastic $5\text{-}HT_{1B}R$

have a high bone mass phenotype, secondary to increases in osteoblast number and bone formation [74]. Disruption of the 5-HTT gene or pharmacological inhibition of 5-HTT by SSRIs leads to a low bone mass phenotype in growing mice [70]. These findings suggest that 5-HT has different age-dependent effects that inhibit peak bone mass accrual in the growing skeleton and keep bone remodeling and bone mass in balance in the adult skeleton. However, this explanation is challenged by the deleterious effects of SSRIs, both on trabecular and cortical bone, in adult mice [78]. These apparently paradoxical data may be explained by the osteoblast stimulatory effect of central 5-HT signaling, which by activating hypothalamic $HT_{2C}R$ alleviates the inhibitory sympathetic tone of bone formation [7].

In humans, SSRIs have emerged as popular drugs in the treatment of mood disorders. Most clinical studies report that antidepressants in general, but mainly SSRIs, are associated with low BMD and a dose-dependent increase in the risk of fractures and low bone mass in children (reviewed in Ref. 79). The reason for these deleterious effects may be linked to dysregulation of the balance between the skeletal, gastrointestinal, and central serotonergic systems, especially after prolonged administration [80].

Neuroleptics

Neuroleptic medications are classified as *typical antipsychotics* that were discovered in the 1950s, and the more recently developed second generation known as *atypical antipsychotics*. Either class of neuroleptics, but mainly the typical antipsychotics, includes members that adversely induce hyperprolactinemia and, consequently, bone loss.

Prolactin is produced by lactotroph cells in the anterior pituitary. Prolactin production is controlled by the dopaminergic and serotonergic systems. The predominant factor is dopamine that tonically inhibits prolactin production by acting on D_2 receptors on lactotrophs, thus restraining prolactin gene transcription. In contrast, 5-HT stimulates prolactin secretion by activating $5HT_{1A}R$ and $5HT_2R$ [81]. Both typical and atypical neuroleptics tend to antagonize receptors in the brain dopamine pathways, including differential inhibition of the D_2 and 5-HT receptors, and cause a dose-dependent increase in serum prolactin levels (reviewed in Ref. 41).

While the major function of prolactin is to promote the development of mammary epithelium and lactation, its clinical significance is related to the reproductive system and the skeleton, as sustained hyperprolactinemia leads to suppression of gonadotropin-releasing hormone (GnRH) secretion, inhibition of LH and FSH, and decreased secretion of estradiol and testosterone. Indeed, hyperprolactinemia-induced bone loss, frequently occurring during pregnancy and lactation, has been mainly attributed to sex steroid deficiency. The severity of bone loss is related to the level and duration of hyperprolactinemia, which impacts on the skeleton of female and male adults and adolescents (reviewed in Ref. 82). In addition, prolactin may affect the skeleton directly through prolactin receptors expressed in osteoblasts and their precursors. *In vitro* studies using differentiating and mature osteoblastic cells suggest that the osteoblastic processes affected depend on the level of hyperprolactinemia. The prolactin concentration typically recorded during lactation (100 ng/ml) inhibits preosteoblast proliferation, osteoblast number, and production of a mineralized extracellular matrix. This prolactin concentration stimulates RUNX2 and alkaline phosphatase expression in early stage osteoblast differentiation and inhibits the same genes in late stages [83]. Higher concentrations (up to 500 ng/ml), such as those often induced by neuroleptics, increase the osteoblastic expression of osteoclastogenic factors such as RANKL, MCP-1, Cox-2, TNF-α, IL-1, and ephrin-B1 [84]. Hence, multiple pathways may communicate the negative impact of neuroleptic medications and hyperprolactinemia on the skeleton.

SUMMARY

The association between neuropsychiatric and skeletal disorders is emerging as an important theme in bone and psychiatric pathophysiology. Comorbidities shared by the two disciplines appear to impact millions of patients of both sexes and all ages, and present a wealth of unanswered basic mechanistic questions and unresolved clinical issues. Perhaps the most urgent of these issues is the conflict between the beneficial effects of psychiatric medications, particularly in mood disorders and schizophrenia, and the deleterious effects of the very same medications on the skeleton.

INTRODUCTION

Bone never forms without vascular interactions [1, 2]. This obvious statement of biological fact does not do justice to the physiological, clinical, and pharmacologic implications of the relationship. The vasculature provides the conduit for osteoprogenitor invasion of avascular cartilaginous templates during endochondral bone formation [2]. Moreover, the vasculature is the conduit for mineral exchange between bone and the rest of the body to acutely meet systemic demands on calcium phosphate homeostasis with feast and famine [3, 4]. The vasculature provides the sustentacular niche for the birth of osteoprogenitors [5]. Mature osteoblasts, in turn, establish the hematopoietic stem cell niche and control the egress of circulating myeloid and endothelial progenitor cells (ePCs) in concert with skeletal CD169+ macrophages and autonomic nerves [6]. Furthermore, vascular endothelial cells elaborate osteogenic morphogens such as BMP2 and Wnt7 that promote osteogenic differentiation of neighboring mesenchymal progenitors [7]. Osteoblasts reciprocally elaborate the expression of vascular endothelial growth factor (VEGF), the prototypic stimulus for angiogenesis and vascular and canalicular permeability in bone [8].

In this chapter, we very briefly relate the vital interplay between vascular biology and bone physiology as relevant to metabolic bone disease. We review data that highlight how prevalent vascular disease processes impair skeletal homeostatic mechanisms.

AVASCULAR NECROSIS

Avascular necrosis (AVN), or osteonecrosis, represents the best-recognized clinical disorder of vascular disease and the skeleton. A large number of risk factors and causes have been identified (Table 121.1) [9, 10]; these can be usefully viewed as reflecting bone ischemia from (a) traumatic, anatomic, or thromboembolic compromise of extrinsic macrovascular blood supply to bone or a bone segment; (b) inflammatory, metabolic, prothrombotic, infectious, or hyperviscosity states that compromise intrinsic microvascular function and bone perfusion; and (c) marrow infiltrative processes or venous thrombosis that increase intraosseous "back-pressure," thus decreasing the pressure gradient supporting marrow perfusion [10]. To be sure, in most clinical settings pathobiology is multifactorial. For example, glucocorticoid excess not only causes fatty marrow expansion but also reduces skeletal VEGF production [11]. Bone microvascular occlusion with sickle cell crisis engenders pain, marrow edema, and congestion that can also alter intraosseous perfusion [12]. AVN arising with rheumatoid arthritis or inflammatory bowel disease often, but not always, occurs in concert with glucocorticoid treatment. Like VEGF antagonists, amino-bisphosphonates exhibit potent angiostatic properties and suppress VEGF expression [13]. Moreover, osteoclast activity is important for skeletal angiogenic responses [14]. However, osteonecrosis of the jaw arising with amino-bisphosphonate use most often occurs in the setting of malignancy with attendant chemotherapeutics and/or radiotherapy [15].

Table 121.1. Risk Factors for Avascular Necrosis/Osteonecrosis

Glucocorticoid therapy, Cushing's disease	Fracture (e.g., Garden type IV fracture of the hip)
Arterial thromboembolic disease	Joint dislocation with artery impingement
Sickle cell disease	Decompression sickness (caisson disease, the bends)
Excessive alcohol use, fatty marrow expansion	Gaucher disease
Radiation and chemotherapy	Bisphosphonate use in osteonecrosis of the jaw
Hyperviscosity syndromes (e.g., CML with leukostasis, Waldenström's macroglobulinemia)	Anti-VEGF signaling therapy (e.g., bevacizumab, sunitinib)
HAART* for HIV/AIDS	Hyperlipidemia (cholesterol, triglycerides) with or without HIV/AIDS
Hyperhomocysteinemia	Type 2 diabetes
Chronic renal insufficiency, transplantation	Idiopathic but anatomic (e.g., Legg–Calvé–Perthes disease of the femoral head; Kienböck's disease of the lunate)
Systemic lupus, rheumatoid arthritis, juvenile dermatomyositis	Inflammatory bowel disease, Behçet's disease, pancreatitis
Chronic graft vs host disease	Osteomyelitis

*Highly active antiretroviral therapy.

Importantly, certain anatomic venues are exquisitely susceptible to impaired arteriovenous perfusion. Examples include the femoral head—primarily supplied by the lone foveal nutrient artery [16]—and those individuals with a single palmar artery branch to the lunate [17]. The relative paucity of collateral vascular supply to the femoral head makes perfusion tenuous [16, 18]. Moreover, the posterior superior retinacular arteries that provide this collateral supply can readily become "kinked" with hip fracture. Thus, increased marrow adiposity, traumatic misalignment, and edema arising in any number of settings will critically impair vascular perfusion in these specific anatomic venues. In addition to impaired vascularity, the attendant colony forming unit-fibroblast (CFU-F) population that gives rise to bone-forming osteoblasts may also be reduced [19].

Diagnosis of AVN is made on the basis of clinical setting and radiographic findings [20]. In AVN of the femoral head or distal femur, pain (e.g., a deep dull ache) is often the only initial symptom often mimicking stress ("hairline") fracture [20]. Magnetic resonance imaging (MRI) with or without technetium-99m medronate bone scintigraphy readily distinguishes between the two. When disease is due to trauma or is severe or long standing, plain radiographs are revealing. Flattening of the femoral head (Fig. 121.1), joint space narrowing with sclerosis, subchondral fracture (crescent sign), and cortical collapse occur in the hip. Sclerotic changes are also seen in other venues such as the wrist, shoulder, vertebrae, and ribs [21]. Disability is related to reduced mobility secondary to pain and osteoarthritic joint malfunction [20]; thus, therapy is usually surgical with decompression or total joint arthroplasty, with recent studies evaluating potential roles for mesenchymal stem cell autografts [22]. In Kienbock's disease, revascularization with bone graft, radial shortening, or complete resection of the lunate may be required [17].

Fig. 121.1. Bilateral avascular necrosis of the femoral head. Pelvic radiograph demonstrating bilateral avascular necrosis of the femoral head in a bone marrow transplant patient with chronic graft versus host disease and steroid-induced osteoporosis. Note the flattening of the femoral head that distorts the normal spherical contour. Disease is worse in the left hip.

Medical approaches to AVN are currently very limited. Several anecdotal reports of treating bisphosphonate-associated osteonecrosis of the jaw (ONJ) with PTH(1-34) (teriparatide) have been recently published [23]. While not rigorously established, this is certainly biologically plausible since parathyroid hormone (PTH) signaling upregulates VEGF expression and reorients skeletal microvascular supply with sites of bone formation at the basic multicellular unit (BMU) [24]. Perhaps paradoxically, amino-bisphosphonates have been used to preserve femoral head structure and function in preclinical rabbit models of hip AVN as one strategy to preserve femoral head shape and stave off osteoathritic responses [25]. One

very small study suggests potential benefit in humans as well [26]. At present, medical approaches to AVN emphasize mitigation of the primary insults causing disease and pain control.

ATHEROSCLEROSIS, ARTERIOSCLEROSIS, AND SKELETAL HEALTH

As McCarthy recently reviewed, blood flow demands in the skeletal vary dependent upon the histoanatomic envelope [27]. Microsphere perfusion assays in preclinical models indicate flow values ranging between 20 mL/min/100 gm tissue in cancellous bone and 5 ml/min/100 gm in periosteal and cortical bone. The endocortical marrow compartment experiences the lowest flow rates (approximately 1 ml/min/100 gm) that potentially relate to the intricacies and needs of the bone remodeling compartment (BRC) [28] and endosteal hematopoietic niche [29]. In healthy young bone, perfusion is largely centrifugal [30]; principal nutrient arteries transverse cortical bone via the nutrient foramen and enter marrow space and bifurcate to form ascending and descending medullary arteries. Radial branches penetrate the endosteal cortex and ramify to form the Haversian capillaries that supply cortical bone and ultimately drain into the periosteal venous plexus. Marrow capillaries form sinusoidal structures that ultimate drain into a central venous sinus; this route of flow exits bone via the nutrient canal as one or two nutrient veins. Importantly, in preclinical models, pharmacological strategies that enhance nutrient artery-mediated marrow blood flow during exercise augment trabecular bone accrual [31]. Arterioles of the periosteum also supply vessels to perforating cortical canals similar to Volkmann's canals that interconnect Haversian systems. With age, this periosteal vascular supply becomes increasingly prominent, such that a centripetal flow vector, i.e., periosteum to cortex to marrow cavity, predominates [30]. The reasons for this are not entirely clear, but may relate to changes in marrow pressure, fat content, and vascular tone. Brinker and colleagues first highlighted that the principal nutrient arteries are more responsive to vasoconstrictors and relatively insensitive to vasodilators [32].

With aging, diabetes, dyslipidemia, hypertension, and uremia, conduit vessels throughout the body undergo arteriosclerosis, i.e., mechanical stiffening [33]. This impairs Windkessel physiology, the rubbery elasticity of conduit arteries necessary for smooth distal tissue perfusion throughout systole and diastole [34]. With each cardiac cycle, a portion of the kinetic energy elaborated during ventricular contraction of systole is stored as potential energy throughout the vascular tree; this energy is released during diastole and helps maintain uniformity of flow in distal capillary beds during the cardiac cycle [33]. Indeed, in preclinical models of murine arteriosclerosis, blood flow to femur as measured by microsphere perfusion is significantly decreased, even though blood flow to other organs such as the kidney is relatively preserved [35]. Thus, age- and metabolism-related changes in macrovascular stiffness and concomitant endothelial dysfunction in nutrient arteries interact to reduce and alter the pattern of skeletal blood flow. Consistent with this Windkessel model, Brenneise and Squier demonstrated that diet-induced carotid atherosclerosis reduces osseous blood flow by 80% to rhesus monkey maxillary and mandibular bone—even in the absence of altered nutrient artery diameter, osseous lumen area, intraosseous vessel wall thickness, or vessel lumen area/tissue area [36]. Of note, arterial stiffness [37] and carotid atherosclerosis [38] are increased in postmenopausal women with osteoporosis or low bone mineral density (BMD).

What are the clinical implications of these findings? Vogt et al. demonstrate that reduced blood flow to the lower extremities was associated with greater rates of bone loss at the hip and calcaneous [39]. As Meunier and colleagues went on to establish, skeletal blood flow is a critical determinant of bone formation and BMU activity in humans [40]. Subsequent noninvasive studies have demonstrated strong correlations between MRI measures of hip bone marrow perfusion and BMD in women, with concomitant increases in marrow fat [41]. Collins and colleagues identified that arteriosclerotic disease was an independent risk factor for low BMD in the hip in men [42]. They went on to show that hip bone loss and non-spine fracture risk in the MrOS study was significantly increased in men with peripheral arterial disease (PAD) as assessed by ankle-brachial indices (ABI) [42]. Of note, both low ABI values (index of conduit vessel atherosclerotic obstruction) and high ABI values (greater than 1.3; index of conduit vessel arteriosclerotic stiffening via medial artery calcification [43, 44]) were associated with increased rates of hip bone loss [42].

Diabetes, dyslipidemia, and renal insufficiency all induce macrovascular arteriosclerotic responses and endothelial dysfunction in addition to compromising bone mass accrual and conveying enhanced fracture risk. The mechanisms are only beginning to be understood, but relate to inflammation, phosphate metabolism, oxidative stress and oxylipid signaling [45]. Demer, Tintut, and colleagues recently demonstrated that multiple oxylipids derived from LDL—a key contributor to atherosclerosis and arteriosclerosis—suppresses osteoblast-mediated bone formation, enhances T-cell receptor activator of nuclear factor-κB ligand (RANKL) production, and impairs skeletal anabolic responses to PTH [46, 47]. Importantly, PTH/PTHrP (PTH-related protein) receptor signaling simultaneously suppresses arteriosclerotic conduit vessel stiffening while supporting skeletal bone mass accrual [48, 49]. Thus, the metabolic milieu that impairs arterial conduit vessel function necessary for healthy bone physiology also favors the "uncoupling" of bone formation and bone resorption.

Fracture, of course, is not the only musculoskeletal manifestation of vascular disease. In diabetes and PAD, the lower extremities bear the brunt of the burden, with amputation and arthropathy also confronting patient and

physicians [50]. Multiple investigators have now demonstrated that arteriosclerotic calcification conveys risk for lower extremity amputation [51–55]. Iliofemoral medial artery calcification in type 2 diabetes increases amputation risk threefold [53]. In bone diabetic and nondiabetic patients, computed tomography (CT) scanning and Agatston scoring to quantify tibial artery calcification outperforms ABI assessment in predicting lower extremity amputation risk [52]. The increasing prevalence of type 2 diabetes, metabolic syndrome, and renal insufficiency will significantly contribute to the arteriosclerotic disease burden in our society and convey risk for fracture, impaired oral bone health, and lower extremity amputation. Whether medical strategies that aggressively target the initiation and progression of vascular disease simultaneously reduce fracture risk and amputation risk remains to be examined.

CONCLUSIONS AND FUTURE DIRECTIONS

Preclinical and clinical studies performed over the past two decades have converged to reinforce and highlight the critical important of bone–vascular interactions in skeletal health. Arterial compliance, perfusion, and remodeling are vital to normal bone anabolic responses, and are regulated by prototypic osteoanabolic hormones like PTH [24, 48]. Signaling is bidirectional, with osteoblast hormones such as fibroblast growth factor-23 (FGF23) [56] and PTH-regulated, marrow-derived ePCs [57] coordinating systemic responses that maintain normal vascular health and perfusion. The perspectives of experts in endocrinology, cardiology, developmental biology, orthopedics, biochemistry, genetics, pathology, engineering and hematology often emphasize different features of the relationship between the vasculature and bone. This integrated picture provides a "toolbox" for devising novel strategies to address unmet needs in skeletal health. Moreover, consideration of the bone–vascular relationship helps explain why, in the setting of malignancy, many of our best therapeutic strategies oftentimes have mechanism-based skeletal toxicities; these are mediated in great part via perturbation of the bone–vascular relationship, tilting the risk-benefit ratio of current antiresorptive and angiostatic regimens toward risk with respect to oral and systemic skeletal health in some patients. As our understanding of bone–vascular interactions improves, so too will our capacity to meet the clinical needs of our patients afflicted with musculoskeletal and vascular diseases.

INTRODUCTION

The National Spinal Cord Injury Statistical Center estimates the incidence of acute spinal cord injury (SCI) in the United States to be about 40 cases per million population each year, or 12,000 individuals annually, with the number of new cases rising with the increasing size of the general U.S. population at risk [1]. It has been estimated that the prevalence of SCI in the U.S. is 721 cases per million population; using assumptions of incidence and life expectancy, it is estimated that there will be about 300,000 persons living with SCI in the United States by 2014 [2]. SCI results in varying degrees of partial or complete loss of sensation, motor function, and autonomic nervous system regulation to tissues and organs below the neurological level of injury. Sympathetic outflow is almost invariably interrupted to tissues and organs below the level of injury, and both sympathetic and parasympathetic efferents to the lower extremities may be disrupted [3]. Approximately 80% of individuals with SCI are male, and tetraplegia occurs in just over half of the cases of new SCI. Complete loss of motor function and sensation below the level of injury occurs in slightly less than half of individuals. With advances in care, except for those with the highest, most complete injuries, patients with SCI are now living for decades after their injury, with life spans approaching those in the general population.

This review will discuss several aspects of the pathophysiology, general clinical considerations, and relevant experimental findings in individuals with acute and chronic SCI. Animal studies are kept at a minimum but are used to clarify the cellular events that occur and appear to be responsible for the clinical changes observed after acute injury. The unique sublesional skeletal resorption that occurs after SCI compared to other conditions associated with generalized, rapid, and substantial bone loss will be described, as well as the far greater magnitude of the sublesional skeletal changes with SCI. In addition, the heightened risk of fracture, as well as its SCI population-specific risk factors, the occurrence of and contributing factors to heterotopic ossification (HO), and the prevalence of vitamin D deficiency in those with SCI, and the reasons for its high prevalence, will be discussed. In closing, the pharmacological and/or mechanical approaches attempted to date in persons with acute and chronic SCI will be presented. However, none has proven to be of convincing efficacy in persons with complete motor SCI who lack the ability to weight bear.

BONE LOSS AFTER ACUTE AND CHRONIC SCI

Loss of bone is an important secondary consequence of acute SCI and is due to a state of heightened skeletal resorption [4, 5]. This becomes a clinical issue during the initial period after SCI when calcium is rapidly resorbed from bone, producing hypercalciuria, which may be complicated by urinary tract stones; individuals with high bone turnover states and/or impaired renal function are also at increased risk for hypercalcemia. In contrast to the more global bone loss associated with postmenopausal or nonparalyzed immobilized individuals, bone loss due to SCI is restricted to that below the neurological level of injury (i.e., sublesional sites).

Bone loss after neurologically more complete forms of SCI is unique for its rate, distribution, and resistance to currently available treatments. In individuals with neurologically motor complete SCI, bone loss may occur at rates approaching 1% of bone mineral density (BMD) per week for the first 6 to 12 months after injury [6–8]. The rate of bone loss after SCI is substantially greater than that observed with microgravity (0.25% per week), bed rest (0.1% per week), or in postmenopausal women who are not taking antiresorptive medications (3–5% per year) [9–11]. The increased rate of bone loss appears to continue beyond the first 12 months of injury and continues at least over the next 3 to 7 years, albeit at a slower rate than initially. Why bone is lost at such an accelerated rate after SCI as compared to immobilization or spaceflight is unknown. This dramatic phenomenon may be related to any number of factors including, but not limited to: the loss of anabolic factors, such as circulating testosterone and/or growth hormone; factors in the local bone milieu; the presence of catabolic factors, such as the administration of methylprednisolone at extremely high doses within hours of the acute event or the production of inflammatory mediators/cytokines locally; and/or the loss of positive central and peripheral neural influences on bone. Bone is richly innervated by sensory and sympathetic nerves, and the former has been suggested to have anabolic influences on bone [12]. There is evidence from a study of monozygotic twins discordant for SCI to indicate that the difference in sublesional BMD between the twins increased with time after SCI for several decades, suggesting that loss of bone may continue at an accelerated rate in those with SCI for an extended period of time [13].

The areas of greatest bone loss are the distal femur and proximal tibia, and fractures are most common in these locations. In a cross-sectional study of eight SCI patients, a change of 35.3% in BMD of the tibial trabecular bone was noted within the first 2 years after SCI, whereas there was only a 12.9% reduction in tibial cortical bone [14]. In a cross-sectional study of 31 patients with SCI for greater than 1 year, Dauty et al. [15] demonstrated a demineralization of –52% for the distal femur and –70% for the proximal tibia, in agreement with the findings of several other investigators [16–19]. In a cross-sectional study of men with motor complete SCI, bone loss in the epiphysis, which is predominantly trabecular bone, was exponential with time [19]. On average, loss of ephiphyseal bone was 50% in the femur and 60% in the tibia [19]. In the diaphyses, which is predominantly cortical bone, losses were 35% in the femur and 25% in the tibia and involved erosion of the thickness of cortical bone by 0.25 mm/year over the initial 5 to 7 years after SCI [19]. This level of depletion places the bones, particularly at the knee, below clinically accepted thresholds for fracture.

FRACTURE AFTER SCI

Peripheral fracture is a significant complication of osteoporosis after SCI. In a prospective study of a cohort of persons with SCI, Morse et al. reported that fractures most often involved the tibia or fibula, followed by the distal femur, with upper extremity fractures being much less common, albeit occurring more frequently in higher cord lesions [20]. Falls from a wheelchair and transfers were the most common causes of fracture, although fractures can also result from merely performing range of motion activities. These findings agree with a recent cross-sectional study that demonstrated 15 out of 98 individuals with SCI who were followed longitudinally sustained 39 fragility fractures of the legs over 1,010 years of combined observation; the mean time to first fracture was about 9 years, with a 1% fracture rate within the first 12 months and 4.6%/year fracture rate if more than 20 years post occurrence of SCI [21]. From these reports, increasing risk for fracture was associated with motor complete SCI, lower level of lesion (e.g., paraplegia versus tetraplegia because of their greater ability to more actively participate in exercise regimens and other forms of physical activity), longer duration of injury, and greater alcohol consumption [20, 21]. The risk of fractures, as expected, has been found to be closely related to the BMD of epiphyseal trabecular bone [22]. Because persons with SCI may lack pain sensation due to the disruption of sublesional somatosensory, they often lack awareness of the acute occurrence of fracture, and they may seek medical attention only for resultant symptoms, which may include swelling, fever, increased muscle spasticity, and/or autonomic dysreflexia.

BONE METABOLISM AFTER SCI

Skeletal unloading as a consequence of SCI, or other severe immobilizing conditions, results in the eventual uncoupling of the osteoblast–osteoclast relationship. However, immediately after injury, there appears to be an increase in both osteoclast and osteoblast function [23]. Over the ensuing months, histomorphometry has

revealed an increase in trabecular osteoclastic resorptive surfaces and an early depression of osteoblastic bone formation [24]. The major osseous effect of SCI in humans is to increase bone resorption, reflected by hypercalciuria [24–26] and elevated markers of bone resorption, specifically serum or urine N-terminal telopeptide (NTX), C-terminal telopeptide (CTX), and pyridinoline and deoxypyridinoline cross-links [26, 27]. Consistent with these changes in metabolic markers of bone resorption, cultures of bone marrow from the iliac crest, a region below the level of the SCI, produced greater numbers of osteoclasts [28]. In persons with long-standing SCI, the bone turnover rate is assumed to be depressed, somewhat analogous to senile osteoporosis.

HETEROTOPIC OSSIFICATION

Ectopic bone formation, or heterotopic ossification (HO), occurs in up to half of patients after acute SCI, depending on the sensitivity of the diagnostic technique employed. The mechanisms for its occurrence have not been elucidated, but its etiology has been postulated to be due to trauma, hemorrhage, deep venous thrombosis, and/or immobility [29, 30]. HO often develops at the major joints, including the hip, which accounts for about 90% of cases, and the knee, distal femur, elbow, and shoulder joints. Clinically significant HO that reduces the range of motion to interfere with function occurs in about 10–20% of cases. The complications of HO may include the inability to sit (due to reduced range of motion), chronic pain, pressure ulcers, deep venous thrombosis, and increased muscle spasticity.

Local swelling may initially occur with the development of HO. Serum alkaline phosphatase (AP) activity is an early (i.e., 2 to 3 weeks after it first appears), nonspecific marker for HO; circulating AP levels do not correlate with the degree of bone activity, and, as such, AP should not be relied on to determine the severity or resolution of the condition. Some additional nonspecific biomarkers include C-reactive protein, erythrocyte sedimentation rate, creatine phosphokinase, hydroxyproline, and 24-hour urinary prostaglandin E_2. The three-phase technetium-99 labeled diphosphonate bone scan remains the earliest and most sensitive indicator to make the diagnosis of HO. Initial radiographic manifestations of HO lag behind its appearance on technetium scans by 3 to 4 weeks, with periarticular bone formation not appearing for 2 to 3 months on radiographs.

Nonsteroidal anti-inflammatory drugs, if administered early after acute SCI, have been shown to have the greatest efficacy in the prevention of HO [31–33]; however, this approach has not been routinely implemented in clinical practice. Treatment has included range of motion exercises with gentle stretching after the acute inflammatory period has resolved, usually after 1 to 2 weeks. Careful mobilization of the affected joints is recommended to prevent further loss of joint mobility. Sodium etidronate administration has been reported to be efficacious in reducing the severity of the condition by reducing the rate of new bone formation once HO has been identified to be present; this agent has no effect on ectopic bone *per se*. In one study, 20 of 27 patients had a decrease in swelling over the initial 2 days of intravenous etidronate therapy (prescribed intravenously for 3 to 5 days), which was followed by 6 months of oral therapy [34]. Longer therapy with etidronate may be more efficacious in preventing progression of HO but would also be anticipated to be associated with defective mineralization. Unfortunately, there is only one report in the literature of five patients using a newer generation bisphosphonate, pamidronate, to treat HO [35]. Radiation therapy and surgical resection of the ectopic calcified tissue have been performed for more severe cases to prevent joint ankylosis [33, 35, 36].

EVALUATION OF SKELETAL MINERAL DENSITY BY DUAL-ENERGY ABSORPTIOMETRY

With the wide availability of dual-energy X-ray absorptiometry (DXA), skeletal integrity in persons after SCI may now be routinely evaluated. Use of DXA methodology has been limited by clinicians because of a lack of accessible automated procedures for analyzing the most relevant regions of interest, specifically the distal femur and the proximal tibia; specialized software applications for the analysis of the knee are only now becoming available through the manufacturers of these imaging devices. Despite the well-appreciated prevalence and severity of bone loss after SCI, DXA scanning was performed in only a fraction of patients admitted with fractures after SCI [20]. As will be discussed below, effective treatments to reduce bone loss after complete motor SCI are not currently available. As such, any screening method for osteoporosis has limited relevance in the most neurologically compromised individuals because it does not provide information that could be acted upon with regard to a therapeutic approach. There may still be value in providing health care professionals information on bone mass in the regions of interest, which would permit them to inform those individuals whose BMD has decreased well below fracture thresholds and to counsel such patients to avoid high risk activities that may result in fracture.

Posterior–anterior (PA) DXA scanning has been shown to provide spurious results when assessing the spine because this technique cannot distinguish vertebral bone from other calcified entities, such as HO, or osteophytes and other degenerative changes that are common after SCI. As may have been expected, SCI subjects with moderate degenerative joint disease (DJD) had significantly higher T-scores by PA DXA than those without, or with mild, DJD [37]. Thus, when assessment of vertebral spine for bone loss is deemed necessary, lateral DXA methodol-

ogy or computerized tomography should provide more reliable information than that of standard PA DXA imaging [37, 38].

VITAMIN D AND CALCIUM

After acute SCI, and because of rapid bone resorption, serum ionized calcium levels are elevated, as reflected by a markedly increased renal clearance of calcium [4]. In the presence of high ionized serum calcium levels, parathyroid hormone (PTH) is suppressed, reducing PTH-mediated tubular absorption of calcium and further aggravating urinary calcium losses. Gut absorption of calcium would be expected to be reduced due to a reduction in renal 1-α hydroxylase activity. As such, modifying calcium intake should have little effect on urinary calcium excretion, as has been shown in patients after subacute SCI [4].

Individuals with severe chronic conditions, including disabilities, have long been recognized to be at high risk for the development of vitamin D deficiency because of reduced sunlight exposure due to lifestyle changes and/or institutionalization and medications [39, 40]. Those with disabilities tend to have a greatly reduced sunlight exposure, and conversion of vitamin D precursors to the active form requires ultraviolet exposure. Several of the drugs prescribed in persons with SCI, especially anticonvulsants and psychotropic agents, may accelerate hydroxylation of vitamin D and increase its renal clearance [40]. Persons with SCI often have a lower calcium intake than the general population, including vitamin D-fortified milk, which is the major dietary source of vitamin D, excluding supplements [41].

Vitamin D deficiency has been reported to be extremely prevalent in the SCI population, as well as in those with other disabilities [42, 43]. Bauman et al. demonstrated that approximately one-third of a veteran SCI population had an absolute deficiency of vitamin D [42]. Oleson and Wuermser recently reported that in subjects with chronic SCI, 81% had 25(OH)D levels below 32 ng/mL in the summer, and the percentage of those deficient in the winter increased to 96%; 54% of these subjects had 25(OH)D levels below 13 ng/dL during the winter months [43]. In one retrospective inpatient study of 100 SCI patients who were consecutively admitted to an acute inpatient rehabilitation facility, the prevalence of 25 hydroxyvitamin [25(OH)D] relative or absolute deficiency was 93% with a mean 25(OH)D value of 16.3 ± 7.7 ng/mL [44]. It should be appreciated that if an efficacious antiresorptive agent becomes available to suppress the unchecked bone resorption of acute SCI, then one must ensure that 25(OH)D levels are sufficient to facilitate gut absorption of calcium to prevent hypocalcemia. In an effort to restore serum vitamin D levels to a level that would serve to optimize gastrointestinal absorption of calcium [45], cholecalciferol, or vitamin D_3, 2,000 IU/day was administered to individuals with SCI in conjunction with daily oral calcium supplementation of 1.3 g elemental calcium/day; in vitamin D-deficient subjects, vitamin D supplementation for 3 months raised the level of vitamin D into the normal range in 85% of subjects, and the mean level of vitamin D for the total group was well above the lower limit of the normal range [25(OH)D greater than 30 ng/mL] [46].

POTENTIAL PHARMACOLOGICAL THERAPIES TO PREVENT OR REDUCE BONE LOSS

Bisphosphonates have a strong affinity for bone and inhibit osteoclast bone resorption, and this class of agents has been used in an attempt to prevent or reduce bone resorption associated with acute SCI. Bisphosphonates act by inhibiting farnesyl pyrophosphate synthase, which interferes with isoprenylation of guanosine triphophatases (GTPases) at the ruffled border of osteoclasts, thereby preventing attachment of osteoclasts to the bone surface, halting resorption, and initiating cell death [47]. However, our experience has raised questions concerning the efficacy of this class of medications in persons with SCI who are non-weight-bearing (i.e., complete motor SCI).

In various animal models of disuse osteoporosis, bisphosphonate administration was not effective at preventing bone loss or maintaining cortical bone strength, findings that differentiate disuse osteoporosis from other models of osteoporosis in which bisphosphonates have been shown to be of greater efficacy [48, 49]. In a human bed rest study in non-SCI individuals, bisphosphonates reduced osteoclast number in cancellous bone, but not in cortical bone [50]. Two relatively small, nonrandomized case series have demonstrated the benefit of bisphosphonates in persons with incomplete motor SCI who are able to bear weight and ambulate [51, 52]. This is an important insight for consideration in the use of bisphosphonates in the SCI population. It may be difficult to determine the efficacy of this class of therapeutic agents unless the authors prospectively and specifically address in their experimental design the varying degrees of motor impairment, the ability to bear weight, and/or ambulate. In the few frequently referenced reports that have addressed the effect of bisphosphonates on BMD after acute paralysis, the results are expressed as a composite of patients with varying degrees of completeness of motor lesions and ability to bear weight [53, 54]. In addition, as is often the case after acute SCI [55], high-dose glucocorticoids were administered in an attempt to preserve neurological function, but the potential effects of glucocorticoids were not controlled for in the experimental design in at least one of these studies, confounding interpretation of the results [54]. Zoledronic acid has been administered to patients with acute motor complete SCI with apparent benefit at the hip at 6 months (e.g., end points determined were BMD, cross-sectional area, and measures of bone strength), but these salutary

effects were almost totally lost by 12 months [56]. Despite the appropriate interest in BMD of the hip and parameters of bone strength in the general population, it should be appreciated that patients with chronic SCI tend to fracture the distal femur and proximal tibia. In an attempt to preserve BMD in patients with acute complete motor SCI, sequential doses of pamidronate preserved BMD of the total leg for the initial several months after acute injury but measurements at multiple sublesional skeletal regions 2 years after SCI were not different from the control group [57]. A recent review on this topic concluded:

> Data were insufficient to recommend routine use of bisphosphonates for fracture prevention in these patients. Current studies are limited by heterogeneity of patient populations and outcome measures. Uniform bone density measurement sites with rigorous quality control and compliance monitoring are needed to improve reliability of outcomes. Future studies should address specific populations (acute or chronic SCI) and should assess fracture outcomes [58].

The major regulators of bone remodeling are the receptor activator of nuclear factor-κB ligand (RANKL), which serves to positively drive osteoclastogenesis and function, and osteoprotegerin (OPG), which serves as a "decoy" receptor for RANKL to downregulate osteoclastic differentiation and activity. Denosamub (XGEVA®, Amgen, Thousand Oaks, CA), a human monoclonal antibody to RANKL, represents an immunological/pharmacological approach to the treatment of osteoporosis that has been recently approved by the FDA. Thus, the mechanism of action of denosamub, while inhibiting the osteoclast, is distinctly different from that of bisphosphonates. Histomorphometic, bone turnover, and bone density findings suggest that the effects of denosumab on bone remodeling are more potent than those of bisphosphonates [59, 60]. The dramatic reduction in eroded bone surfaces with denosumab may be especially relevant to preventing or reducing bone loss after acute SCI because of the robust osteoclastosis/bone resorption that develops shortly after paralysis.

Animal models of immobilization have shown that paralysis, casting of limbs, prolonged bed rest, or weightlessness cause substantial bone loss due to an initial phase of accelerated bone resorption and a prolonged phase of decreased formation [61, 62]. Manipulation of the OPG/RANKL system was highly effective at maintaining cortical bone mass in several disuse models, including spaceflight, tail suspension, and sciatic nerve injury [63]. Our group has preliminary evidence in a rodent model of SCI to suggest that there is a several-fold increase in RANKL expression after acute SCI, while the expression of OPG is reduced, making the ratio of RANKL to OPG highly unfavorable acutely after SCI (unpublished observation). In *ex vivo* cell cultures from our animal model of acute SCI, there was also an almost twofold increase in osteoclast differentiation markers; in contrast, osteoblast differentiation markers were markedly depressed. Thus, in acute SCI there appears to be the dual challenge to maintain bone integrity in the presence of increased osteoclastic activity and reduced osteoblastic function. Because we have found excessive RANKL expression after acute SCI in a rodent model, it may be postulated that the drug of choice may be an agent that directly antagonizes RANKL to markedly reduce function of the osteoclast. However, denosumab has yet to be investigated in the "high bone turnover" state of acute/subacute SCI.

EFFECTS OF MECHANICAL LOADING AND ELECTROMAGNETIC FIELDS ON BONE

Insights into the possibility that reloading may preserve or rebuild bone after prolonged unloading come from studies of bone mass in individuals returning to Earth after prolonged periods in space, in whom substantial bone loss had occurred during zero-gravity conditions. After 4–6 months of unweighting during spaceflight, 1 year of loading from the Earth's gravity led to substantial increases in BMD [64]. These findings provide insight, as well as hope, that it may be possible to increase bone mass and strength after the extensive sublesional skeletal loss that occurs after SCI.

Static mechanical loading of bone has been ineffective in slowing bone loss after SCI [65, 66]. Cyclical reloading provided by partial body-weight-supported treadmill training has also been ineffective in slowing bone loss or increasing bone mass in persons with SCI [67, 68]. To date, the mechanical intervention that has been shown to be beneficial to bone after SCI is cyclical muscle contraction elicited by functional electrical stimulation (FES). During FES, electrical stimulation of nerves is employed to stimulate muscular contraction, usually with surface electrodes. One study that was initiated within several months of acute SCI evaluated the effects of isometric contraction of the soleus muscle of one leg for 4 to 6 years of treatment using the tibia of the contralateral leg for comparison. Whereas the untreated leg lost BMD progressively over time, FES partially preserved bone along the posterior aspect of the tibia; and BMD of this region was more than double that for the untrained leg and only 25% lower than that in able-bodied controls [69]. Trabecular BMD of the central core of the tibia cross-section was 41% higher in the FES-trained leg than in the untrained leg. There is preliminary evidence to suggest that combining FES with standing may have a greater beneficial effect on BMD of the hip and the knee in a subset of subjects with SCI than FES alone, whereas the standing alone subset had a decrease in BMD of these regions [70]. FES was less effective in increasing bone mass in individuals with SCI who had long-established bone loss [71] that was likely associated with greater loss of trabecular architecture; however, the finding that modest increases in bone mass occurred with FES training using a cycle ergometer [72] or knee extension against

resistance [73] suggests that even years after SCI it may be possible to stimulate net accrual of bone if bone integrity is still somewhat preserved. In the latter study, the effect of FES-mediated extension of the left knee against resistance for 1 hour a day, 5 days each week for 24 weeks in a group of 14 individuals with SCI applied for greater than 1 year was compared to the right leg, which was untreated; this approach of FES-resistance training resulted in a 30% increase in BMD at the distal femur and proximal tibia [73]. Thus FES, if administered at the time of acute injury, prevents bone loss at the site applied, or, if administered sometime thereafter, improves bone mass at the site that is receiving the load. Translation to clinical care has been fraught with considerable difficulty due to the labor-intensive nature of the present approaches and the awareness that any effect on bone is rapidly lost when FES is discontinued.

Low-intensity, high-frequency vibration is an intervention delivered by an oscillating platform that has been found to reduce bone loss in children with disuse osteoporosis due to neurological impairments and in postmenopausal women [74, 75]. A study has recently demonstrated the feasibility of delivering low-intensity mechanical signals through the lower appendicular and axial skeleton while supine in subjects with SCI; transmission of signal increased with increasingly upright body positions [76]. This observation supports the feasibility for the use of low intensity vibration as a possible mechanical intervention to be studied in the prevention or reduction of bone loss in patients with SCI. Future studies are needed to investigate the effectiveness of long-term exposure to low-intensity vibration on preservation of BMD in persons with acute and subacute SCI. Animal and clinical trials should be considered to define the effects of frequency, intensity, and duration of low-intensity vibration on regional BMD and bone microarchitecture.

Findings from studies of electromagnetic stimulation in tissue culture and animal models have shown a remarkable effect to modulate human mesenchymal stem cell osteogenesis, to favorably alter cytokine profiles during disuse osteoporosis, to promote bone formation and repair, to regulate proteoglycan and collagen synthesis, and to increase bone formation in models of endochondral ossification [77–80]. In the able-bodied population, electromagnetic field stimulation is of possible value in successful spine fusion. In 201 patients who underwent spine fusion surgery and who were evaluated at 9 months, 64% of those administered electromagnetic treatment postoperatively healed compared with 43% of those treated with placebo devices [81]. In a review comprising four studies of 125 patients who were diagnosed with union or nonunion of the long bones (predominantly nonunion of the tibia) who received either electromagnetic fields (three of the studies) or capacitive coupled electric fields (one study), electromagnetic field stimulation appeared to offer some benefit in the treatment of delayed union and nonunion long bone fractures; overall, though, these findings were inconclusive [82]. The single report to date in individuals with SCI addressed the effect of pulsed electromagnetic fields applied unilaterally at the knee in subjects at least 2 years after acute SCI [83]. This study revealed increased BMD of the stimulated knee and decreased BMD of the contralateral knee at 3 months, a return to baseline levels of BMD at 6 months, and a fall in BMD of both knees by 12 months, with generally larger magnitude of changes closer to the site of stimulation; these findings suggested a complex effect that included both local and systemic effects of pulsed electromagnetic field stimulation on BMD above and below the knee [83].

COMBINED PHARMACOLOGICAL AND MECHANICAL THERAPY

The possibility of using a combined mechanical and pharmacological approach to reduce or prevent bone loss after acute SCI may also be entertained. Because of the obvious difficulty in instituting a mechanical intervention immediately after acute SCI, it may be necessary to begin therapy with drug interventions. It is conceivable that early after SCI a pharmacological approach to target and inhibit RANKL in an effort to suppress rampant osteoclastosis may be prove efficacious, as well as practical. Another consideration is that patients who are acutely or subacutely paralyzed are commonly hypogonadal [84], a hormonal deficiency state that may occur precipitously and, as such, may be assumed to worsen the bone loss of acute immobilization. Because high-dose methylprednisolone is frequently prescribed at the time of acute paralysis [55], and there are recent animal studies supporting the role of androgens to antagonize the effects of glucocorticoids on muscle [85, 86] and bone [87], this may be yet another reason to consider testosterone replacement therapy if a patient is diagnosed as hypogonadal shortly after injury.

When the patient is sufficiently stabilized after the acute traumatic event, which may be 2 to 6 months after acute SCI, a combination approach with mechanical intervention with at least one pharmacological therapy may be envisioned. Albeit purely conjecture at this time, it may be postulated that the sooner a physical intervention can be integrated into the care plan in the form of practical and cost-effective mechanical stimulation to restore forces that had been suddenly removed from the skeleton at time of injury, the greater the likelihood of preserving bone mass. The initiation of a mechanical approach may be reinforced by innovative, and temporally appropriate, pharmacological maneuvers. Thus, it may be hypothesized that along with a mechanical stimulation, a pharmacological anabolic therapy, such as teriparatide (FORTEO®, Eli Lilly and Company, Indianapolis, IN), an anabolic steroid, or another drug to stimulate depressed function of the osteoblast, may prove of added clinical value.

INTRODUCTION

One of the critical and unique functions of the skeleton in terrestrial vertebrates is to provide the anatomical spaces for production and storage of hematopoietic progenitors and precursors. The most immature cells of the hematopoietic system, hematopoietic stem cells (HSCs), are also found in bone marrow. A true HSC is defined as a single cell capable of generating the entire hematopoietic system throughout the lifetime of an adult [1]. To perform this task HSCs must constantly balance self-renewal and differentiation. While cell autonomous processes play a role in HSC cell fate decisions, *in vitro* studies have continuously demonstrated a loss of long-term engraftment capacity when HSCs are grown in culture without a supportive stromal cell layer [2]. In addition, several studies have shown that disruptions in the microenvironment can lead to aberrant hematopoiesis and even hematopoietic malignancies in mice [3–5]. This has led to the hypothesis that a specific microenvironment or niche is necessary for the maintenance and regulation of normal adult hematopoiesis and HSCs. Due to the singular homing of HSC to bone marrow spaces, it has long been suspected that non-hematopoietic cells contained in the skeleton, as well as their secreted products, including the matrix, may provide cellular and molecular components that are critical for the regulation of hematopoiesis and HSCs. This chapter will review the principal cell types and skeletal signals that have been implicated as regulatory cellular components of the HSC niche. These components not only illustrate the extraordinary complexity of skeletal tissue, but also provide critical clues to novel therapeutic targets for HSC expansion in conditions of myeloablative injury.

THE HSC NICHE

Osteoblastic cells

Schofield first proposed the concept that HSCs are regulated by microenvironmental interactions in 1978 [6]. It would take nearly 20 years before the first studies elucidating the cellular components of the HSC niche would be performed, and osteoblastic cells were identified early on as supportive of HSCs. *In vitro*, osteoblastic cells can maintain the stem cell activity of bone marrow [7–9]. Additional murine studies have demonstrated that transplanted HSCs preferentially engraft at the endosteal surface and in close contact with osteoblastic cells [10–13]. They also demonstrated that, *in vivo*, HSCs with high proliferative and long-term engrafting potential tightly adhered to the endosteal surface [14]. Increased osteoblastic numbers correlate with increased HSCs [9, 12], and the converse experiments have shown that a loss of the osteoblastic lineage of cells results in disrupted hematopoiesis [15, 16].

While osteoblasts produce many soluble factors that are known to be important for hematopoiesis [7, 9, 17], direct cell contact is necessary for osteoblastic cell

support of HSC self-renewal *in vitro* [9]. Treatment with parathyroid hormone (PTH) is capable of stimulating self-renewal of HSCs and increasing the HSC population despite the fact that HSCs do not express the PTH receptor (PTH1R), indicating a microenvironmentally mediated effect [9]. In addition to increasing HSCs, studies utilizing either PTH treatment or the constitutive activation of PTH1R on osteoblastic cells revealed that PTH signaling increases bone volume and the expression of the Notch ligand Jagged1 on osteoblastic cells [9, 18]. Notch signaling is known to support stem cell self-renewal in other stem cell systems and has been implicated in the support of HSCs [19–22]. Further, the inhibition of Notch signaling ablates the PTH-dependent increase in HSC number [9, 18]. Additional studies have further suggested that Notch signaling between osteoblasts and HSCs plays a role in maintaining repopulating potential [23, 24]. A separate study questioned the importance of canonical Notch signaling in the HSC niche, and work remains to be done elucidating the precise role Notch signaling plays in microenvironmental regulation of HSCs [25].

Annexin 2 (Anxa2) is expressed by both osteoblasts and endothelial cells in the bone marrow, and treatment of mice with Anxa2 inhibitors impairs HSC homing and engraftment [26]. Angiopoietin-1 (Ang-1) is expressed by osteoblasts and promotes stronger adhesion and quiescence in HSCs through interactions with the receptor tyrosine kinase Tie2 [27]. Genetic deletion of both Tie1 and Tie2 in mice results in a loss of maintenance of HSCs in the marrow, again suggesting a role of Ang-1 [28]. Osteoblastic cells also express thrombopoietin, a regulator of HSC quiescence [29, 30]. Moreover, osteolineage cells produce CXCL12, a critical regulator of HSC homing and maintenance [31].

Short–lived secreted signals are also potential osteoblastic-dependent HSC regulators. Prostaglandin E_2 (PGE_2) is an arachidonic acid derivative that is produced by multiple cell types within the bone marrow, including osteoblastic cells. Treatment of mice with PGE_2 increases short-term repopulating HSCs [32] and *ex vivo* treatment of HSCs with dimethyl-PGE_2 increases HSC repopulating potential both in mouse bone marrow and in human cord blood samples [33–35], one of the first illustrations of how identification of HSC regulatory signals can be used pharmacologically for therapeutic purposes.

Osteoblastic cells are also critical regulators of osteoclastic activity, and recent data suggest that osteoclastic cells are necessary for the formation of the osteoblastic HSC niche [36]. Osteoclastic cells were first implicated as playing a direct role in HSC regulation when data demonstrated that lack of the calcium sensor impaired the inability of HSCs to home to the skeleton [37]. High concentrations of calcium would be expected to colocalize with actively resorbing functional osteoclasts. Moreover, it was noted that treatment with strontium, which increases the osteoblastic pool but inhibits osteoclasts, did not expand HSCs [38]. In addition, increased osteoclastic bone resorption reduces the levels of local CXCL12 and stimulates mobilization of HSCs from the bone marrow [39, 40]. Together, these data have suggested a supportive role for osteoclasts in the HSC niche, and inhibition of osteoclasts has recently been associated with reduction of HSC numbers *in vivo* [38]. However, recent data using genetic murine models have suggested that osteoclasts are dispensable for HSC maintenance and mobilization [41].

While numerous studies, using both *in vivo* and *in vitro* experimental models, firmly implicate cells of the osteoblastic lineage in HSC maintenance and regulation, the differentiation stage of the osteolineage cell that supports HSCs has begun to emerge, and it has supported the hypothesis that immature cells in the osteoblastic lineage are critical for HSC regulation. Self-renewing osteoprogenitor cells in the marrow can form supportive HSC niches [42]. Most recently, Nestin positive putative mesenchymal stem cells (MSCs) have been demonstrated to express high levels of genes implicated in HSC maintenance. Additionally, these Nestin positive cells are spatially colocated with HSCs, and depletion of the Nestin positive population results in HSC mobilization [43]. A recent study defines the population of proliferative osteoblastic progenitors as MX-1 positive bone marrow stromal cells. This cell population is functionally restricted to an osteoblastic fate *in vivo*, and further investigation into this population's possible role in the HSC niche is warranted [44]. Conversely, even activation of the PTH1R in terminally mature osteocytes, in spite of expansion in the osteoblastic pool, did not increase microenvironmental support for HSCs [45]. The precise characteristics of the osteolineage cells responsible for HSC support remain of great interest since they could predict whether therapeutic strategies that stimulate osteoblastic cells could also achieve beneficial HSC effects.

Endothelial cells

The endothelium gives rise to the first definitive HSCs in the developing embryo [46, 47], and there is mounting evidence that endothelial cells also play an important role in the maintenance of HSCs in the adult marrow. HSCs and hematopoietic progenitor cells localize to endothelial structures near the endosteal surface [48, 49]. Angiocrine factors produced by endothelial cells support HSCs following myeloablation [50, 51] and expand immature hematopoietic cells *ex vivo* [52]. Additionally, genetic models have demonstrated that endothelial cells and a heterogeneous population of perivascular cells express high levels of CXCL12. Further, the conditional deletion of CXCL12 from endothelial cells resulted in the loss of HSC retention in the marrow [53]. *In vivo* imaging shows HSC localization to areas of close spatial relationship between vascular endothelial cells and endosteal osteoblasts, suggesting that both structures may be necessary components of a singular niche [11, 54].

CXCL12 abundant reticular cells

C-X-C motif ligand 12 (CXCL12) also known as stromal cell-derived factor 1 (SDF1) is a chemokine produced by osteoblasts and endothelial cells [31]. CXCL12 signals through its receptor C-X-C motif receptor 4 (CXCR4) on HSCs to induce migration to and retention in the bone marrow [40, 55, 56]. HSCs were shown to be closely associated with CXCL12 abundant reticular (CAR) cells that are in turn closely associated with endothelial cells [57]. The identity of these cells remains to be further characterized.

Sympathetic nervous system neuronal cells and glia

Treatment with granulocyte colony stimulating factor (G-CSF) results in migration of HSCs from the marrow into the bloodstream through inhibition of osteoblastic cells and downregulation of the C-X-C motif ligand 12 (CXCL12) [58–61]. Convincing data have suggested that this phenomenon is at least in part regulated by sympathetic nervous system (SNS) neurons [62]. SNS neurons coordinate the circadian oscillation of HSC numbers in the marrow, and ablation of SNS neurons results in a loss of circadian controlled release of HSCs into the periphery. In addition, sympathectomy of one tibia in a mouse results in altered expression of CXCL12 while the sham-operated contralateral tibia is unaffected [63]. Transforming growth factor β (TGF-β) also regulates HSC dormancy *ex vivo* [64]. Glial cells are a major source of activated TGF-β in the bone marrow, are closely associated with HSCs, and produce numerous factors previously identified as playing roles in the HSC niche [65]. Ablation of this population in the bone marrow results in a loss of HSC dormancy and ultimately of HSC numbers [65]. Therefore, neuronal cells and glia have been recently implicated in HSC regulation in the bone marrow.

Adipocytes

Adipocytic cells make up a large portion of the adult marrow. One adypocytic product, the adipokine adiponectin, has been demonstrated to increase proliferation of HSCs while retaining their repopulating potential [66]. Adiponectin, however, is not solely produced by adypocytes in the marrow, but is also expressed by osteoblastic cells [67]. In contrast to these pro-HSC effects of adipocytes, adipocyte numbers have more recently been described as inversely related to the number of HSCs in the marrow by comparing anatomically distinct regions of the skeleton that display varying levels of adiposity [68]. Additional studies demonstrated that loss of adipocytes in the marrow either genetically or pharmacologically resulted in enhanced engraftment of HSCs and improved hematopoietic recovery following myeloablative injury [68]. Therefore, a dominant inhibitory effect of adipocytes on HSC has recently been elucidated.

Macrophages and monocytes

Macrophages and monocytes are recent additions to the HSC niche's cellular milieu. They are involved in the G-CSF dependent mobilization of HSCs out of the marrow, and depletion of the macrophage population results in loss of osteoblastic cells and increased HSC mobilization into the periphery [69, 70]. In addition, reduction of monocytic phagocytes from the marrow reduces the expression of genes associated with HSC retention in Nestin positive cells, and specific ablation of macrophage populations resulted in the egress of HSCs from the marrow [71]. It is unclear whether macrophages and monocytes specifically interact with HSCs or function only in support of other niche components; however, it has been recently established that they play a pivotal role in the regulation of the HSC niche.

A NICHE FOR B LYMPHOPOIESIS

In addition to HSCs, there is emerging evidence that B lymphopoiesis is regulated by microenvironmental factors in the bone marrow. B-cell precursors are in direct contact with stromal cells in the marrow space that express CXCL12 [72]. Osteoblastic cells can support the development of B lymphocytes from HSCs *in vitro* [73], and ablation of osteoblasts results in a loss of B lymphocytes prior to the loss of HSCs [16, 73]. Osteoblastic support for B lymphopoiesis appears to be mediated by $G_s\alpha$ signaling as the loss of $G_s\alpha$ in osteolineage cells results in a decrease in B-cell precursors in the bone marrow [74] (Fig. 123.1).

MALIGNANCY AND THE HSC NICHE

While cancer metastasis is described elsewhere in the *Primer*, it is important to note that recent data have suggested that metastatic cancers home to benign HSC niches [75]. Therefore, as therapeutic targets are identified for HSC expansion through manipulation of niche components, the effect of their stimulation on malignant cells should be monitored, particularly in the setting of a prior cancer diagnosis.

An area of current interest is the role of the benign niche in hematopoietic malignancies. Data in xenograft models have suggested that malignant leukemic cells disrupt normal interactions between HSCs and their microenvironment [76] and induce changes in the marrow that decrease normal HSC niches and increase malignant niches. Recent data also demonstrate an inhibitory effect of leukemic cells on osteoblastic cells in a murine model

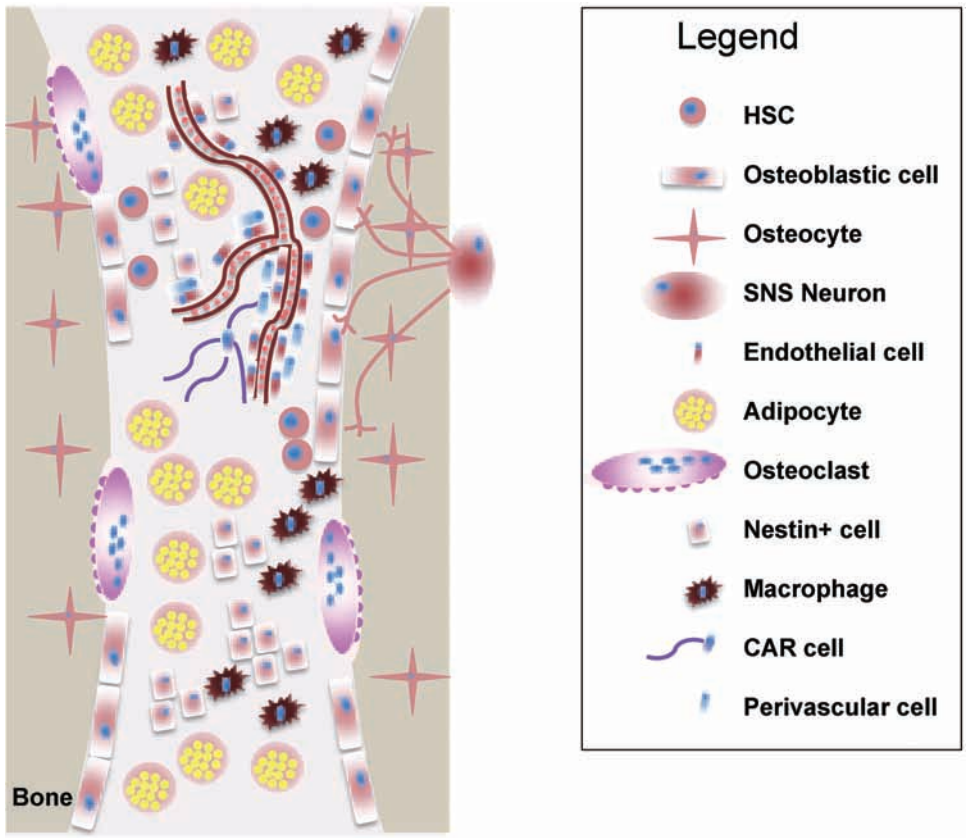

Fig. 123.1. Complexity of the cellular components of the HSC niche. Schematic representation of the cellular components of the HSC niche within the bone marrow space.

of acute myelogenous leukemia (AML), indicating a likely effect on the HSC niche [77]. Additional data have suggested that the marrow microenvironment can protect malignant stem cells as immature AML cells have been shown to reside near the endosteal surface of bone, and these endosteal associated AML cells were resistant to chemotherapy treatment in xenograft models [78, 79]. Further, migration of AML cells out of the marrow by disrupting the CXCL12/CXCR4 axis can sensitize malignant cells to chemotherapeutics [80, 81]. Future discoveries of the cellular and molecular components of normal and malignant niches are therefore needed in order to safely manipulate the microenvironment in the context of malignancy.

CONCLUSIONS

The importance of the skeletal microenvironment in hematopoietic regulation is beginning to be elucidated and holds great promise for translational therapies aimed at hematopoietic recovery and treatment of hematopoietic malignancies as well as metastatic disease. While it is tempting to postulate there are as many HSC niches in the marrow as cell types that have been demonstrated as supportive of HSCs, the reality is almost certainly much more complex. Many cell types likely coordinate to provide one regulatory niche, and equally as likely there are separate niches providing support for distinct and separate populations of HSCs, and/or different potential HSC fates. Further study in this area has benefited greatly from interactions of the field of hematopoiesis with bone biology and will likely continue to rapidly progress to increase our understanding and therapeutic use of the complex cellular relationships within the bone marrow.

Introduction 1036
Roles for RANKL and NF-κB in Osteoclast Formation and Immune Responses 1036
References 1040

INTRODUCTION

For many years before the identification, in the mid-1990s, of receptor activator of nuclear factor-κB ligand (RANKL) as the critical osteoclastogenic factor expressed by osteoblastic cells, it was known that osteoblastic cells regulated osteoclast precursor (OCP) differentiation and osteoclast (OC) activation [1]. It was also recognized that inflammatory and infectious diseases affecting the skeleton induced localized or generalized osteolysis through the effects of pro-inflammatory cytokines and other factors. However, the molecular mechanisms mediating bone loss and how immune cells interacted with bone cells in pathologic processes were poorly understood. In the mid-to-late 1980s, nuclear factor-kappa B (NF-κB) was identified as a set of transcription factors that regulate immune cell differentiation and immune responses [2], and later was shown to play essential roles in osteoclastogenesis downstream of RANK, the receptor for RANKL [3, 4]. Calcitonin and a few inflammatory mediators, including PGE2 and interferon γ, were known to inhibit OC-mediated bone resorption, but there were no data to suggest that OCs or OCPs might positively or negatively regulate their own functions or those of osteoblastic and other cell types.

Since the discovery of RANKL [5], understanding of the molecular mechanisms that regulate osteoclastogenesis and how bone and immune cells interact with one another has increased significantly. In addition, numerous other factors and mechanisms have been shown to regulate interactions among mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs), and osteoblastic, hematopoietic, and immune cells in normal and pathologic states [6, 7, 8]. These interactions maintain skeletal and hematopoietic homeostasis, and they are readily disturbed in a number of pathologic conditions affecting the skeleton. RANKL and NF-κB mediate many normal and pathologic processes; they play a central role linking bone and immune cell functions and immune responses, and discovery of their roles in these processes has spawned the new field of osteoimmunology. This chapter reviews current understanding of how these interactions affect the skeleton.

ROLES FOR RANKL AND NF-κB IN OSTEOCLAST FORMATION AND IMMUNE RESPONSES

RANKL

Bone cells consist of osteoblasts (OBs), osteocytes, chondroblasts, chondrocytes, and their progenitors, which are all derived from mesenchymal stem cells (MSCs) [8, 9]. Osteoclasts, which degrade bone, are hematopoietic cells and like immune cells, such as B cells, T cells, and macrophages and their various progenitors, they are derived from hematopoietic stem cells (HSCs) [8, 9]. Bone and hematopoietic cells are in close contact with one another

within the marrow cavity. Osteoblastic/stromal cells from the marrow have long been considered to regulate OC formation from precursors in the myeloid lineage by a combination of direct cell–cell contact and expression of a variety of factors and cytokines [9], including macrophage-colony stimulating factor (M-CSF) and RANKL [5, 9]. M-CSF induces expression of RANK on the surface of OC precursors [10], thus priming them for completion of their differentiation into mature OCs. Recent studies reported the surprising finding that during adult bone remodeling in mice, osteocytes within bone, rather than marrow stromal cells, appear to regulate OC formation by expressing RANKL [11, 12]. Interestingly, osteocytes do not fulfill this function in developing long bones during skeletogenesis. Other studies suggest that during long bone growth, hypertrophic chondrocytes in growth plates may be a major source of RANKL, which they express in response to vitamin D_3 [13] and locally expressed bone morphogenetic protein 2 (BMP2) [14]. RANKL secreted at the interface between the cartilage and newly formed bone could attract OCPs circulating in the blood [15, 16] from the prominent vascular channels seen at this site. The precise mechanism whereby RANKL expressed by osteocytes regulates bone remodeling remains to be identified, but presumably the cells secrete RANKL locally at sites destined for resorption to attract OCPs.

NF-κB

RANKL interaction with RANK activates NF-κB, a family of transcription factors that has essential functions in OCPs for their differentiation into OCs [5]. Importantly, in the context of immune responses and bone, NF-κB also regulates the differentiation and activation of immune cells, including B and T cells, maintenance of immune responses, and the development of lymph nodes [3, 4]. B and T cells also express RANKL and thus can cooperate with osteoblastic cells to enhance OC formation at sites of inflammation in bone where expression of pro-inflammatory cytokines, such as tumor necrosis factor (TNF), interleukin-1 (IL-1), and IL-6, typically is increased [17]. TNF and IL-1, like RANKL, also induce NF-κB expression in OCPs and other immune cells [18]; NF-κB in turn upregulates the expression of TNF, IL-1, and IL-6 [19]. Thus, inflammatory reactions tend to induce autocrine and paracrine auto-amplifying cycles within immune cells that maintain and upregulate immune responses, and thus can lead to more aggressive bone destruction [19].

TNF, which is secreted by macrophages in inflamed joints, promotes OCP egress from the bone marrow by inhibiting production of stromal cell-derived factor-1 (SDF-1) by marrow stromal cells and increases osteoclast precursor mobilization from bone marrow to the peripheral blood [20]. It also appears to attract OCPs to affected joints by increasing local expression of SDF-1 [20]. TNF not only induces expression of RANKL by accessory cells, but it also induces OC formation directly [21].

T and B lymphocytes

Numerous inflammatory processes affect the skeleton and typically result in localized or generalized bone resorption. These include common conditions, such as acute and chronic bacterial osteomyelitis and rheumatoid arthritis (RA). In patients with RA, important roles have been identified for subsets of T cells [17], particularly helper T (Th) and regulatory T (Treg) cells, B cells, and macrophages, which are abundant in the synovium of affected joints [22–24]. Inflamed synoviocytes and activated T cells secrete RANKL, which can attract circulating OCPs to inflamed joints and are now considered to be major players in inflammation-mediated joint destruction in RA [22–24]. In addition to the activated T cells that induce bone resorption, there are other T cells that produce cytokines, which potently inhibit osteoclastogenesis. For example, Tregs overall appear to inhibit OC formation mainly by direct contact with OCPs through cytotoxic T lymphocyte antigen 4 [25] and production of IL-4 and IL-10, which can potently inhibit osteoclastogenesis [17, 22].

B cells and plasma cells are found commonly in chronic inflammatory processes in bone.

Recent studies have implicated T cells in the bone loss that occurs as a result of sex steroid deficiency following ovariectomy (Ovx) in mice, which is associated with increased production of pro-inflammatory cytokines by T cells and macrophages. For example, Pacifici and colleagues have reported that T-cell-deficient nude mice, wild-type mice depleted of T cells, and mice lacking the T-cell co-stimulatory molecule, CD40 ligand, do not lose bone after Ovx [26, 27]. These results have been confirmed by some, but not other, investigators, leaving the findings somewhat controversial [26]. However, they are supported by other studies showing that estrogen inhibits differentiation of the Th17 subset of $CD4^+$ helper cells, which express high levels of IL-17, RANKL, and TNF, and low levels of the osteoclastogenesis inhibitor, interferon gamma (IFNγ) [26]. Although the roles of RANKL and TNF are well established in Ovx-induced bone loss, the role of IL-17 is controversial [26]. The role of T cells in Ovx-induced bone loss is also supported by reports that transgenic mice overexpressing Tregs are protected against Ovx-induced bone loss; that estrogen increases Treg numbers and regulates TNF production by T cells by inhibiting production of the osteoclastogenic cytokine, IL-7; and that estrogen deficiency expands the pool of TNF-producing T cells [26].

Ovx is also associated with increased production of reactive oxygen species (ROS) in the bone marrow by numerous cell types, including T cells and macrophages [28]. ROS increase the production of mature dendritic cells (DCs) expressing the co-stimulatory molecule, CD80, increase DC-mediated antigen presentation, and increase osteoclast formation [26, 28]. Upregulation of expression of major histocompatability molecules (MHCs) and co-stimulatory molecules, such as CD40 and CD80, by mature DCs is necessary for antigen

presentation by them and for their activation of T cells during immune responses. Importantly, like DCs, OCs also express the Fc receptor common γ subunit (FcRγ), MHC, CD40, and CD80, and function as antigen-presenting cells to activate T cells [29]. Thus, OCs could potentially amplify Ovx-induced T-cell proliferation and activation. However, OCs also can inhibit T-cell proliferation and suppress T-cell production of TNFα and IFNγ [30], and thereby potentially could also limit the role of T cells in Ovx-induced bone loss. Full discussion of the mechanisms whereby immune cells, including OCs, regulate sex steroid-related bone loss is beyond the scope of this review, but there clearly is a lot more to be learned about the interactions between bone and immune cells in this setting.

Plasma cells develop from B cells and secrete antibodies in chronic inflammation, but they can also express autoantibodies in autoimmune diseases. These include rheumatoid factor and anti-cyclic citrullinated peptide antibody in patients with RA where increased serum levels correlate with the level of disease activity [31]. B cells express numerous cytokines, including RANKL and OPG, but conflicting data that reported increased production of both RANKL [31] and OPG [32] have resulted in their roles in osteoclastogenesis being controversial and requiring further investigation. Full coverage of all aspects of the important field of osteoimmunology is beyond the scope of this review, but they have been covered in a number of recent reviews [17, 22, 33].

Other roles for RANKL

Numerous other cells types express RANKL in various pathologic settings, in addition to osteoblastic, synovial, and immune cells. For example, RANKL is expressed by intestinal cells in inflammatory bowel disease where it may contribute to generalized bone loss in affected patients [34]; it centrally controls body temperature and fever in females [35]; it is expressed in atheromatous plaques in arteries where immune cells have a pathogenetic role, and aberrant expression of RANKL and OPG has been implicated in hypertension, cardiovascular disease [36], and diabetes; and it regulates the proliferation and metastasis of breast cancer cells to bone [37, 38].

Osteoclast-rich lesions outside bone

Given the widespread expression of RANKL, it is perhaps not surprising that osteoclasts are also found in inflammatory and neoplastic lesions outside of bone. For example, they are present in the nodular lesions around joints in pigmented villonodular synovitis (PVNS) [39]; in giant cell tumor of tendon sheath, an inflammatory lesion similar to PVNS; and in some malignant tumors, including leiomyosarcoma, and carcinomas of pancreas, breast, and bladder [40]. Stromal cells in PVNS and giant cell tumor of tendon sheath express M-CSF, and the cells derived from them form OCs in response to RANKL [39]. Although it is likely that malignant tumors with OCs present within them express RANKL, to date there have been no reports describing this, let alone what the functions of OCs in these pathologic settings might be. However, as will be seen below, numerous positive and negative regulatory roles have been identified for OCs and OCPs in the past few years, and it is possible that they have supportive roles in some pathologic processes.

Co-stimulatory signaling in osteoclastogenesis

In addition to RANKL expressed by various cell types during inflammatory processes, so-called co-stimulatory signaling can also directly induce osteoclast formation [22, 41] through immunoglobulin-like receptors, including triggering receptor expressed in myeloid cells-2 (TREM-2) and osteoclast-associated receptor (OSCAR) [38]. Adaptor molecules, including DNAX-activating protein 12 (DAP12) and FcRγ, associate with these receptors. Through a series of phosphorylation events involving immunoreceptor tyrosine-based activation motifs (ITAMs) within these adaptor proteins [22] and phospholipase Cγ (PLCγ), calcium fluxes increase within OCPs and nuclear factor of activated T cells (NFATc1), the so-called master regulator of osteoclastogenesis, is activated by its dephosphorylation by calcineurin [22]. The ligands for co-stimulatory signaling receptors remain largely unidentified; however, OSCAR appears to be activated in OCPs by parts of collagen fibers [42], which become exposed in resorbing bone surfaces. These recent findings suggest that OSCAR can induce OC formation during normal bone resorption and presumably also at sites of inflammation in bone.

RANK and co-stimulatory signaling actually appear to be linked directly within OCPs through scaffold proteins to increase PLCγ/calcineurin-induced activation of NFATc1 and thus OC formation [43]. For example, in response to RANKL, Bruton (Btk) and Tec tyrosine kinases bind to RANK, and they also phosphorylate PLCγ. [22] They associate with B-cell linker protein (BLNK), which also binds to proteins in the co-stimulatory signaling pathway [43]. Thus, RANK and co-stimulatory signaling together activate PLCγ through BLNK and likely augment OC formation to mediate enhanced OC formation in inflammatory diseases affecting the skeleton. Calcium fluxes induced by RANK and co-stimulatory signaling also involve activation of cyclic adenosine monophosphate responsive-element-binding protein (CREB) by calcium/calmodulin-dependent protein kinase IV (CaMKIV) [44]. This results in activation of c-Fos, another transcription factor downstream from NF-κB whose expression is also necessary for OC formation by directing myeloid precursors otherwise destined to be macrophages down the OC differentiation pathway [18, 45]. Although these are complex intracellular signaling systems, they play crucial roles in basal and inflammation-mediated osteoclastogenesis; fuller understanding of the

molecular mechanisms involved could lead to development of novel therapies to prevent not only bone resorption in common inflammatory disease, but also the inflammation that accompanies it.

Acute and chronic osteomyelitis

Acute and chronic bone infections (osteomyelitis) typically result in localized lytic lesions at affected sites where increased osteoclastogenesis is induced by a number of mechanisms. Osteomyelitis is typically bloodborne from a distant site of acute infection, particularly in children. However, it can also result from direct inoculation of bacteria, fungi, or other organisms. This can occur in compound fractures that result from severe force and cause the bone to protrude through the skin or through infected gangrenous soft tissues of patients with severe peripheral vascular disease. However, most cases of post-traumatic osteomyelitis are caused by hospital-acquired bacteria [46]. Osteomyelitis can also occur in healthy patients undergoing elective arthroplasty for degenerative joint disease where methicillin-resistant *Staphylococcus aureus* (MRSA) infections have reemerged as a significant, predominantly hematogenous complication. In addition, new infections caused by organisms, such as *Acinetobacter baumannii*, have emerged at unprecidented levels in soldiers wounded in recent military conflicts in the Middle East.

Acute bacterial infections quickly activate complements in the innate immune response, leading to local vasodilatation, migration of polymorphonuclear leukocytes (PMNs), bacterial coating with ospsonins, which facilitate their intracellular uptake, and release of cytokines, including IL-1, IL-6, and TNF. These cytokines attract and activate PMNs and macrophages, which release reactive oxygen species, and, like cytokines, they stimulate OC formation and activity. The acquired immune response is activated days later and involves cytotoxic or CD8+ T cells, which lyse bacteria-infected host cells, and B lymphocytes, which produce antibacterial antibodies that clear persistent bacteria and prevent recurrence of the same infection. Osteoblastic cells also appear to be a significant line of defense against colonization by bacteria and bacterial formation of biofilms, which protect the organisms from phagocytosis in infections in bone. They express Toll-like receptors (TLRs) 2, 4, and 9 [47], which enable them to respond to bacterial cell surface lipopolysaccharides and DNA (CpG oligonucleotides). Following activation of these receptors by bacterial ligands, osteoblasts produce a variety of antimicrobial peptides to limit the effects of infection in bone. These include beta defensin-3 [48], the chemokines, CCL2 and –5, CXCL8 and –10, inflammatory cytokines (IL-6), co-stimulatory molecules (CD40), and MHC II, which are expressed typically by lymphocytes and antigen-presenting phagocytic immune cells in soft tissues and other organs during infections. Thus, these findings suggest that osteoblasts play an unexpected important role in the cellular immune response to bacterial infections. Osteoblasts also appear to internalize bacteria *in vitro* [49] and *in vivo* as well as the *S. aureus* sigma B regulon, a key mediator of bacterial infection, which could promote infection by inducing osteoblast apoptosis.

Interactions between osteoblastic and osteoclastic cells that influence bone mass in inflammatory responses

Bone formation typically is inhibited within sites of acute and chronic infections in bone where bone resorption is stimulated, but is seen around the periphery of affected sites as part of the inflammatory/repair process. Resolution of the infection typically is accompanied by osteoblastic new bone formation, which eventually fills in the lytic lesions. The molecular mechanisms that initially inhibit and later stimulate new bone formation in this setting have not been studied in detail, but high concentrations of pro-inflammatory cytokines, such as TNF, can inhibit OB formation and survival. Interestingly, TNF can also stimulate MSC differentiation into OBs at lower concentrations, which appear to be present in the early phases of fracture repair [50]. Thus, it is possible that as cytokine concentrations fall in the resolving phase of inflammation, they stimulate new bone formation. Another possibility is that secretion of OB inhibitors, such as dikkoff-1 by immune cells [51], decreases as inflammation is resolving.

Recent studies suggest that bone mass may be affected by direct interactions between osteoclastic and osteoblastic cells in normal and disease states. For example, osteoblastic cells appear to regulate OC formation negatively by direct cell–cell interaction through so-called reverse signaling via the ligand, ephrin B2, expressed by OCPs during its interaction with its receptor, Eph4, on the surface of osteoblast precursors. The reverse signaling downregulates expression in OCPs of c-Fos and NFATc1 and thus inhibits osteoclastogenesis. In contrast, forward signaling through Eph4 inactivates RhoA and thus stimulates OB differentiation from precursors [52]. This could provide an additional mechanism to mediate new bone formation in resolving inflammation. Eph4B expression by OBs and osteocytes is increased in samples of subchondral bone from patients with osteoarthritis (OA), which typically is sclerotic, and in OBs from bone samples from some OA subjects [53]. However, Eph4B activation in these cells is inhibited by IL-1, IL-6, and matrix metalloproteases (MMPs), which mediate joint destruction in OA [53].

Ephrin/Eph signaling regulates numerous other cellular functions, such as those in which cell processes extend over relatively large distances. These include neuronal axon pathfinding and arteriovenous linkup during embryonic development, interactions between osteoblastic cells where their signaling is increased by PTH or PTHrP, migration of endothelial cells, and T

lymphocytes during immune responses, tissue development, and angiogenesis [54, 55]. Ephrin/Eph signaling can also be disturbed in pathologic processes involving immune cells. For example, myeloma cells, like OCPs, appear to downregulate expression of Eph4 in osteoprogenitors; this could account in part for the inhibited bone formation seen typically in lytic myeloma lesions [56]. Osteoclastic cells can also negatively regulate OB formation by means of a secretory mechanism mediated by Atp6v0d2, a subunit of the proton pump, which secretes H^+ to combine with Cl^- and generate HCl to dissolve the mineral component of bone. Atp6v0d2 also positively regulates OCP fusion, a role identified unexpectedly when Atp6v0d2–/– mice were generated and found to be osteopetrotic due to a combination of defective OCP fusion and increased new bone formation [57]. How or if these recently identified regulatory mechanisms are functional in inflammatory bone lesions and exactly how they regulate basal bone remodeling remains to be determined.
