About ASBMR xxiv
President's Preface: *Lynda F. Bonewald* xxv
About the Companion Website xxvi

Section I: Molecular, Cellular, and Genetic Determinants of Bone Structure and Formation 1
Section Editor Karen M. Lyons

1 Skeletal Morphogenesis and Embryonic Development 3
Yingzi Yang

2 Signal Transduction Cascades Controlling Osteoblast Differentiation 15
David J.J. de Gorter and Peter ten Dijke

3 Osteoclast Biology and Bone Resorption 25
F. Patrick Ross

4 Osteocytes 34
Lynda F. Bonewald

5 Connective Tissue Pathways That Regulate Growth Factors 42
Gerhard Sengle and Lynn Y. Sakai

6 The Composition of Bone 49
Adele L. Boskey and Pamela Gehron Robey

7 Assessment of Bone Mass and Microarchitecture in Rodents 59
Blaine A. Christiansen

8 Animal Models: Genetic Manipulation 69
Karen M. Lyons

9 Animal Models: Allelic Determinants for BMD 76
Robert D. Blank

10 Neuronal Regulation of Bone Remodeling 82
Florent Elefteriou and Gerard Karsenty

11 Skeletal Healing 90
Michael J. Zuscik

12 Biomechanics of Fracture Healing 99
Elise F. Morgan and Thomas A. Einhorn

13 Human Genome-Wide Association (GWA) Studies 106
Douglas P. Kiel

14 Circulating Osteogenic Cells 111
Robert J. Pignolo and Moustapha Kassem

Section II: Skeletal Physiology 119
Section Editor Ego Seeman

15 Human Fetal and Neonatal Bone Development 121
Tao Yang, Monica Grover, Kyu Sang Joeng, and Brendan Lee

16 Skeletal Growth and Peak Bone Strength 127
Qingju Wang and Ego Seeman

17 Ethnic Differences in Bone Acquisition 135
Shane A. Norris, Lisa K. Micklesfield, and John M. Pettifor

18 Calcium and Other Nutrients During Growth 142
Tania Winzenberg and Graeme Jones

19 Growing a Healthy Skeleton: The Importance of Mechanical Loading 149
Mark R. Forwood

20 Pregnancy and Lactation 156
Christopher S. Kovacs and Henry M. Kronenberg

21 Menopause **165**
Ian R. Reid

Section III: Mineral Homeostasis 171
Section Editor Ego Seeman

22 Regulation of Calcium and Magnesium **173**
Murray J. Favus and David Goltzman

23 Fetal Calcium Metabolism **180**
Christopher S. Kovacs

24 Fibroblast Growth Factor-23 (FGF23) **188**
Kenneth E. White and Michael J. Econs

25 Gonadal Steroids **195**
Stavros C. Manolagas, Maria Almeida, and Robert L. Jilka

26 Parathyroid Hormone **208**
Robert A. Nissenson and Harald Jüppner

27 Parathyroid Hormone-Related Protein **215**
John J. Wysolmerski

28 Ca^{2+}-Sensing Receptor **224**
Edward M. Brown

29 Vitamin D: Production, Metabolism, Mechanism of Action, and Clinical Requirements **235**
Daniel Bikle, John S. Adams, and Sylvia Christakos

Section IV: Investigation of Metabolic Bone Diseases 249
Section Editor Douglas C. Bauer

30 DXA in Adults and Children **251**
Glen Blake, Judith E. Adams, and Nick Bishop

31 Quantitative Computed Tomography in Children and Adults **264**
C.C. Glüer

32 Magnetic Resonance Imaging of Bone **277**
Sharmila Majumdar

33 Radionuclide Scintigraphy in Metabolic Bone Disease **283**
Gary J.R. Cook, Gopinath Gnanasegaran, and Ignac Fogelman

34 FRAX®: Assessment of Fracture Risk **289**
John A Kanis

35 Biochemical Markers of Bone Turnover in Osteoporosis **297**
Pawel Szulc, Douglas C. Bauer, and Richard Eastell

36 Bone Biopsy and Histomorphometry in Clinical Practice **307**
Robert R. Recker

37 Diagnosis and Classification of Vertebral Fracture **317**
James F. Griffith, Judith E. Adams, and Harry K. Genant

38 Approaches to Genetic Testing **336**
Christina Jacobsen, Yiping Shen, and Ingrid A. Holm

Section V: Osteoporosis 343
Section Editors Paul D. Miller and Socrates E. Papapoulos

39 Osteoporosis Overview **345**
Michael Kleerekoper

40 The Epidemiology of Osteoporotic Fractures **348**
Nicholas Harvey, Elaine Dennison, and Cyrus Cooper

41 Overview of Pathogenesis **357**
Ian R. Reid

42 Nutrition and Osteoporosis **361**
Connie M. Weaver and Robert P. Heaney

43 The Role of Sex Steroids in the Pathogenesis of Osteoporosis **367**
Matthew T. Drake and Sundeep Khosla

44 Translational Genetics of Osteoporosis: From Population Association to Individualized Prognosis **376**
Bich H. Tran, Jacqueline R. Center, and Tuan V. Nguyen

45 Prevention of Falls **389**
Heike A. Bischoff-Ferrari

46 Exercise and the Prevention of Osteoporosis **396**
Clinton T. Rubin, Janet Rubin, and Stefan Judex

47 Calcium and Vitamin D **403**
Bess Dawson-Hughes

48 Estrogens, Estrogen Agonists/Antagonists, and Calcitonin **408**
Nelson B. Watts

49 Bisphosphonates for Postmenopausal Osteoporosis **412**
Socrates E. Papapoulos

50 Denosumab **420**
Michael R. McClung

51 Parathyroid Hormone Treatment for Osteoporosis **428**
Felicia Cosman and Susan L. Greenspan

52 Strontium Ranelate in the Prevention of Osteoporotic Fractures **437**
René Rizzoli

53 Combination Anabolic and Antiresorptive Therapy for Osteoporosis **444**
John P. Bilezikian and Natalie E. Cusano

54 Compliance and Persistence with Osteoporosis Medications **448**
Deborah T. Gold

55 Cost-Effectiveness of Osteoporosis Treatment **455**
Anna N.A. Tosteson

56 Future Therapies of Osteoporosis **461**
Kong Wah Ng and T. John Martin

57 Juvenile Osteoporosis **468**
Nick Bishop and Francis H. Glorieux

58 Glucocorticoid-Induced Bone Disease **473**
Robert S. Weinstein

59 Inflammation-Induced Bone Loss in the Rheumatic Diseases **482**
Steven R. Goldring

60 Secondary Osteoporosis: Other Causes **489**
Neveen A.T. Hamdy

61 Transplantation Osteoporosis **495**
Peter R. Ebeling

62 Osteoporosis in Men **508**
Eric S. Orwoll

63 Premenopausal Osteoporosis **514**
Adi Cohen and Elizabeth Shane

64 Skeletal Effects of Drugs **520**
Juliet Compston

65 Orthopedic Surgical Principles of Fracture Management **527**
Manoj Ramachandran and David G. Little

66 Abnormalities in Bone and Calcium Metabolism After Burns **531**
Gordon L. Klein

Section VI: Disorders of Mineral Homeostasis 535
Section Editors Marie Demay and Suzanne M. Jan de Beur

67 Approach to Parathyroid Disorders **537**
John P. Bilezikian

68 Primary Hyperparathyroidism **543**
Shonni J. Silverberg

69 Familial Primary Hyperparathyroidism (Including MEN, FHH, and HPT-JT) **553**
Andrew Arnold and Stephen J. Marx

70 Non-Parathyroid Hypercalcemia **562**
Mara J. Horwitz, Steven P. Hodak, and Andrew F. Stewart

71 Hypocalcemia: Definition, Etiology, Pathogenesis, Diagnosis, and Management **572**
Anne L. Schafer and Dolores Shoback

72 Hypoparathyroidism and Pseudohypoparathyroidism **579**
Mishaela R. Rubin and Michael A. Levine

73 Pseudohypoparathyroidism **590**
Harald Jüppner and Murat Bastepe

74 Disorders of Phosphate Homeostasis **601**
Mary D. Ruppe and Suzanne M. Jan de Beur

75 Vitamin D–Related Disorders **613**
Paul Lips, Natasja M. van Schoor, and Nathalie Bravenboer

76 Vitamin D Insufficiency and Deficiency **624**
J. Christopher Gallagher

77 Pathophysiology of Chronic Kidney Disease Mineral Bone Disorder (CKD–MBD) **632**
Keith A. Hruska and Michael Seifert

78 Treatment of Chronic Kidney Disease Mineral Bone Disorder (CKD–MBD) **640**
Hala M. Alshayeb and L. Darryl Quarles

79 Disorders of Mineral Metabolism in Childhood **651**
Thomas O. Carpenter

80 Paget's Disease of Bone **659**
Ethel S. Siris and G. David Roodman

Section VII: Cancer and Bone 669
Section Editor Theresa A. Guise

81 Overview of Mechanisms in Cancer Metastases to Bone **671**
Gregory A. Clines

82 Clinical and Preclinical Imaging in Osseous Metastatic Disease **677**
Geertje van der Horst and Gabri van der Pluijm

83 Metastatic Solid Tumors to Bone **686**
Rachelle W. Johnson and Julie A. Sterling

84 Hematologic Malignancies and Bone **694**
Rebecca Silbermann and G. David Roodman

85 Osteogenic Osteosarcoma **702**
Jianning Tao, Yangjin Bae, Lisa L. Wang, and Brendan Lee

86 Skeletal Complications of Breast and Prostate Cancer Therapies **711**
Catherine Van Poznak and Pamela Taxel

87 Bone Cancer and Pain **720**
Patrick W. O'Donnell and Denis R. Clohisy

88 Radiation Therapy-Induced Osteoporosis **728**
Jeffrey S. Willey, Shane A.J. Lloyd, and Ted A. Bateman

89 Skeletal Complications of Childhood Cancer **734**
Ingrid A. Holm

90 Treatment and Prevention of Bone Metastases and Myeloma Bone Disease **741**
Jean-Jacques Body

91 Radiotherapy of Skeletal Metastases **754**
Edward Chow, Luluel M. Khan, and Øyvind S. Bruland

92 Concepts and Surgical Treatment of Metastatic Bone Disease **760**
Kristy Weber and Scott L. Kominsky

Section VIII: Sclerosing and Dysplastic Bone Diseases 767
Section Editor Richard W. Keen

93 Sclerosing Bone Disorders **769**
Michael P. Whyte

94 Fibrous Dysplasia **786**
Michael T. Collins, Mara Riminucci, and Paolo Bianco

95 Osteochondrodysplasias **794**
Yasemin Alanay and David L. Rimoin

96 Ischemic and Infiltrative Disorders **805**
Richard W. Keen

97 Tumoral Calcinosis—Dermatomyositis **810**
Nicholas Shaw

98 Fibrodysplasia Ossificans Progressiva **815**
Frederick S. Kaplan, Robert J. Pignolo, and Eileen M. Shore

99 Osteogenesis Imperfecta **822**
Joan C. Marini

100 Skeletal Manifestations in Marfan Syndrome and Related Disorders of the Connective Tissue **830**
Emilio Arteaga-Solis and Francesco Ramirez

101 Enzyme Defects and the Skeleton **838**
Michael P. Whyte

Section IX: Approach to Nephrolithiasis 843
Section Editor Rajesh V. Thakker

102 Renal Tubular Physiology of Calcium Excretion **845**
Peter A. Friedman and David A. Bushinsky

103 Epidemiology of Nephrolithiasis **856**
Murray J. Favus

104 Diagnosis and Evaluation of Nephrolithiasis **860**
Stephen J. Knohl and Steven J. Scheinman

105 Kidney Stones in the Pediatric Patient **869**
Amy E. Bobrowski and Craig B. Langman

106 Treatment of Renal Stones **878**
John R. Asplin

107 Genetic Basis of Renal Stones **884**
Rajesh V. Thakker

Section X: Oral and Maxillofacial Biology and Pathology 893
Section Editor Laurie K. McCauley

108 Development of the Craniofacial Skeleton **895**
Maiko Matsui and John Klingensmith

109 Development and Structure of Teeth and Periodontal Tissues **904**
Petros Papagerakis and Thimios Mitsiadis

110 Craniofacial Disorders Affecting the Dentition: Genetic **914**
Yong-Hee P. Chun, Paul H. Krebsbach, and James P. Simmer

111 Pathology of the Hard Tissues of the Jaws **922**
Paul C. Edwards

112 Bisphosphonate-Associated Osteonecrosis of the Jaws **929**
Hani H. Mawardi, Nathaniel S. Treister, and Sook-Bin Woo

113 Periodontal Diseases and Oral Bone Loss **941**
Mary G. Lee and Keith L. Kirkwood

114 Oral Manifestations of Metabolic Bone Diseases **948**
Roberto Civitelli and Charles Hildebolt

Section XI: The Skeleton and Its Integration with Other Tissues 959
Section Editor Mone Zaidi

115 Central Neuronal Control of Bone Remodeling **961**
Shu Takeda and Paul Baldock

116 The Pituitary–Bone Connection **969**
Mone Zaidi, Tony Yuen, Li Sun, Terry F. Davies, Alberta Zallone, and Harry C. Blair

117 Skeletal Muscle Effects on the Skeleton **978**
William J. Evans

118 Glucose Control and Integration by the Skeleton **986**
Patricia Ducy and Gerard Karsenty

119 Obesity and Skeletal Mass **993**
Sue Shapses and Deeptha Sukumar

120 Neuropsychiatric Disorders and the Skeleton **1002**
Itai Bab and Raz Yirmiya

121 Vascular Disease and the Skeleton **1012**
Dwight A. Towler

122 Spinal Cord Injury: Skeletal Pathophysiology and Clinical Issues **1018**
William A. Bauman and Christopher P. Cardozo

123 Hematopoiesis and Bone **1028**
Benjamin J. Frisch and Laura M. Calvi

Formation of the skeletal system is one of the hallmarks that distinguish vertebrates from invertebrates. In higher vertebrates (i.e., birds and mammals), the skeletal system contains mainly cartilage and bone, which are mesoderm-derived tissues formed by chondrocytes and osteoblasts, respectively, during embryogenesis. A common mesenchymal progenitor cell, also referred as the osteochondral progenitor, gives rise to both chondrocytes and osteoblasts. The first overt sign of skeletal development is the formation of mesenchymal condensations, in which mesenchymal progenitor cells aggregate at future skeletal locations. Mesenchymal cells in different parts of the embryo come from different cell lineages. Neural crest cells give rise to craniofacial bones, the sclerotome compartment of the somites gives rise to most axial skeletal elements, and lateral plate mesoderm forms the limb mesenchyme, from which limb skeletons are derived (Fig. 1.1). Skeletal formation proceeds through two major mechanisms: intramembranous and endochondral ossification. In intramembranous ossification, osteochondral progenitors differentiate directly into osteoblasts to form membranous bone; during endochondral ossification, osteochondral progenitors differentiate into chondrocytes to form a cartilage template of the future bone. The location of each skeletal element determines its ossification mechanism and anatomic properties such as shape and size. This positional identity is acquired early in embryonic development, before mesenchymal condensation, through a process called pattern formation.

Cell–cell communication plays a critical role in pattern formation, and is mediated by several major signaling pathways. These include Wnts, Hedgehogs (Hhs), bone morphogenetic proteins (Bmps), fibroblast growth factors (Fgfs), and Notch/Delta. These pathways are also used later in skeletal development to control cell fate determination, proliferation, maturation, and polarity.

EARLY SKELETAL PATTERNING

Craniofacial patterning

Neural crest cells are the major source of cells establishing the craniofacial skeleton [1]. Reciprocal signaling between and among neural crest cells and epithelial cells (surface ectoderm, neural ectoderm or endodermal cells) ultimately establishes the identities of craniofacial skeletal elements [2].

Axial patterning

The most striking feature of axial skeletal patterning is the periodic organization of the vertebral column into multiple vertebrae along the anterior–posterior (A–P) axis. This pattern is established when somites, which are segmented mesodermal structures located on either side

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

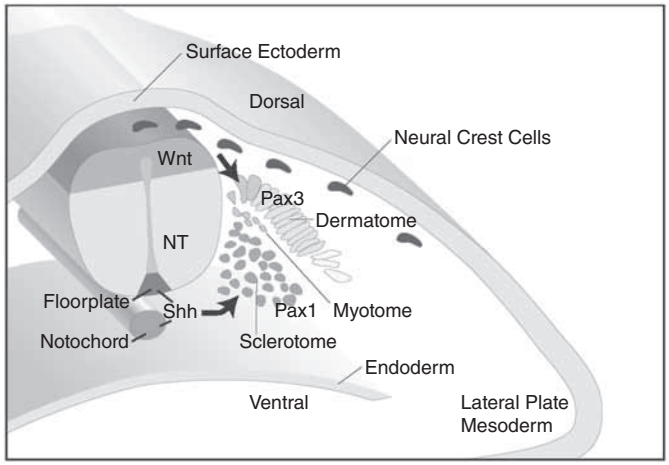

Fig. 1.1. Cell lineage contribution of chondrocytes and osteoblasts. Neural crest cells are born at the junction of dorsal neural tube and surface ectoderm. In the craniofacial region, neural crest cells from the branchial arches differentiate into chondrocytes and osteoblasts. In the trunk, axial skeletal cells are derived from the ventral somite compartment, sclerotome. Shh secreted from the notochord and floor plate of the neural tube induces the formation of sclerotome, which expresses Pax1. Wnts produced in the dorsal neural tube inhibit sclerotome formation and induce the dermomyotome, which expresses Pax3. Cells from the lateral plate mesoderm will form the limb mesenchyme, from which limb skeletons are derived.

of the neural tube, bud off at a defined pace from the anterior tip of the presomitic mesoderm (PSM) [3]. Somites give rise to the axial skeleton, striated muscle, and dorsal dermis [4–7]. The patterning of the axial skeleton is controlled by a molecular oscillator, or segmentation clock, that acts in the PSM [Fig. 1.2(A)]. The segmentation clock is operated by a traveling wave of gene expression (or cyclic gene expression) along the embryonic A–P axis, which is generated by an integrated network of the Notch, Wnt/β-catenin and fibroblast growth factor (FGF) signaling pathways [Fig. 1.2(B)] [8, 9].

The Notch signaling pathway mediates short-range communication between contacting cells [10]. The majority of cyclically expressed genes in the segmentation clock are targets of the Notch signaling pathway. The Wnt/β-catenin and FGF pathways mediate long-range signaling across several cell diameters. Upon activation of the Wnt pathway, β-catenin is stabilized and translocates to the nucleus where it activates the expression of downstream genes that are rhythmically expressed in the PSM [9, 11–13]. FGF signaling is also activated periodically in the posterior PSM [14, 15]. There is extensive cross-talk among these major oscillating signaling pathways; it is likely that each of the three pathways has the capacity to generate its own oscillations, while interactions among them allow efficient coupling and entrainment [16, 17]. Retinoic acid (RA) signaling controls somitogenesis by regulating the competence of PSM cells to undergo segmentation via antagonizing FGF signaling [Fig. 1.2(A)] [18, 19].

The functional significance of the segmentation clock in human skeletal development is highlighted by congenital axial skeletal diseases. For instance, mutations in Notch signaling components cause at least two human disorders, spondylocostal dysostosis (SCD, #277300, #608681, and #609813) and Alagille syndrome (AGS, OMIM# 118450 and #610205), both of which include vertebral column segmentation defects.

Once formed by the segmentation mechanism described above, somites are patterned along the dorsal–ventral axis by secreted signals derived from the surface ectoderm, neural tube and notochord (Fig. 1.1). The sclerotome forms from the ventral region of the somite, and gives rise to the axial skeleton and the ribs. Sonic hedgehog (Shh) from the notochord and ventral neural tube is required to induce sclerotome formation [20, 21] (Fig. 1.1) [22, 23]. In mice that lack *Shh*, the vertebral column and posterior ribs fail to form [24].

Limb patterning

Limb skeletons are patterned along the proximal–distal (P–D, shoulder to digit tip), anterior–posterior (A–P, thumb to little finger), and dorsal–ventral (D–V, back of the hand to palm) axes (Fig. 1.3). Along the P–D axis, the limb skeletons form three major segments: humerus or femur at the proximal end, radius and ulna or tibia and fibula in the middle, and carpal/tarsal, metacarpal/metatarsal, and digits in the distal end. Along the A–P axis, the radius and ulna have distinct morphological features; so do each of the five digits. Skeletal elements are also patterned along the D–V limb axis. For instance, the sesamoid processes are located ventrally whereas the patella forms on the dorsal side of the knee. Limb patterning events are regulated by three signaling centers in the early limb primodium, known as the limb bud, that act prior to mesenchymal condensation.

The apical ectoderm ridge (AER), a thickened epithelial structure formed at the distal tip of the limb bud, is the signaling center that directs P–D limb outgrowth (Fig. 1.3). Canonical Wnt signaling activated by Wnt3 induces AER formation [25], whereas BMP signaling leads to AER regression to halt limb extension [26]. Multiple FGF family members are expressed in the AER, but Fgf8 alone is sufficient to mediate the function of AER [27–29]. Fgf10 is expressed in the presumptive limb mesoderm and is required for initiation of limb bud formation; it subsequently controls limb outgrowth by maintaining *Fgf8* expression in the AER [30–32].

The second signaling center is the zone of polarizing activity (ZPA), a group of mesenchymal cells located at the posterior distal margin of the limb bud, immediately adjacent to the AER [Fig. 1.3(B)]. The ZPA patterns digit identity along the A–P axis. When ZPA tissue is grafted to a host limb bud on the anterior side under the AER, it leads to digit duplications in a mirror image of the

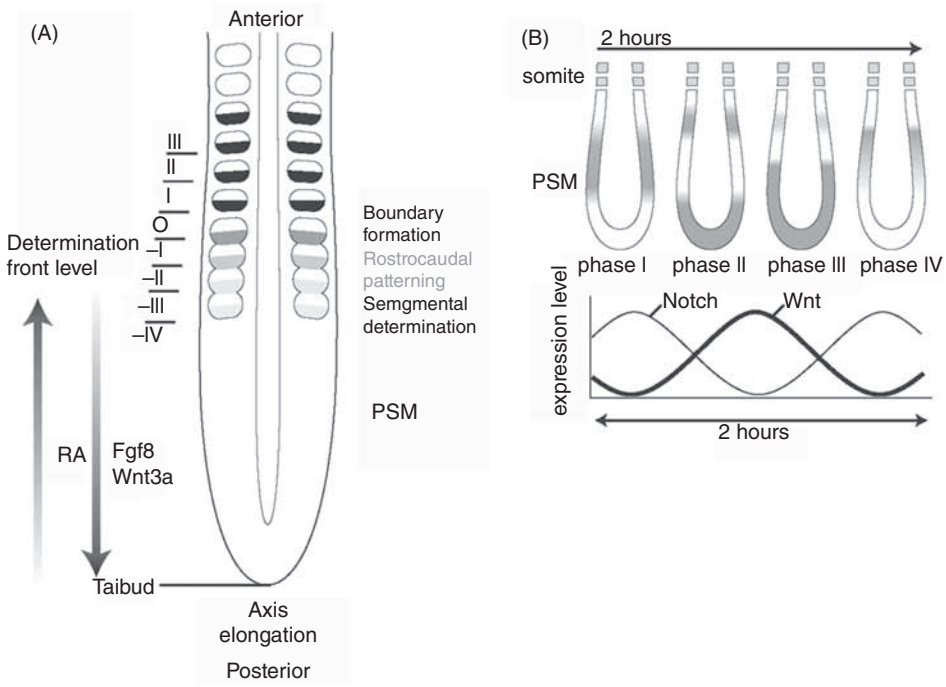

Fig. 1.2. Periodic and left–right symmetrical somite formation is controlled by signaling gradients and oscillations. (A) Somites form from the presomitic mesoderm (PSM) on either side of the neural tube in an anterior to posterior (A–P) wave. Each segment of the somite is also patterned along the A–P axis. Retinoic acid signaling controls the synchronization of somite formation on the left and right side of the neural tube. The most recent visible somite is marked by "0," whereas the region in the anterior PSM that is already determined to form somites is marked by a determination front that is determined by Fgf8 and Wnt3a gradients. This FGF signaling gradient is antagonized by an opposing gradient of retinoic acid. (B) Periodic somite formation (one pair of somite/2 hours) is controlled by a segmentation clock, the molecular nature of which is oscillated expression of signaling components in the Notch and Wnt pathways. Notch signaling oscillates out of phase with Wnt signaling.

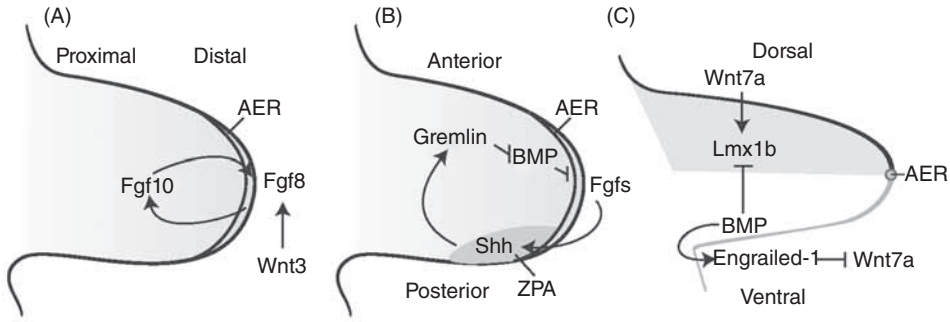

Fig. 1.3. Limb patterning and growth along the proximal–distal (P–D), anterior–posterior (A–P) and dorsal–ventral (D–V) axes are controlled by signaling interactions and feedback loops. (A) A signaling feedback loop between Fgf10 in the limb mesoderm and Fgf8 in the AER is required to direct P–D limb outgrowth. Wnt3 is required for AER formation. (B) Shh in the ZPA controls A–P limb patterning. A–P and P–D limb patterning and growth are also coordinated through a feedback loop between Shh and Fgfs expressed in the AER. Fgf signaling from the AER is required for Shh expression. Shh also maintains AER integrity by regulating Gremlin expression. Gremlin is a secreted antagonist of BMP signaling that promotes AER degeneration. (C) D–V patterning of the limb is determined by Wnt7a and BMP signaling through regulating the expression of Lmx1b in the limb mesenchyme.

endogenous ones [33]. *Shh* is expressed in the ZPA and is necessary and sufficient to mediate ZPA activity [34, 35]. However, the A–P axis of the limb is established prior to Shh signaling. This pre-Shh A–P limb patterning is controlled by combined activities of multiple transcription factors, including Gli3, Alx4, and the basic helix-loop-helix (bHLH) transcription factors dHand and Twist1. Mutations in the human *TWIST1* gene cause Saethre-Chotzen syndrome (SCS, OMIM#101400). The hallmarks of this syndrome are premature fusion of the calvarial bones and limb abnormalities. Mutations in the *GLI3* gene cause Greig cephalopolysyndactyly syndrome (GCPS, OMIM#175700) and Pallister-Hall syndrome (PHS, OMIM#146510), which are characterized by limb malformations.

The third signaling center is the non-AER limb ectoderm that covers the limb bud. This tissue controls D–V polarity of the ectoderm itself and also of the underlying mesoderm [Fig. 1.3(C)] (reviewed in Refs. 36 and 37). Wnt and BMP signaling control D–V limb polarity. *Wnt7a* is expressed in the dorsal limb ectoderm and activates the expression of *Lmx1b*, which encodes a dorsal-specific LIM homeobox transcription factor that determines the dorsal identity [38, 39]. *Wnt7a* expression is suppressed by the transcription factor En-1 in the ventral ectoderm [40]. The BMP signaling pathway is also ventralizing in the early limb [Fig. 1.3(C)]. The effects of BMP signaling in this ventralization are mediated by the transcription factors Msx1 and Msx2. The function of BMP signaling in the early limb ectoderm is upstream of En-1 in controlling D-V limb polarity [41]. However, BMPs also have En-1-independent ventralization activity by directly signaling to the limb mesenchyme to inhibit *Lmx1b* expression [42].

Limb development is a coordinated three-dimensional event. Indeed, the three signaling centers interact with each other through interactions of the mediating signaling molecules. First, there is a positive feedback loop between Shh expressed in the ZPA to maintain expression of FGFs in the AER, which connects A–P limb patterning with P–D limb outgrowth [Fig. 1.3(B)] [43–45]. This positive feedback look is antagonized by an FGF/Grem1 inhibitory loop that attenuates FGF signaling and thereby terminates limb outgrowth in order to maintain a proper limb size [46]. Second, the dorsalizing signal Wnt7a is also required for maintaining the expression of Shh that patterns the A–P axis [47, 48]. Third, Wnt/β-catenin signaling is both distalizing and dorsalizing [49–51].

EMBRYONIC CARTILAGE AND BONE FORMATION

The early patterning events described above determine where and when mesenchymal cells condense. Subsequently, the osteochondral progenitors in these condensations must form either chondrocytes or osteoblasts. Sox9 and Runx2 are master transcription factors that are required for the determination of chondrocyte and osteoblast cell fates, respectively [52–55]. Both are expressed in the osteochondral progenitor cells that constitute the mesenchymal condensations in the limb. *Sox9* expression precedes that of *Runx2* [56]. Coexpression of Sox9 and Runx2 in osteochondral progenitors is terminated when Sox9 and Runx2 expression is segregated into differentiated chondrocytes and osteoblasts, respectively [57]. The requirement for Runx2 in bone formation was demonstrated by the finding that *Runx2*$^{-/-}$ mice have no differentiated osteoblasts [52, 53]. Humans carrying heterozygous null mutations of the *RUNX2* gene have cleidocranial dysplasia (CCD, OMIM#119600), an autosomal-dominant condition characterized by hypoplasia/aplasia of clavicles, patent fontanelles, supernumerary teeth, short stature, and other changes in skeletal patterning and growth [53].

A number of transcriptional regulators that interact with Runx2 to control osteoblast differentiation have been identified. Zfp521 regulates osteoblast differentiation by HDAC3-dependent attenuation of Runx2 activity [58]. In addition, Runx2 mediates the function of Notch signaling in regulating osteoblast differentiation [59, 60].

Signaling through the Wnt and Indian hedgehog (Ihh) pathways is required for cell fate determination of osteoprogenitors into chondrocytes or osteoblasts by controlling the expression of *Sox9* and *Runx2*. Enhanced Wnt/β-catenin signaling increased bone formation and *Runx2* expression, but inhibited chondrocyte differentiation and *Sox9* expression [61–63]. Conversely, blocking Wnt/β-catenin signaling by removing β-*catenin* or *Lrp5* and *Lrp6* in osteochondral progenitor cells resulted in ectopic chondrocyte differentiation at the expense of osteoblasts [63–66]. Therefore, Wnt/β-catenin signaling levels in the condensation determine the outcome of bone formation. Relatively high Wnt/β-catenin signaling in intramembranous ossification allows direct osteoblast differentiation in the condensation, whereas during endochondral ossification, Wnt/β-catenin signaling in the condensation is initially lower, such that only chondrocytes differentiate. At later stages of endochondral ossification, Wnt/β-catenin signaling is upregulated at the periphery of the cartilage, driving osteoblast differentiation.

Ihh signaling is required for osteoblast differentiation only during endochondral bone formation by activating Runx2 expression [67, 68]. When Ihh signaling is inactivated in perichondrial cells, they ectopically form chondrocytes that express Sox9 at the expense of Runx2. Genetic epistatic tests showed that that β-*catenin* is required downstream of *Ihh* to promote osteoblast maturation [69]. In accordance, Ihh signaling is not (required once osteoblasts express osterix *Osx*) [70], a maker for cells committed to the osteoblast fate [71].

BMPs are transforming growth factor β (TGFβ) superfamily members that were identified as secreted proteins able to promote ectopic cartilage and bone formation [72]. Unlike Ihh and Wnt signaling, BMP signaling pro-

motes the differentiation of both osteoblasts and chondrocytes from mesenchymal progenitors. Reducing BMP signaling by removing BMP receptors leads to impaired chondrocyte and osteoblast differentiation and maturation [73]. The mechanisms underlying this unique property of BMPs have been under intense investigation for the past two decades. Our understanding of BMP action in chondrogenesis and osteogenesis has benefited greatly from molecular studies of BMP signal transduction [74].

The functions of FGF pathways in mesenchymal condensation and osteochondral progenitor differentiation remain to be elucidated, as complete genetic inactivation of FGF signaling in mesenchymal condensations has not been achieved. Nevertheless, it is clear that FGFs act in mesenchymal condensations to control intramembranous bone formation. FGF signaling can promote or inhibit osteoblast proliferation and differentiation depending on the cell context. Mutations in the genes encoding FGFR 1, 2, and 3 cause craniosynostosis (premature fusion of the cranial sutures). All of these mutations are autosomal dominant and many of them are activating mutations. The craniosynostosis syndromes involving FGFR1, 2, 3 include Apert syndrome (AS, OMIM# 101200), Beare-Stevenson cutis gyrata (OMIM#123790), Crouzon syndrome (CS, OMIM#123500), Pfeiffer syndrome (PS, OMIM#101600), Jackson-Weiss syndrome (JWS, OMIM#123150), Muenke syndrome (MS, OMIM#602849), crouzonodermoskeletal syndrome (OMIM#134934), and osteoglophonic dysplasia (OGD, OMIM#166250).

CHONDROCYTE PROLIFERATION AND DIFFERENTIATION IN THE DEVELOPING CARTILAGE

During endochondral bone formation, chondrocytes differentiate from osteochondral progenitor cells to form cartilage, which provides a growth template for the future bone. Chondrocytes undergo a tightly controlled program of progressive proliferation and hypertrophy, which is required for endochondral bone formation. In the developing cartilage of the long bone, chondrocytes at different stages of differentiation are located in distinct zones along the longitudinal axis and such organization is required for long bone elongation [Fig. 1.4(A)]. Proliferating chondrocytes express *Col2a1* (ColII), whereas hypertrophic chondrocytes express *Col10a1* (ColX). The chondrocytes that have exited the cell cycle, but have not yet become hypertrophic, are known as prehypertrophic chondrocytes. Chondrocytes either remain in one zone (i.e., those in the permanent cartilage) or transit to other zones in order (i.e., those in the growth plate) during development or homeostasis. This progression is precisely regulated by multiple signaling pathways.

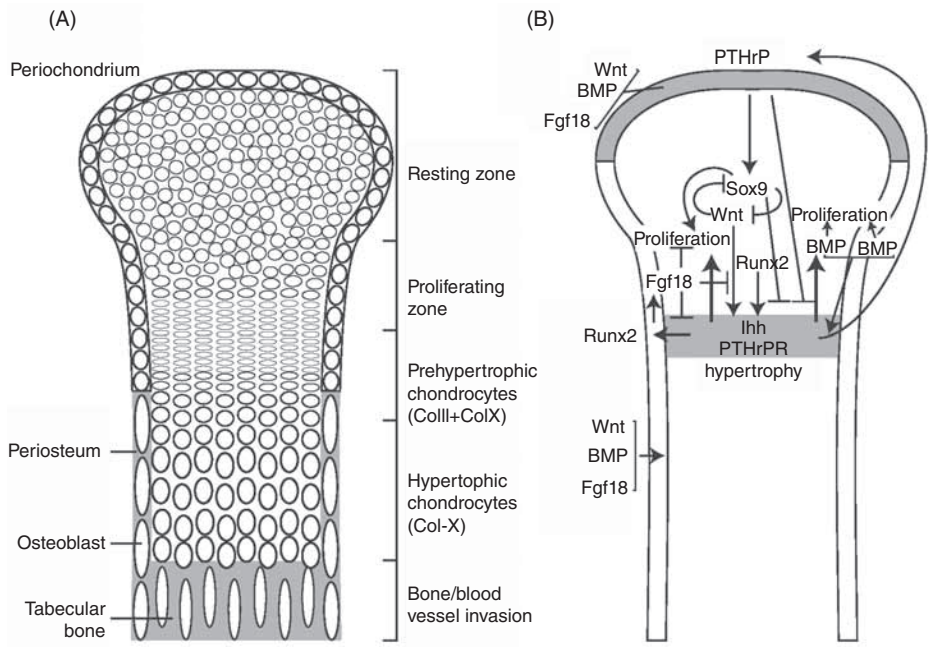

Fig. 1.4. Chondrocyte proliferation and hypertrophy are tightly controlled by signaling pathways and transcription factors. (A) Schematic drawing of a developing long bone cartilage. Chondrocytes with different properties of proliferation have different morphologies and are located in distinct locations along the longitudinal axis. See text for details. (B) Molecular regulation of chondrocyte proliferation and hypertrophy. Ihh, PTHrP, Wnt, FGF, and BMP are major signaling pathways that control chondrocyte proliferation and hypertrophy. A negative feedback loop between Ihh and PTHrP is fundamental in regulating the pace of chondrocyte hypertrophy. Transcription factors Sox9 and Runx2 act inside the cell to integrate signals from different pathways. See text for details.

Ihh is expressed in prehypertrophic and early hypertrophic chondrocytes and acts as a master regulator of endochondral bone development by promoting chondrocyte proliferation, controlling the pace of chondrocyte hypertrophy and coupling cartilage development with bone formation by inducing osteoblast differentiation in the adjacent perichondrium [67].

Ihh$^{-/-}$ mice have striking skeletal defects, including a lack of endochondral bone formation and smaller cartilage elements due to a marked decrease in chondrocyte proliferation and acceleration of hypertrophy [67, 75]. Ihh controls the pace of chondrocyte hypertrophy by activating the expression of parathyroid hormone related peptide (*PTHrP*) in articular cartilage and periarticular cells [67, 76]. PTHrP acts on the same G-protein-coupled receptors used by parathyroid hormone (PTH). These PTH/PTHrP receptors (*PPR*s) are expressed at high levels by prehypertrophic and early hypertrophic chondrocytes. PTHrP signaling is required to inhibit precocious chondrocyte hypertrophy primarily by keeping proliferating chondrocytes in the proliferating pool [77, 78]. Ihh and PTHrP form a negative feedback loop to control the chondrocyte's decision whether or not to leave the proliferating pool and become hypertrophic [Fig. 1.4(B)]. In this model, PTHrP, secreted from cells at the ends of cartilage, acts on proliferating chondrocytes to keep them proliferating. When chondrocytes displaced far enough from the source of PTHrP that the PPRs are no longer activated, they exit the cell cycle and become Ihh-producing prehypertrophic chondrocytes. Ihh diffuses through the growth plate to stimulate PTHrP expression at the ends of cartilage as way to slow down hypertrophy. This model is supported by experiments using chimeric mouse embryos [79]. Clones of *PPR*$^{-/-}$ chondrocytes differentiate into hypertrophic chondrocytes and produce Ihh within the wild type proliferating chondrocyte domain. This ectopic Ihh expression leads to ectopic osteoblast differentiation in the perichondium, upregulation of PTHrP expression, and a consequent lengthening of the columns of wild type proliferating chondrocytes. These studies demonstrate that the lengths of proliferating columns, and hence the elongation potential of cartilages, are critically determined by the Ihh–PTHrP negative feedback loop. Indeed, mutations in *IHH* in humans cause brachydactyly Type A1 (OMIM#112500), which is characterized by shortened digit phalanges and short body statue [80].

Several Wnt ligands are expressed in the cartilage and perichondrium of mouse embryos [62, 81]. Some activate canonical (β-catenin-dependent) and others activate noncanonical (β-catenin-independent) pathways to regulate chondrocyte proliferation and hypertrophy. In the absence of either canonical or noncanonical Wnt signaling, chondrocyte proliferation is altered and hypertrophy is delayed [63, 81, 82]. Furthermore, both canonical and noncanonical Wnt pathways act in parallel with Ihh signaling to regulate chondrocyte proliferation and differentiation [69, 81]. Wnt and Ihh signaling may regulate common downstream targets such as Sox9 (see below) [81, 82].

Many FGF ligands and receptors (FGFRs) are expressed in the developing cartilage. The significant role of FGF signaling in skeletal development was first realized by the discovery that achondroplasia (ACH, OMIM#100800), the most common form of skeletal dwarfism in humans, was caused by a missense mutation in *FGFR3*. Later, hypochondroplasia (HCH, OMIM#146000), a milder form of dwarfism, and thanatophoric dysplasia (TD, OMIM# 187600 & 187601), a more severe form of dwarfism, were also found to result from mutations in *FGFR3*. Signaling through FGFR3 negatively regulates chondrocyte proliferation and hypertrophy [83–90], in part by direct signaling in chondrocytes [83, 84] to activate Janus kinase–signal transducer and activator of transcription-1 (Jak–Stat1) and the MAPK pathways [85]. FGFR3 signaling also interacts with the Ihh/PTHrP/BMP signaling pathways [86, 87].

Since *Fgf18*$^{-/-}$ mice exhibit a phenotype including increased chondrocyte proliferation that closely resembles the cartilage phenotypes of *Fgfr3*$^{-/-}$ mice, Fgf18 is likely a physiological ligand for FGFR3 in the mouse. However, the phenotype of the *Fgf18*$^{-/-}$ mouse is more severe than that of the *Fgfr3*$^{-/-}$ mice, suggesting that Fgf18 signals through FGFR1 in hypertrophic chondrocytes and through FGFR2 and -1 in the perichondrium. Mice conditionally lacking FGFR2 develop skeletal dwarfism with decreased bone mineral density [88, 89)]. Osteoblasts also express FGFR3, and mice lacking *Fgfr3* are osteopenic [90, 91]. Thus in osteoblasts, FGF signaling positively regulates bone growth by promoting osteoblast proliferation. Interestingly, mice lacking *Fgf2* also show osteopenia, though much later in development than in *Fgfr2*-deficient mice [92], suggesting that Fgf2 may be a homeostatic factor that replaces the developmental growth factor, Fgf18, in adult bones. It is still not clear which FGFR responds to Fgf2/18 in osteoblasts.

Like the other major signaling pathways mentioned above, BMP signaling also acts during later stages of cartilage development. Both *in vitro* explant experiments and *in vivo* genetic studies showed that BMP signaling promotes chondrocyte proliferation and *Ihh* expression. The addition of BMPs to limb explants increases proliferation of chondrocytes whereas Noggin blocks chondrocyte proliferation [86, 93]. In addition, conditional removal of both *BmpRIA* and *BmpRIB* in differentiated chondrocytes leads to reduced chondrocyte proliferation and Ihh expression. BMP signaling also regulates chondrocyte hypertrophy, as removal of *BmpRIA* in chondrocytes leads to an expanded hypertrophic zone due to accelerated chondrocyte hypertrophy and delayed terminal maturation of hypertrophic chondrocytes [94]. BMP signaling regulates chondrocyte proliferation and hypertrophy at least in part through regulating Ihh expression.

BMP and FGF signaling pathways are mutually antagonistic in cartilage [86]. Comparison of cartilage phenotypes of BMP and FGF signaling mutants indicate that these two signaling pathways antagonize each other in regulating chondrocyte proliferation and hypertrophy [94)].

The above signaling pathways mediate the majority of their effects on cell proliferation, differentiation, and survival by regulating the expression of key transcription factors. Sox9 and Runx2 are two critical transcription factors that integrate inputs from these signaling pathways. When *Sox9* was removed from differentiated chondrocytes, chondrocyte proliferation and the expression of matrix genes and the Ihh–PTHrP signaling components were reduced in the cartilage [56]. This phenotype is very similar to that of mice lacking both *Sox5* and *Sox6*, two other Sox-family members that require Sox9 for expression. Sox5 and Sox6 cooperate with Sox9 to maintain the chondrocyte phenotype to regulate chondrocyte specific gene expression [95]. Haploinsufficiency for *SOX9* in humans causes campomelic dysplasia (CD, OMIM# 114290), a condition that is recapitulated in $Sox9^{+/-}$ mice, and which includes cartilage hypoplasia and a perinatal lethal osteochondrodysplasia [96]. Chondrocyte hypertrophy is accelerated in the $Sox9^{+/-}$ cartilage, but delayed in *Sox9*-overexpressing cartilage [82, 96]. Sox9 acts in both the PTHrP and Wnt signaling pathways to control chondrocyte proliferation. PTHrP signaling in chondrocytes activates PKA, which promotes Sox9 transcriptional activity by phosphorylating it [97]. In addition, Sox9 inhibits Wnt/β–catenin signaling activity by promoting β–catenin degradation [82, 98]. Thus, Sox9 is a master transcription factor that acts in many critical stages of chondrocyte proliferation and differentiation as a central node inside prechondrocytes and chondrocytes to receive and integrate multiple signaling inputs.

In addition to its role in early osteoblast differentiation, Runx2 is expressed in prehypertrophic and hypertrophic chondrocytes and controls chondrocyte proliferation and hypertrophy. Chondrocyte hypertrophy is significantly delayed and Ihh expression is reduced in $Runx2^{-/-}$ mice, whereas *Runx2* overexpression in the cartilage results in accelerated chondrocyte hypertrophy [99, 100]. Furthermore, removing both *Runx2* and *Runx3* completely blocks chondrocyte hypertrophy and Ihh expression in mice, suggesting that Runx transcription factors control Ihh expression [101]. Thus, as with Sox9, Runx2 can be viewed as a master controlling transcription factor and a central node through which other signaling pathways are integrated in coordinate chondrocyte proliferation and hypertrophy. In chondrocytes, Runx2 acts in the Ihh-PThrP pathway to regulate cartilage growth by controlling the expression of Ihh. However, this cannot be its only function, as *Runx2* upregulation leads to accelerated chondrocyte hypertrophy, whereas *Ihh* upregulation leads to delayed chondrocyte hypertrophy. One of Runx2's Ihh-independent activities is to act in the perichondrium to inhibit chondrocyte proliferation and hypertrophy by regulating Fgf18 expression [102]. Interestingly, this role of Runx2 in the perichondrium is antagonistic to its role in chondrocytes. Recent studies have shown that histone deacetylase 4 (HDAC4), which governs chromatin structure and represses the activity of specific transcription factors, regulates chondrocyte hypertrophy and endochondral bone formation by inhibiting the activity of Runx2 [103]. Runx2 interacts with the Gli3 repressor form Gli3rep, which inhibits DNA binding by Runx2 [104]. Therefore, one mechanism whereby Hh signaling promotes osteoblast differentiation may be through enhancing Runx2 DNA binding by reducing the generation of Gli3rep.

Developing skeletal elements have distinct morphologies, which are required for their function. For example, the limb and the long bones preferentially elongate along the P–D axis. Although the molecular mechanism underlying such directional morphogenesis was poorly understood in the past, there is evidence that alignment of columnar chondrocytes in the growth plate is regulated by planar cell polarity (PCP) pathways during directional elongation of the cartilage [105, 106]. PCP is an evolutionarily conserved pathway that is required in many directional morphogenetic processes including left–right asymmetry, neural tube closure, body axis elongation and brain wiring [107–109]. Recently, a major breakthrough has been made by demonstrating that newly differentiated chondrocytes in developing long bones are polarized along the P–D axis. Vangl2 protein, a core regulatory component in the PCP pathway, is asymmetrically localized on the proximal side of chondrocytes [110]. The asymmetrical localization of Vangl2 requires a Wnt5a signaling gradient. In the $Wnt5a^{-/-}$ mutant limb, the cartilage forms a ball-like structure, and Vangl2 is symmetrically distributed on the cell membrane [110] (Fig. 1.5). Mutations in genes encoding PCP pathway components, such as *WNT5a* and *ROR2*, have been found in skeletal malformations such as the Robinow Syndrome and brachydactyly type B1, both of which are short-limb dwarfisms [111–115].

REGULATION OF CHONDROCYTE SURVIVAL

Apart from its proliferation, differentiation and polarity, chondrocyte survival is also highly regulated. The Wnt/β-catenin, Hh, and BMP pathways signaling are all important in chondrocyte survival. Chondrocyte cell death is significantly increased when β-catenin is removed [69]. Cartilage is also special as it is an avascular tissue that develops under hypoxia because chondrocytes, particularly those in the middle of the cartilage, do not have access to vascular oxygen delivery [116]. As in other hypoxic conditions, the transcription factor hypoxia-inducible factor 1 (Hif-1), and its oxygen-sensitive component Hif-1α, is the major mediator of the hypoxic response in developing cartilage. Removal of *Hif-1α* in cartilage results in chondrocyte cell death in the interior of the growth plate. A downstream target of Hif-1 in regulating the hypoxic response of chondrocytes is VEGF [117]. The extensive cell death seen in the cartilage of mice lacking *Vegfa* has a striking similarity to that observed in mice in which *Hif-1α* is removed in cartilage [116]. The Wnt/β-catenin, Hh, and BMP pathways signaling are all important in chondrocyte survival.

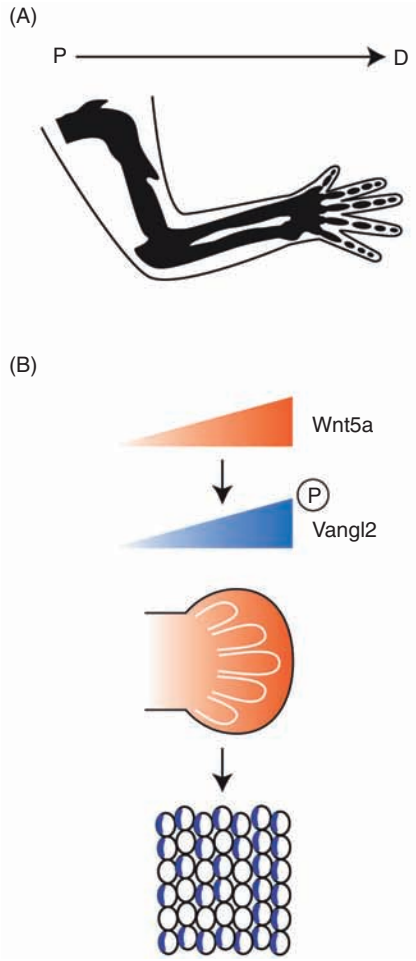

Fig. 1.5. Wnt5a gradient controls directional morphogenesis by regulating Vangl2 phosphorylation and asymmetrical localization. (A) Schematics of skeletons in a human limb that preferentially elongates along the proximal–distal axis. (B) A model of a Wnt5a gradient controlling P–D limb elongation by providing a global directional cue. Wnt5a is expressed in a gradient (orange) in the developing limb bud, and this Wnt5a gradient is translated into an activity gradient of Vangl2 by inducing different levels of Vangl2 phosphorylation (blue). In the distal limb bud of an E12.5 mouse embryo showing the forming digit cartilage, the Vangl2 activity gradient then induces asymmetrical Vangl2 localization (blue) and downstream polarized events.

Chondrocyte cell death is significantly increased when β-catenin is removed [69].

CONCLUSIONS

Skeletal formation is a process that has been perfected and highly conserved during vertebrate evolution. Understanding the molecular mechanisms regulating cartilage and bone formation during development will allow us to redeploy these pathways to promote skeletal tissue repair using endogenous cells, autologous cells and tissues, or iPS (induced pleuripotent stem) cells. Understanding skeletal development is also indispensable for understanding pathological mechanisms in skeletal diseases, finding therapeutic targets, promoting consistent cartilage or bone repair *in vivo* and eventually growing functional cartilage or bone *in vitro*.

INTRODUCTION

Mesenchymal stem cells (MSCs) are pluripotent cells located in bone marrow, muscles, and fat that can differentiate into a variety of tissues, including bone, cartilage, muscle and fat [1, 2]. Differentiation toward these lineages is controlled by a multitude of cytokines, which regulate the expression of cell-lineage specific sets of transcription factors. Among the cytokines involved in osteoblast differentiation are the Hedgehogs, BMPs, TGF-β, PTH, and WNTs. The signal transduction cascades initiated by these cytokines and their effect on osteoblast differentiation will be discussed in this chapter. Osteoblasts and chondrocytes are thought to differentiate from a common mesenchymal precursor, the osteochondrogenic precursor (Fig. 2.1). The osteoblastic differentiation process can be divided into several stages, including proliferation, extracellular matrix deposition, matrix maturation, and mineralization [3]. To investigate osteoblast differentiation, the expression levels of distinct differentiation markers are used, including alkaline phosphatase (ALP), type I collagen (Col1), bone sialoprotein (BSP), osteopontin (OPN), and osteocalcin (OC). Whereas ALP is used as an early marker, OC is considered to be a late marker for osteoblast differentiation.

RUNX2 AND OSTERIX TRANSCRIPTION FACTORS

An essential event in osteoblast differentiation, and a point of convergence of many signal transduction pathways involved, is the activation of the transcription factor Runx2 [also known as core-binding factor α subunit (Cbfa1) or AML3]. Runx2 is a master switch for osteoblast differentiation. This is demonstrated by the fact that *Runx2*-deficient mice completely lack osteoblasts and fail to form hypertrophic chondrocytes, and they produce a cartilaginous skeleton that is completely devoid of mineralized matrix [4]. In humans, heterozygous insertions, deletions, and nonsense mutations leading to translational stop codons in the DNA-binding domain or in the C-terminal transactivating region of the *Runx2* gene underlie the rare skeletal disorder cleidocranial dysplasia (CCD). CCD is characterized by defective development of the cranial bones and the complete or partial absence of the collar bones, emphasizing the importance of Runx2 in bone formation [5]. By interacting with many transcriptional activators and repressors and other coregulatory proteins, Runx2 can either positively or negatively regulate expression of a variety of osteoblast-specific genes including Col1, ALP, OPN, osteonectin (ON) and OC [6, 7].

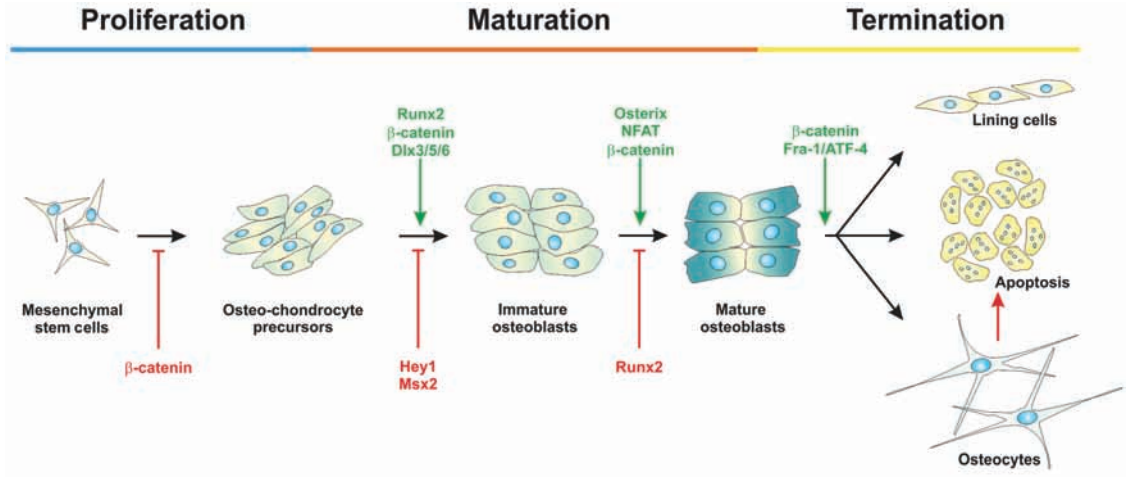

Fig. 2.1. Schematic model of MSC differentiation toward the osteoblastic linage and the impact of transcriptional regulators in this process. ATF4: Activating transcription factor-4; Dlx: Distalless homeobox; FRA: Fos-related antigen; Osx: Osterix; Runx2: Runt-related transcription factor2.

In addition, Runx2 regulates expression of the zinc-finger-containing transcription factor Osterix. The promoter of the *Osx* (*Sp7*) gene (which encodes Osterix) contains a consensus Runx2-binding sequence, suggesting that *Osx* is a direct Runx2 target gene [8]. Whereas Runx2 expression is not affected in $Osx^{-/-}$ mice, Osterix expression is lost in *Runx2*-deficient mice [9]. Similar to mice deficient in *Runx2*, $Osx^{-/-}$ mice lack osteoblasts, showing the requirement of this transcription factor in bone formation. Osterix can interact with the nuclear factor for activated T cells 2 (NFAT2), which cooperates with Osterix in controlling the transcription of target genes such as osteocalcin, osteopontin, osteonectin, and collagen1 [9, 10]. Since nuclear localization of NFAT transcription factors is regulated by the Ca^{2+}-calcineurin pathway, signaling pathways that modulate intracellular Ca^{2+} levels can potentially control Osterix-mediated osteoblast differentiation via NFAT activation.

Other transcription factors that are involved in osteoblast differentiation are homeobox proteins such as Msx2, Distalless homeobox(Dlx)-3, Dlx-5, Dlx-6, and members of the activator protein-1 (AP-1) family such as Fos, Fos-related antigen (Fra), and activating transcription factor-4 (ATF4) (Fig. 2.1). However, deficiency of these genes does not result in complete loss of osteoblasts like in $Runx2^{-/-}$ mice and $Osx^{-/-}$ mice, pointing at a facilitating role in osteoblastogenesis.

BMP SIGNALING

BMPs belong to the TGF-β superfamily and were originally identified as the active components in bone extracts capable of inducing bone formation at ectopic sites [11]. BMPs are expressed in skeletal tissue and are required for skeletal development and maintenance of adult bone homeostasis, and they play an important role in fracture healing [12, 13]. Conditional knockout mice deficient in specific BMP members in bone display skeletal defects, and several naturally occurring mutations in BMPs or their receptors underlie inherited skeletal disorders [12, 13]. For example, fibrodysplasia ossificans progressiva (FOP), in which bone is progressively formed at ectopic sites, has been linked to a heterozygous activating mutation in the BMP type I receptor activin receptor-like kinase (ALK)2 [14, 15]. Several preclinical studies in primates and other mammals have proven the effectiveness of using BMPs in restoring large segmental bone defects, and BMPs are used therapeutically in open fractures of long bones, non-unions, and spinal fusion [16].

BMPs bind as dimers to type-I and type-II serine/threonine receptor kinases, forming an oligomeric complex (Fig. 2.2). Upon oligomerization, the constitutively active type II receptors phosphorylate and consequently activate the type I receptors. Subsequently, the activated type I receptors phosphorylate the intracellular signaling mediators BMP receptor-regulated Smads, Smad1, -5 and -8, at their extreme C-termini. The receptor-regulated Smads then associate with the Co-Smad, Smad4, and translocate into the nucleus, where they together with other transcription factors bind promoters of target genes and control their expression (Fig. 2.2) [17, 18]. For example, Runx2 interacts with Smad1 and -5, and cooperates in controlling BMP-induced osteoblast-specific gene expression and osteogenic differentiation [19, 20]. Interestingly, a nonsense mutation found in a CCD patient results in the expression of a truncated Runx2 mutant that displayed impaired Smad1 interaction and inhibited BMP-induced ALP activity [21]. Moreover, BMP signaling induces expression of both BMPs and Runx2 thereby generating a positive feedback loop [19, 22]. In

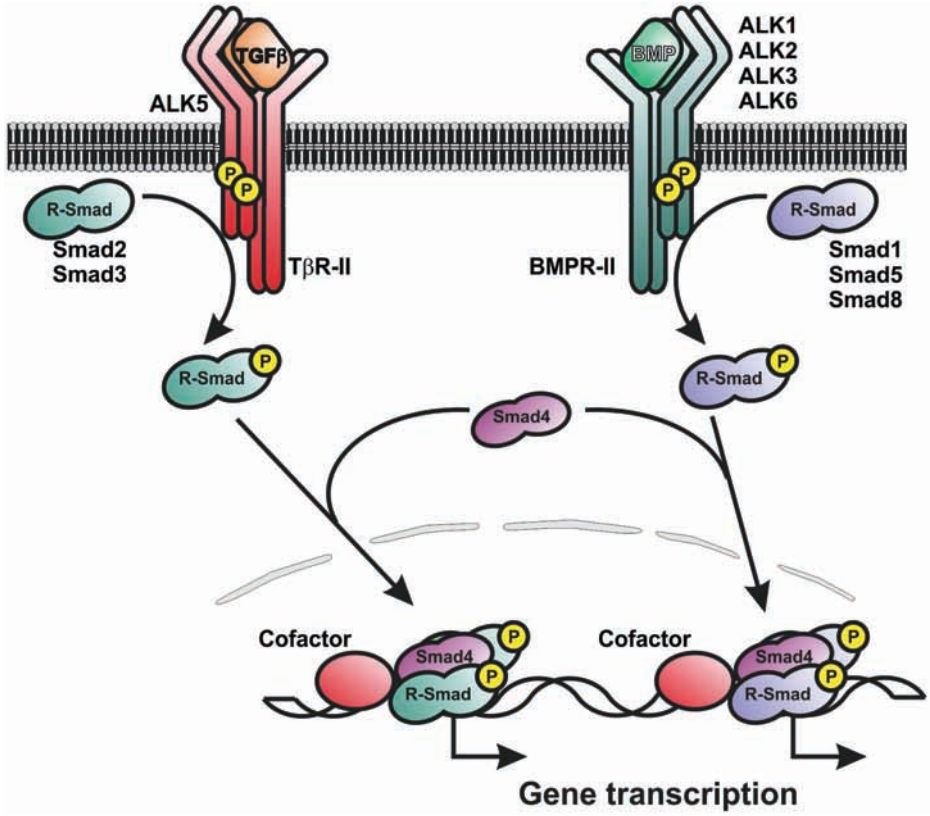

Fig. 2.2. Schematic model illustrating the TGF-β and BMP signaling pathway in osteoblasts. TGF-β and BMP signal via heteromeric complexes of type I and type II transmembrane serine/threonine kinase receptors and specific intracellular Smad effector proteins. Activated heteromeric complexes between R-Smad and Smad4 can act as transcription factors and regulate gene transcriptional responses, ultimately stimulating alkaline phosphatase activity and bone formation.

addition, BMPs control the expression of Id (inhibitor of differentiation or inhibitor of DNA binding) proteins [23, 24]. Id proteins are dominant negative inhibitors of basic helix–loop–helix proteins, which inhibit osteoblast differentiation. Indeed, BMP-induced bone formation *in vivo* was found to be suppressed in Id1/Id3 heterozygous knockout mice [25]. Furthermore, BMP-2 was found to induce expression of Osterix, which besides Runx2 also seems to be mediated by the p38 and JNK MAP kinases [9, 26, 27].

TGF-β SIGNALING

TGF-β is implicated in the control of proliferation, migration, differentiation, and survival of many different cell types. TGF-β is one of the most abundant cytokines in bone matrix and plays a major role in development and maintenance of the skeleton, affecting both cartilage and bone metabolism [28]. Interestingly, TGF-β can have both positive and negative effects on bone formation depending on the context and concentration [28-30].

TGF-β signals via a similar mechanism as the related BMPs. However, upon binding to its specific receptors, TGF-β induces activation of Smad2 and -3 (Fig. 2.2) [17, 18]. Smad3 overexpression in mouse osteoblastic MC3T3-E1 cells enhanced the levels of bone matrix proteins, ALP activity, and mineralization [31]. As is the case for Smad1 and -5, Runx2 also interacts with Smad3 and cooperates in regulating TGF-β-induced transcription [29]. This interaction requires a functional Runx2 C-terminal domain, since the truncated Runx2 mutant derived from a CCD patient is unable to interact with Smad3 [21, 29, 32]. The effects of TGF-β/Smad3 signaling on the function of Runx2 depend on the cell type and promoter context [29].

WNT SIGNALING

WNTs are secreted glycoproteins that transduce their signals via 7-transmembrane spanning receptors of the frizzled family, and co-receptors low-density lipoprotein receptor-related protein (LRP)-5 and -6, to β-catenin

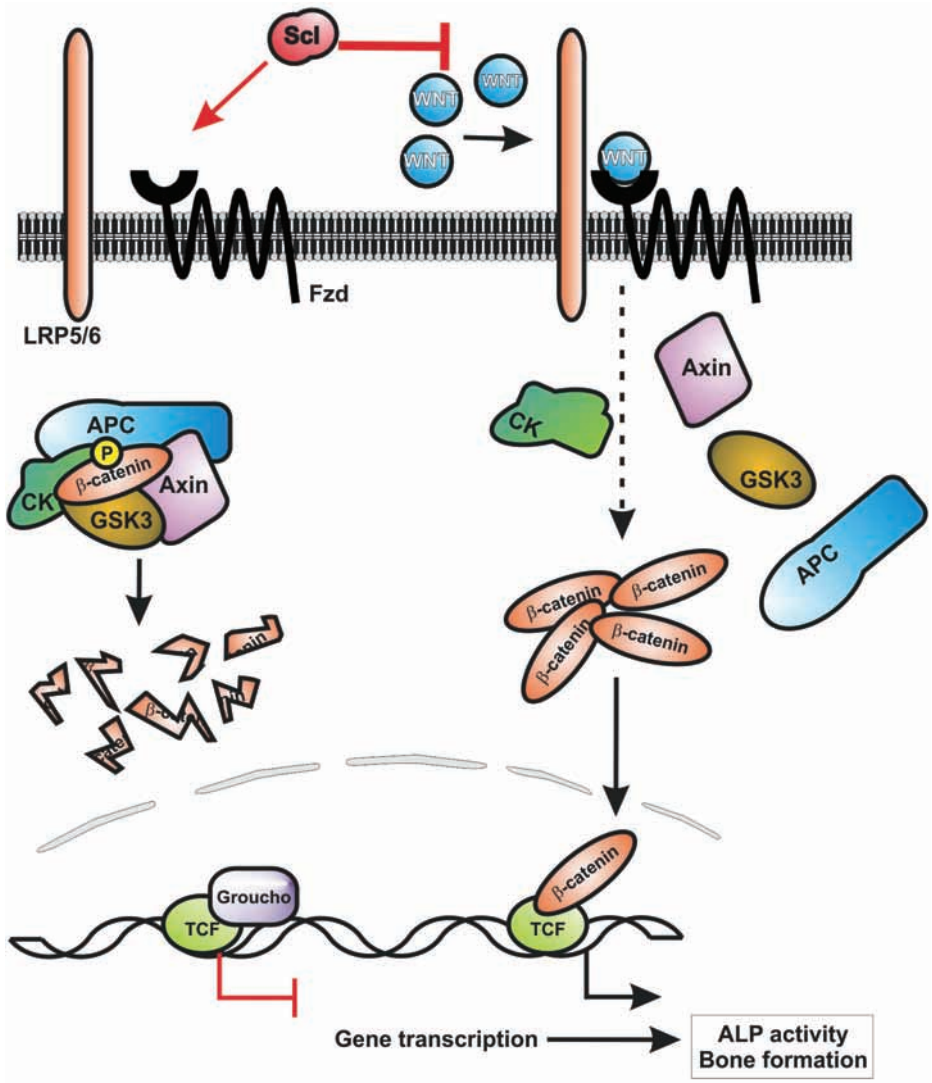

Fig. 2.3. Schematic model illustrating the canonical WNT signaling pathway in osteoblasts. In the absence of WNT, β-catenin is forming a complex with APC, Axin, GSK3, and CK1, and becomes phosphorylated, ubiquitinated and targeted for proteosomal degradation. WNT binding to frizzled (Fzd) receptors and LRP5/6 coreceptors prevents formation of the complex, leading to stabilization of β-catenin and regulation of gene expression through LEF/TCF transcription factors, ultimately stimulating alkaline phosphatase activity and bone formation. Sclerostin (Scl) proteins antagonize Wnt responses by binding to LRP5/6.

(Fig. 2.3) [33]. In the absence of a WNT ligand, β-catenin forms a complex with adenomatous polyposis coli (APC), Axin, glycogen synthase kinase 3 (GSK3), and casein kinase I (CK1). This complex facilitates phosphorylation and proteosomal degradation of β-catenin. In the presence of the WNT ligand, this complex dissociates, leading to accumulation of cytoplasmic β-catenin and its translocation into the nucleus, where it initiates the transcription of target genes via complex formation with T-cell factor (TCF)/lymphoid enhancing factor (Lef1) transcription factors [33]. Conditional deletion of β-catenin led osteochondroprogenitor cells to differentiate into chondrocytes instead of osteoblasts during both intramembranous and endochondral ossification, whereas ectopic WNT signaling enhanced osteoblast differentiation [34–36], indicating that WNT signaling drives differentiation of osteochondroprogenitor cells towards the osteoblast lineage (Fig. 2.1). Moreover, WNT signaling in osteocytes plays an essential role in controlling normal bone homeostasis, while mice deficient in β-catenin expression in osteocytes display progressive bone loss [37]. Furthermore, loss or gain of function mutations in *LRP5* have been associated with bone diseases characterized by low or high bone mass due to decreased or increased osteoblast activity, respectively [38–40]. In addition, mutations in the coding region or in regulatory elements of *SOST*, the gene encoding the osteocyte-derived WNT antagonist sclerostin, underlie the rare high bone mass disorders sclerosteosis and Van Buchem disease, respectively (Fig. 2.3) [41]. All these findings demonstrate

the importance of WNT signaling in controlling bone formation.

HEDGEHOG SIGNALING

There are three Hedgehog proteins in mammals (Sonic, Indian, and Desert hedgehog), and they are critically important for development. In the endochondral skeleton, Indian hedgehog (Ihh) was found to be indispensable for osteoblast development, since mice deficient in Ihh completely lack osteoblasts in bones formed by endochondral ossification [42, 43].

Cellular responses to the Hh signal are controlled by two transmembrane proteins: the tumor suppressor 12-transmembrane protein Patched-1 (Ptch) and the 7-transmembrane receptor and oncoprotein Smoothened (Smo). The latter has homology to G protein–coupled receptors and transduces the Hh signal. In the absence of Hh, Ptch maintains Smo in an inactive state. With the binding of Hh, Ptch inhibition of Smo is released, and intracellular signaling is initiated [44]. The transcriptional response to Hh signaling is mediated by three closely related zinc finger transcription factors termed Gli proteins: Gli1, Gli2, and Gli3, each with different roles and a distinct set of target genes. Gli2 functions mainly as a transcriptional activator. In the absence of Hh, Gli3 is processed into a transcription repressor. In the presence of Hh, however, full-length Gli3 translocates into the nucleus, which has transcriptional activation properties. Gli1 acts only as transcriptional activator and is induced by Hh signals [44]. Gli3 has a pivotal role in limb bud development and regulation of digit number and identity [45, 46]. Ihh regulates osteoblast differentiation via a Gli2-mediated increase in expression and function of Runx2 [47].

PTH SIGNALING

Parathyroid hormone (PTH) and its related peptide PTHrP can have both anabolic and catabolic effects on bone. Whereas intermittent PTH administration induces bone formation, continuous treatment of PTH leads to bone loss [48]. The critical role of PTH(rP) in bone development is evident from loss of function of these genes and their receptors in mice and humans. Mice lacking PTHrP die perinatally, likely from respiratory failure due to abnormalities in endochondral bone development [49]. A less severe phenotype is found for mice deficient in PTH, which are viable and display a slightly expanded hypertrophic zone [50]. Transgenic mice that overexpress PTHrP under control of the collagen type II promoter develop shortened limbs due to delayed mineralization and chondrocyte maturation in the growth plate [51]. Mice lacking the PTH receptor PTHR1 demonstrate growth plate abnormalities due to premature chondrocyte maturation [52]. In humans, loss of function in PTH1R has been linked to Blomstrand lethal osteochondrodysplasia [53]. These patients suffer also from advanced skeletal maturation and premature ossification of the skeleton.

PTH(rP) signals via the 7-transmembrane G protein coupled receptor PTHR1; and, upon ligand binding, several intracellular signaling pathways can be activated, including the cAMP/protein kinase A (PKA) and protein kinase C (PKC) pathways. Different mechanisms have been suggested to explain the anabolic and catabolic effects of PTH; PTH may have diverse effects on the proliferation, commitment, differentiation or apoptosis of the osteoblasts. Effects of PTH and PTHrP appear highly context dependent; their action varies with cell type, stage of cell differentiation, dosage, and exposure time. For example, the bone anabolic effects of PTH involve an increase in expression and PKA-dependent activation of Runx2 (Fig. 2.4) [54]. On the other hand, PTH has also shown to repress Runx2 and Osterix expression in osteoblastic cells [55].

IGF-1 SIGNALING

Insulin-like growth factor-1 (IGF-1) is secreted by skeletal cells and is considered to be an auto- or paracrine regulator of osteoblastic cell function [56]. IGF-1-deficient mice were found to develop a smaller, but more compact bone structure [57]. IGF-1 signals via the IGF1 receptor, which like many other tyrosine kinase receptors activates the phosphatidylinositol 3-kinase (PI3K)-Akt and Ras-ERK MAP kinase pathways (Fig. 2.4). Interestingly, Akt1/Akt2 double-knockout mice show a phenotype that resembles that of mice deficient in the IGF-1 receptor, which includes impaired bone development [58]. Moreover, osteoblastic differentiation by forced expression of Runx2 was found to be inhibited by the co-expression of dominant negative Akt, or by treatment with IGF-1 antibodies or the pharmacological PI3K-inhibitor LY294002 [59]. IGF-1-induced Akt activation results in phosphorylation and nuclear exclusion of forkhead transcription factor Foxo1, thereby relieving the inhibitory effect of Foxo1 on the binding of Runx2 to the promoters of its target genes, and thus promoting osteoblast differentiation [60]. In addition, IGF-1 was found to induce expression of Osterix, which occurs in an ERK-, p38-, and c-Jun N-terminal kinase (JNK)-dependent manner [26]. JNK activity was also found to be required for late-stage osteoblast differentiation by controlling ATF-4 expression (Fig. 2.1) [61]. Via these mechanisms, IGF-1 can stimulate osteoblast differentiation.

FGF SIGNALING

Fibroblast growth factors (FGFs) are important regulators of endochondral and intramembranous bone formation,

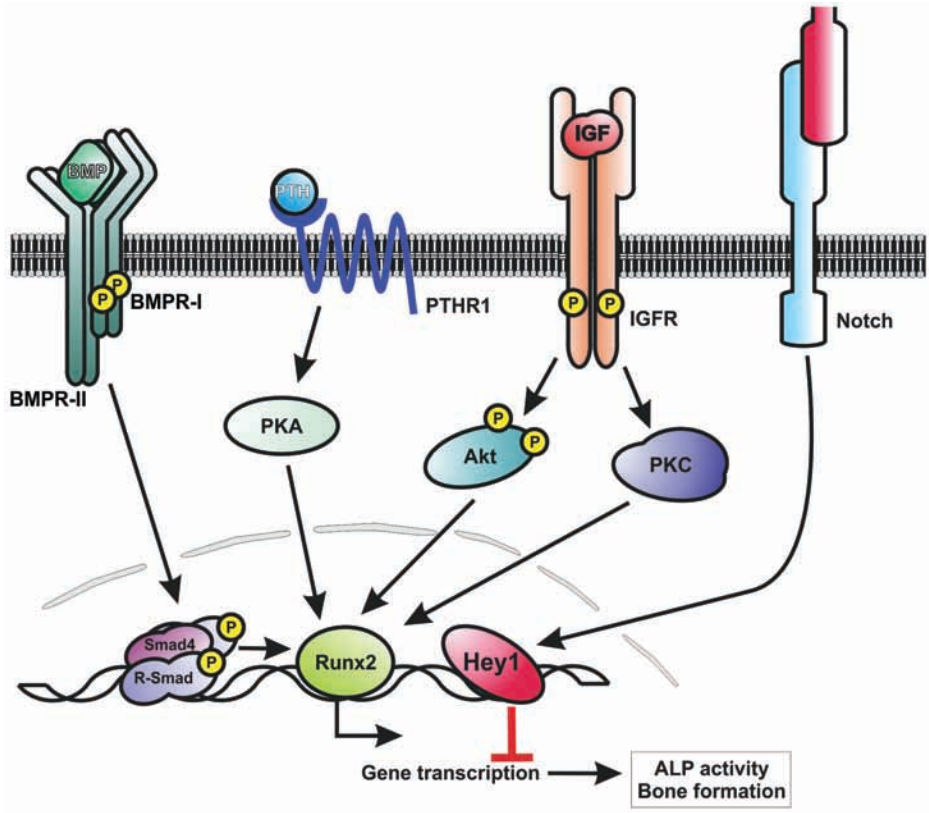

Fig. 2.4. Schematic model illustrating signaling pathways controlling Runx2-mediated osteoblast differentiation.

development and apoptosis, affecting both chondrogenesis and osteogenesis [62]. Many human craniosynostosis disorders have been linked to activating mutations in FGF receptors (FGFRs) [62]. Disruption of FGFR2 signaling in skeletal tissues results in skeletal dwarfism and decreased bone density due to disruption of the proliferation of osteoprogenitors and the anabolic function of mature osteoblasts while osteoblast differentiation was found not to be affected [63, 64]. FGFs are known to induce proliferation of immature osteoblasts via the Ras/ERK MAPK pathway. In addition, FGF signaling was demonstrated to stimulate expression, DNA-binding and transcriptional activities of Runx2, mainly in a PKC-dependent manner [65].

NOTCH SIGNALING

Notch proteins are transmembrane receptors that control cell fate decisions and inhibit osteoblastic differentiation [66–69]. The binding of the transmembrane Notch ligands Delta, Serrate, and Lag2 to Notch receptors induces cleavage of the Notch extracellular domain near the transmembrane region [66]. The resulting membrane-associated Notch is then cleaved by presenilin, generating the Notch intracellular domain (NICD), which then translocates into the nucleus. Here the NCID forms a complex with members of the CSL family {C promoter-binding factor 1 (CBF1), Suppressor of Hairless [Su(H)], and longevity assurance gene-1 (LAG-1)} of DNA binding proteins, which recruits coactivators to drive transcription of target genes [66]. In osteoblast precursor cells, Notch stimulates the expression of Hey1, which physically interacts with Runx2 and thereby inhibits its transcriptional activity and consequently the differentiation of MSCs into osteoblasts (Figs 2.1, 2.4) [68, 69]. Mice in which Notch signaling was disrupted in the limb skeletogenic mesenchyme displayed reduced numbers of mesenchymal stem cells and increased trabecular bone mass, and they developed severe osteopenia [69].

CONCLUDING REMARKS

The effect certain signaling events evoke during the osteoblast differentiation process is highly dependent on which signaling molecules are activated or inhibited, the magnitude and the duration of the response, and the differentiation stage of the responding cell. Given that regulation of Runx2 activity is a point of convergence of many of the signal transduction routes discussed in this chapter, there is also a high degree of cross-talk between

these pathways. For example, apart from its C-terminal phosphorylation by BMP type I receptors, Smad1 can be phosphorylated by the ERK, p38, and JNK MAP kinases and subsequently by GSK3, which results in cytoplasmic retention and increased proteosomal degradation of Smad1 [70, 71]. In this manner, FGF and WNT signaling can control the duration of BMP signaling [70–72]. On the other hand, β-catenin-TCF/Lef1 can interact with Smad1 and -3 proteins to cooperate in transcription of target genes [73, 74]. TGF-β can inhibit BMP2-induced transcription and osteoblast differentiation [30, 75]; however, these inhibitory effects depend on the timing and environmental conditions of the co-stimulation, and under specific conditions TGF-β can actually promote BMP-induced differentiation toward the osteoblast lineage [76, 77]. Notch-1 overexpression inhibits osteoblast differentiation by suppressing WNT signaling [67], Gli2 mediates BMP2 expression in osteoblasts in response to Hh signaling [78], and Hh signaling is required for accurate β-catenin-mediated WNT signaling in osteoblasts [36]. tumor necrosis factor-α (TNF-α) inhibits BMP2-induced Smad activation through induction of NF κB [79] and in part through JNK signaling [80]. The TGF-β type II receptor associates with and phosphorylates the PTHR1, leading to internalization of both receptors and attenuation of both TGF-β and PTH signaling [81]. Thus, the combined action of the signal transduction pathways induced by bone-promoting cytokines determines the commitment of MSCs toward the osteoblast lineage and the efficiency of bone formation.

ABBREVIATIONS

ALK	activin receptor-like kinase
ALP	alkaline phosphatase
AP-1	activator protein-1
APC	adenomatous polyposis coli
ATF4	activating transcription factor-4
BMP	bone morphogenetic protein
BSP	bone sialoprotein
CCD	cleidocranial dysplasia
CK1	casein kinase I
Col1	type I collagen
Dlx	Distalless homeobox
ERK	extracellular signal-regulated kinase
FGF	fibroblast growth factor
FOP	fibrodysplasia ossificans progressiva
Fra	Fos-related antigen
Fzd	frizzled
GSK3	glycogen synthase kinase 3
Id	inhibitor of differentiation/inhibitor of DNA binding
IGF-1	insulin-like growth factor-1
Ihh	Indian hedgehog
JNK	c-Jun N-terminal kinase
LAG-1	longevity assurance gene-1
Lef1	lymphoid enhancing factor
LRP	low-density lipoprotein receptor-related protein
MAPK	mitogen-activated protein kinase
MSC	mesenchymal stem cell
NFAT	nuclear factor for activated T cells
NF κB	nuclear factor-κB
NICD	Notch intracellular domain
OC	osteocalcin
ON	osteonectin
OPN	osteopontin
PI3K	phosphatidylinositol 3-kinase
PKA	protein kinase A
PKC	protein kinase C
Ptch	patched
PTH	parathyroid hormone
Runx2	Runt-related transcription factor2
Smo	Smoothened
TCF	T-cell factor
TGF-β	transforming growth factor-β
TNF-α	tumor necrosis factor-α

CELL BIOLOGY OF THE OSTEOCLAST

Pathological bone loss, regardless of etiology, invariably represents an increase in the rate at which the skeleton is degraded by osteoclasts relative to its formation by osteoblasts. Thus, the prevention of conditions such as osteoporosis requires an understanding of the molecular mechanisms of bone resorption.

The osteoclast, the exclusive bone resorptive cell (Fig. 3.1), is a member of the monocyte-macrophage family and a polykaryon that can be generated *in vitro* from mononuclear phagocyte precursors resident in a number of tissues [1]. There is, however, general agreement that the principal physiological osteoclast precursor is the bone marrow macrophage. Two cytokines are essential and sufficient for basal osteoclastogenesis, the first being receptor activator of nuclear factor-κB ligand (RANKL) [1, 2] and the second being macrophage-colony stimulating factor (M-CSF), also designated CSF-1 [3]. These two proteins, which exist as both membrane-bound and soluble forms (the former is secreted by activated T cells) [4], are produced by marrow stromal cells and their derivative osteoblasts. Thus, physiological recruitment of osteoclasts from their mononuclear precursors requires the presence of these nonhematopoietic, bone-residing cells [1]. RANKL, a member of the tumor necrosis factor (TNF) superfamily, is the key osteoclastogenic cytokine, because osteoclast formation requires its presence or its priming of precursor cells. M-CSF contributes to the proliferation, survival, and differentiation of osteoclast precursors, as well as the survival and cytoskeletal rearrangement required for efficient bone resorption (Fig. 3.2); a brief summary of the integrated signaling pathways for each osteoclastic regulator discussed in this review is provided in Fig. 3.3.

The discovery of RANKL was preceded by identification of its physiological inhibitor osteoprotegerin (OPG), to which it binds with high affinity [5]. In contrast, M-CSF is a moiety long known to regulate the broader biology of myeloid cells, including osteoclasts [3] (see Fig. 3.2).

Our understanding of how osteoclasts resorb bone derives from two major sources: biochemistry and genetics [2]. The unique osteoclastogenic properties of RANKL permit generation of pure populations of osteoclasts in culture and hence the performance of meaningful biochemical and molecular experiments that provide insights into the molecular mechanisms by which osteoclasts resorb bone. Further evidence has come from our capacity to generate mice that lack specific genes, plus the positional cloning of genetic abnormalities in people with abnormal osteoclast function. Key to the resorptive event is the capacity of the osteoclast to form a microenvironment between itself and the underlying bone matrix [Fig. 3.4(A)]. This compartment, which is isolated

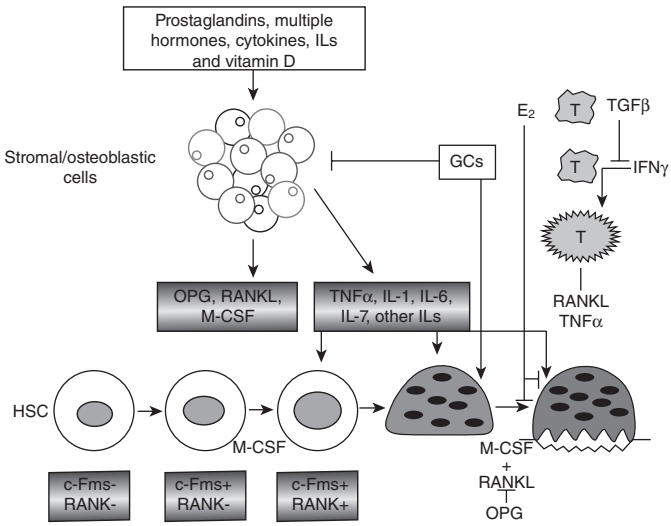

Fig. 3.2. Role of cytokines, hormones, steroids, and prostaglandins in osteoclast formation. Under the influence of other cytokines (data not shown), hematopoietic stem cells (HSCs) commit to the myeloid lineage, express c-Fms and RANK, the receptors for M-CSF and RANKL, respectively, and differentiate into osteoclasts. Mesenchymal cells in the marrow respond to a range of stimuli, secreting a mixture of pro- and anti-osteoclastogenic proteins, the latter primarily OPG. Glucocorticoids suppress bone resorption indirectly but possibly also target osteoclasts and/or their precursors. Estrogen (E2), by a complex mechanism, inhibits activation of T cells, decreasing their secretion of RANKL and TNF-α; the sex steroid also inhibits osteoblast and osteoclast differentiation and lifespan. A key factor regulating bone resorption is the RANKUOPG ratio.

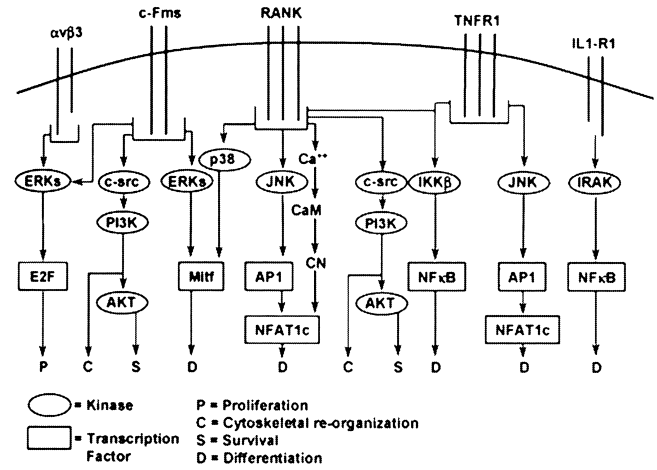

Fig. 3.3. Osteoclast signaling pathways. Summary of the major receptors, downstream kinases, and effector transcription factors that regulate osteoclast formation and function. Proliferation (P) of precursors is driven chiefly through ERKs and their downstream cyclin targets and E2F. Maximal activation of this pathway requires combined signals from c-Fms and the integrin αvβ3. As expected, the cyloskeleton (C) is independent of nuclear control but depends on a series of kinases and their cytoskeletal-regulating targets, whereas differentiation (D) is regulated largely by controlling gene expression. The calcium/calmodulin (CaM)/calcineurin (CN) axis enhances nuclear translocation of NFATlc, the most distal transcription factor characterized to date. See Refs. 2, 3, 10, 28, 40, and 53–56 for details.

from the general extracellular space, is acidified by an electrogenic proton pump (H+- ATPase) and a Cl- channel to a pH of 4.5 [6]. The acidified milieu mobilizes the mineralized component of bone, exposing its organic matrix, consisting largely of type I collagen that is subsequently degraded by the lysosomal enzyme cathepsin K. The critical roles that the proton pump, Cl- channel, and cathepsin K play in osteoclast action is underscored by the fact that diminished function of each results in a human disease of excess bone mass, namely osteopetrosis or pyknodysostosis [2, 6]. Degraded protein fragments are endocytosed and transported in undefined vesicles to the basolateral surface of the cell, where they are discharged into the surrounding intracellular fluid [7, 8]. It

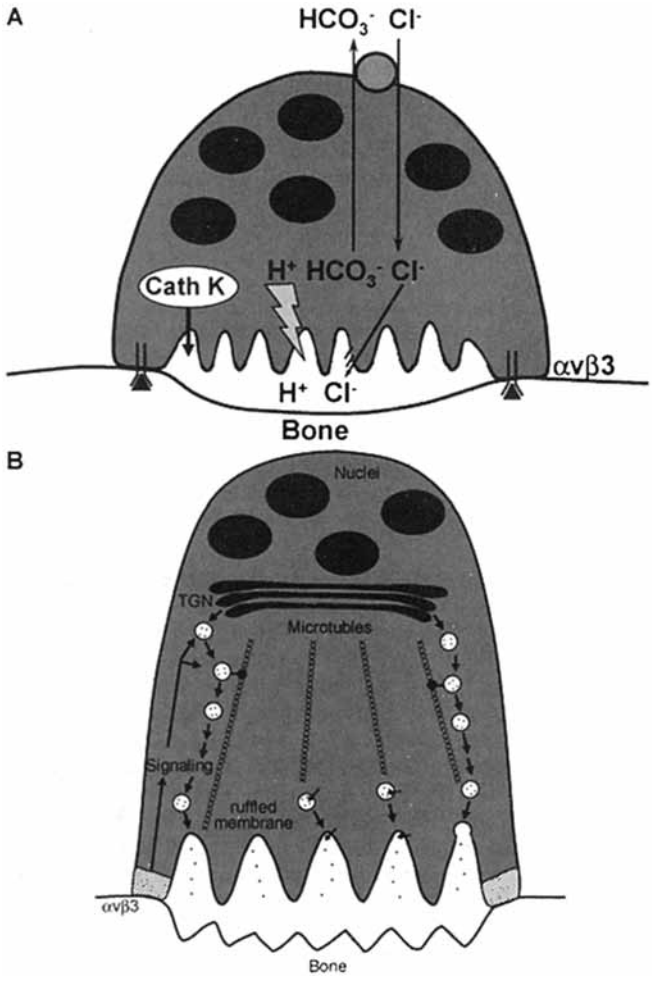

Fig. 3.4. Mechanism of osteoclastic bone resorption. (A) The osteoclast adheres to bone through the integrin αvβ3, creating a sealing zone, into which is secreted hydrochloric acid and acidic proteases such as cathepsin K, MMP9, and MMP13. The acid is generated by the combined actions of a vacuolar H^+ ATPase; it coupled chloride channel and a basolatcral chloride–bicarbonate exchanger. Carbonic anhydrase converts CO, into H^+ and HCO^+ (data not shown). (B) Integrin engagement results in signals that target acidifying vesicles (+ = proton pump complex) containing specific cargo (black dots) to the bone-apposed face of the cell. Fusion of these vesicles with the plasma membrane generates a polarized cell capable of secreting the acid and proteases required for bone resorption.

is also likely that retraction of an osteoclast from the resorptive pit results in release of products of digestion.

The above model of bone degradation clearly depends on physical intimacy between the osteoclast and bone matrix, a role provided by integrins. Integrins are *alpha beta* heterodimers with long extracellular and single transmembrane domains [9]. In most instances, the integrin cytoplasmic region is relatively short, consisting of 40–70 amino acids. Integrins are the principal cell matrix attachment molecules and they mediate osteoclastic bone recognition. Members of the β1 family of integrins, which recognize collagen, fibronectin, and laminin, are present on osteoclasts, but αvβ3 is the principal integrin mediating bone resorption [10]. This heterodimer, like all members of the alpha V integrin family, recognizes the amino acid motif Arg- Gly-Asp (RGD), which is present in a variety of bone-residing proteins such as osteopontin and bone sialoprotein. Thus, osteoclasts attach to and spread on these substrates in an RGD-dependent manner, and, most importantly, competitive ligands arrest bone resorption *in vivo*. Proof of the pivotal role that αvβ3 has in the resorptive process came with the generation of the β3 integrin knockout mouse, which develops a progressive increase in bone mass because of osteoclast dysfunction. Based on a combination of these *in vitro* and *in vivo* observations, small molecule inhibitors of osteoclast function that target αvβ3 have been developed [11].

Bone resorption also requires a polarization event in which the osteoclast delivers effector molecules like HC1 and cathepsin K into the resorptive microenvironment. Osteoclasts are characterized by a unique cytoskeleton, which mediates the resorptive process. Specifically, when the cell contacts bone, it generates two polarized structures, which enable it to degrade skeletal tissue. In the first instance, a subset of acidified vesicles containing specific cargo, including cathepsin K and other matrix metalloproteases (MMPs), are transported, probably through microtubules and actin, to the bone-apposed plasma membrane [12] to which they fuse in a manner not currently understood, but which may involve PLEKHM1, a nonsecretory adaptor protein found in endosomal vesicles [13]. Insertion of these vesicles into the plasmalemma results in formation of a villous structure, unique to the osteoclast, called the ruffled membrane. This resorptive organelle contains the abundant H^+ transporting machinery to create the acidified microenvironment, whereas the accompanying exocytosis serves as the means by which cathepsin K is secreted [Fig. 3.4(B)].

In addition to inducing ruffled membrane formation, contact with bone also prompts the osteoclast to polarize its fibrillar actin into a circular structure known as the "actin ring." A separate "sealing zone" surrounds and isolates the acidified resorptive microenvironment in the active cell, but its composition is almost completely unknown. The actin ring, like the ruffled membrane, is a hallmark of the degradative capacity of the osteoclast, because structural abnormalities of either occur in conditions of arrested resorption [14]. In most cells, such as fibroblasts, matrix attachment prompts formation of stable structures known as "focal adhesions" that contain both integrins and a host of signaling and cytoskeletal molecules, which mediate contact and formation of actin stress fibers. In keeping with the substitution of the actin ring for stress fibers in osteoclasts, these cells form podosomes instead of focal adhesions. Podosomes, which in resorbing osteoclasts are present in the actin ring, consist of an actin core surrounded by αvβ3 and associated cytoskeletal proteins.

The integrin β3 subunit knockout mouse serves as an important tool for determining the role of αvβ3 in the

capacity of the osteoclast to resorb bone. Failure to express αvβ3 results in a dramatic osteoclast phenotype, particularly regarding the actin cytoskeleton. The $\beta3^{-/-}$ osteoclast forms abnormal ruffled membranes *in vivo* and, whether generated *in vitro* or directly isolated from bone, the mutant cells fail to spread when plated on immobilized RGD ligand or mineralized matrix in physiological amounts of RANKL and M-CSF. Confirming their attenuated resorptive activity, $\beta3^{-/-}$ osteoclasts generate fewer and shallower resorptive lacunae on dentin slices than do their wild type counterparts. In keeping with attenuated bone resorption *in vivo*, $\beta3^{-/-}$ mice are substantially hypocalcemic [6].

INTEGRIN SIGNALING

Whereas integrins were viewed initially as merely cell attachment molecules, it is now apparent that their capacity to transmit signals to and from the cell interior is equally important, an event that requires that the integrin convert from a default low affinity state to one in which its capacity to bind matrix is significantly enhanced. The process, termed "activation," arises from either integrin ligation of their multivalent ligands or indirectly by growth factor signaling [15].

Integrin αvβ3 is absent from osteoclast precursors, but their differentiation under the action of RANKL results in marked upregulation of this heterodimer. The capacity of integrins to transmit intracellular signals to the cytoskeleton heightened interest in the cytoplasmic molecules mediating these events in osteoclasts, and αvβ3 signaling in this context is reasonably well understood. The initial signaling event involves the proto-oncogene c-src, which, acting as a kinase and an adaptor protein, regulates formation of lamellipodia and disassembly of podosomes, indicating that c-src controls formation of resorptive organelles of the cell, such as the ruffled membrane, and also arrests migration on the bone surface. There is continuing debate surrounding the molecules that link c-src to the cytoskeleton, one proposal being that the focal adhesion kinase family member Pyk2, acting in concert with c-Cbl, a proto-oncogene and ubiquitin ligase [16]. A second strong candidate is Syk, a nonreceptor tyrosine kinase that is recruited to the active conformation of αvβ3 in osteoclasts in a c-src-dependent manner [17], where it targets Vav3 [10], a member of the large family of guanine nucleotide exchange factors (GEFs) that convert Rho GTPases from their inactive GDP to their active GTP conformation.

SMALL GTPases

The Rho family of GTPases is central to remodeling of the actin cytoskeleton in many cell types [18] and as such

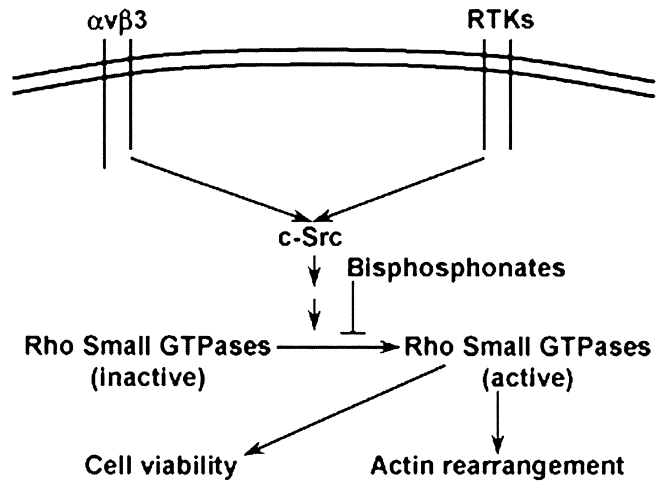

Fig. 3.5. Regulation and role of small GTPases in osteoclasts. Signals from αvβ3 and/or receptor tyrosine kinases (RTKs) activate small GTPases of the Rho family in a c-src-dependent manner. Bisphosphonates, the potent antiresorptive drugs, block addition of hydrophobic moieties onto the GTPases, preventing their membrane targeting and activation. The active GTPases also regulate cell viability and thus bisphosphonates induce osteoclast death.

plays a central role in osteoclastic bone resorption (Fig. 3.5). On attachment to bone, Rho and Rac bind GTP and translocate to the cytoskeleton. Whereas both small GTPases impact the actin cytoskeleton, Rac and Rho exert distinctive effects. Rho signaling mediates formation of the actin ring and a constitutively active form of the GTPase stimulates podosome formation, osteoclast motility, and bone resorption, whereas dominant negative Rho arrests these events [19]. Rac stimulation in osteoclast precursors prompts appearance of lamellipodia, thus forming the migratory front of the cell to which αvβ3 moves when activated [20]. In sum, it is likely that Rho's effect is principally on cell adhesion, whereas Rac mediates the cytoskeleton's migratory machinery. Importantly, absence of Vav3 blunts Rac but not Rho activity in the osteoclast [21].

FACTORS REGULATING OSTEOCLAST FORMATION AND/OR FUNCTION

Proteins

In addition to the two key osteoclastogenic cytokines MCSF and RANKL, a number of other proteins play important roles in osteoclast biology, either in physiological and/or pathophysiological circumstances.

As discussed previously, OPG, a high-affinity ligand for RANKL that acts as a soluble inhibitor of RANKL, is secreted by cells of mesenchymal origin, both basally and in response to other regulatory signals, including cyto-

kines and bone-targeting steroids [5]. Pro-inflammatory cytokines suppress OPG expression while simultaneously enhancing that of RANKL, with the net effect being a marked increase in osteoclast formation and function. Genetic deletion of OPG in both mice and humans leads to profound osteoporosis [22], whereas overexpression of the molecule under the control of a hepatic promoter results in severe osteopetrosis [23]. Together, these observations indicate that skeletal, and perhaps circulating, OPG modulates the bone resorptive activity of RANKL and helps to explain the increased bone loss in clinical situations accompanied by increased levels of TNF-α, interleukin (IL)-1, parathyroid hormone (PTH), or PTH-related protein (PTHrP). Serum PTH levels are increased in hyperparathyroidism of whatever etiology, whereas PTHrP is secreted by metastatic lung and breast carcinoma [24, 25]. F antibodies or a soluble TNF receptor-IgG fusion protein potently suppress the bone loss in disorders of inflammatory osteolysis such as rheumatoid arthritis [26]. The molecular basis of this observation seems to be that the inflammatory cytokine synergizes with RANKL in a unique manner, most likely because RANKL and TNF-α each activate a number of key downstream effector pathways, leading to nuclear localization of a range of osteoclastogenic transcription factors (see Fig. 3.3). Recent evidence suggests a new paradigm linking TNF-α, IL-1, and the natural secreted inhibitor for the latter cytokine, IL-1 receptor antagonist, which blocks IL-1 function. Specifically, it seems that, at least in murine osteoclasts and their precursors, many of the effects of TNF are mediated through TNF's stimulation of IL-1, which in turn increases expression and secretion of IL-1 receptor antagonist (IL-1ra), a set of events that represent a complex control pathway. The significance of the IL receptor antagonist is shown by the fact an IgG fusion protein containing the active component of this molecule has been developed and enhances the ability of anti-TNF antibodies to decrease bone loss in rheumatoid arthritis [27].

Elegant studies suggest that interferon y (IFNy) is an important suppressor of osteoclast formation and function [28]. Nevertheless, these findings seem to be in conflict with other *in vivo* observations, including the report that IFNy treatment of children with osteopetrosis ameliorates the disease [29] and the fact that a number of *in vivo* studies indicate that IFNy stimulates bone resorption [30, 31]. This conundrum highlights the importance of discriminating between *in vitro* culture experiments using single cytokines and results *in vivo*. Many additional studies have implicated a range of other cytokines in the regulation of the osteoclast. These include a range of interleukins, GM-CSF, IFNβ, stromal cell-derived factor 1 (SDF-1), macrophage inflammatory protein 1 (MIP-1), and monocyte chemoattractant protein 1 (MCP-l), but at this time the results are either contradictory, as for GM-CSF in the murine vs human systems, or lack direct proof in humans. Future studies are likely to clarify the currently confusing data set. Finally, interactions between immune receptors such as DNAX activating protein of 12 kDa (DAP12) and FC receptor y (FcRy), present on osteoclasts and their precursors, and their ligands on cells of the stromal and myeloid/lymphoid lineages are important for transmission of RANK-derived signals [28]. IL-17 is a product of Th17 cells, a recently identified T-cell subset that is generated from uncommitted precursors under the influence of TGF-β, IL-23, and 1L-6 [32, 33].

Small molecules

The active form of vitamin D, 1,25-dihydroxyvitamin D, has all the characteristics of a steroid hormone, including a high-affinity nuclear receptor that binds as a heterodimer with the retinoid X receptor to regulate transcription of a set of specific target genes. Generated by successive hydroxylation in the liver and kidney, this active form of vitamin D is a well-established stimulator of bone resorption when present at supraphysiological levels. Studies over many years have indicated that this steroid hormone increases mesenchymal cell transcription of the *RANKL* gene, while diminishing that of OPG [5]. Separately, 1,25-dihydroxyvitamin D suppresses synthesis of the pro-osteoclastogenic hormone PTH [34] and enhances calcium uptake from the gut. Taken together, the two latter effects would seem to be antiresorptive, but many studies in humans indicate the net osteolytic action resulting from high levels of this steroid hormone, suggesting that its ability to stimulate osteoclast function overrides any bone anabolic actions.

Loss of estrogen (E_2), most often seen in the context of menopause, is a major reason for the development of significant bone loss in aging. Interestingly, it is now clear that estrogen is the main sex steroid regulating bone mass in both men and women [35]. The mechanisms by which estrogen mediates its osteolytic effects are still not completely understood, but significant advances have been made over the past decade. The original hypothesis, now considered to be only part of the explanation, is that decreased serum E2 led to increased production, by circulating macrophages, of osteoclastogenic cytokines such as IL-6, TNF, and IL-1. These molecules act on stromal cells and osteoclast precursors to enhance bone resorption by regulating expression of pro- (RANKL, M-CSF) and anti- (OPG) osteoclastogenic cytokines (in the case of mesenchymal cells) and by synergizing with RANKL itself (in the case of myeloid osteoclast precursors; see Fig. 3.2). However, the understanding that lymphocytes play a key role in mediating several aspects of bone biology has led to a growing realization that the cellular and molecular targets for E2 are more widespread than previously believed. A model proposes that E2 impacts the resorptive component of bone turnover (the steroid has separate effects on osteoblasts), at least in part by modulating production by T cells of RANKL and TNF [30]. This effect is itself indirect, with E2 suppressing antigen presentation by dendritic cells and macrophages by enhancing expression by the same

cells of TGFβ. Antigen presentation activates T cells, thereby enhancing their production of RANKL and TNF. As discussed previously, the first molecule is the key osteoclastogenic cytokine, whereas the second potentiates RANKL action and stimulates production by stromal cells of M-CSF and RANKL. This newly discovered interface between T cells and bone resorption also clarifies aspects of inflammatory osteolysis. Finally, some studies indicate that E2 modulates signaling in preosteoclasts and that, acting through reactive oxygen species, it increases the lifespan and/or function of mature osteoclasts [36].

Both endogenous glucocorticoids and their synthetic analogs, which have been and continue to be a major mainstay of immunosuppressive therapy, are members of a third steroid hormone family having a major impact on bone biology [37].

One consequence of their chronic mode of administration is severe osteoporosis arising from decreased bone formation and resorption with the latter absolutely decreased (low turnover osteoporosis). The majority of the evidence focuses on the osteoblast as the prime target with the steroid increasing apoptosis of these bone-forming cells. However, numerous human studies document a rapid initial decrease in bone resorption, suggesting that the osteoclast and/or its precursors may also be targets. The molecular basis for this latter finding is unclear. However, because osteoblasts are a requisite part of the resorptive cycle, one consequence of their long-term diminution could be decreased osteoclast formation and/or function secondary to lower levels of RANKL and/or M-CSF production. Alternatively, glucocorticoids have been shown to decrease osteoclast apoptosis [38].

A wide range of clinical information shows that excess prostaglandins stimulate bone loss, but once again, the cellular basis has not been established. Prostaglandins target stromal and osteoblastic cells, stimulating expression of RANKL and suppressing that of OPG [30]. This increase in the RANKL/OPG ratio, seen in a variety of human studies, is sufficient of itself to explain the clinical findings of increased osteoclastic activity. However, highlighting again the dilemma of interpreting *in vitro* studies, there have been a number of studies in which prostaglandins regulate osteoclastogenesis *per se* in murine cell culture.

Phosphoinositides play distinct and important roles in organization of the osteoclast cytoskeleton [39, 40]. Binding of M-CSF or RANKL to their cognate receptors, c-Fms and RANK, or activation of αvβ3, recruits phosphoinositol-3-kinase (PI3K) to the plasma membrane, where it converts membrane-bound phosphatidylinositol 4,5-bisphosphate into phosphatidylinositol 3,4,5-trisphosphate (Fig. 3.3). The latter compound is recognized by specific motifs in a wide range of cytoskeletally active proteins [41], and thus PI3K plays a central role in organizing the cytoskeleton of the osteoclast, including its ruffled membrane. Akt is a downstream target of PI3K and plays an important role in osteoclast function, particularly by mediating RANKL and/or M-CSF-stimulated proliferation and/or survival [40].

CELL–CELL INTERACTIONS IN BONE MARROW

Recent evidence has indicated that a number of additional cell types are important for osteoclast biology in a variety of situations (Fig. 3.6). First, as discussed previously, T cells play a key role in estrogen deficiency bone loss but also are important in a range of inflammatory diseases, most notably rheumatoid arthritis [42] and periodontal disease [43]; here the Th17 subset likely secretes TNF and IL-17, a newly described osteoclastogenic cytokine. Given that both osteoclast precursors and the various lymphocyte subsets, such as T, B, and NK cells, arise from the same stem cell, it is not surprising that some of the same receptors and ligands that mediate the immune process also govern the maturation of osteoclast precursors and the capacity of the mature cell to degrade bone. This interface has given rise to the new discipline of osteoimmunology, which promises to provide important and exciting findings in the future.

Second, whereas it is well established that mesenchymal cells are major mediators of cytokine and prostaglandin action on osteoclasts, it has become clear recently that cells of the same lineage, residing on cortical and trabecular bone, are the site of a hematopoietic stem cell (HSC) niche [44]. Specifically, HSCs reside close to osteoblasts as a result of multiple interactions involving recep-

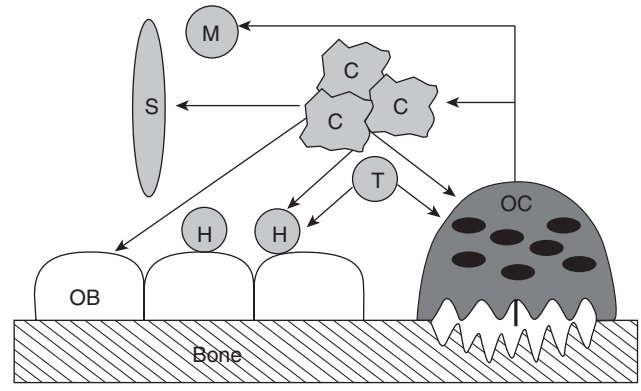

Fig. 3.6. Cell–cell interactions in bone marrow. Hematopoietic stem cells (H), the precursors of both T cells (T) and osteoclasts (OC), reside in a stem cell niche provided by osteoblasts (OB), which, together with stromal cells (S), derive from mesenchymal stem cells (M). Bone degradation results in release of matrix-associated growth factors (thick vertical line), which stimulate mesenchymal cells and thus bone formation. This "coupling" is an essential consequence of osteoclast activity. After activation, T cells secrete molecules that stimulate osteoclastogenesis and function. Cancer cells (C) release cytokines that activate bone resorption; in turn, matrix-derived factors stimulate cancer cell proliferation, the so-called vicious cycle.

tors and ligands on both cells types [45]. Furthermore, the mesenchymally derived cells secrete both membrane-bound and soluble factors that contribute to survival and proliferation of multipotent osteoclast precursors, as well as molecules that influence osteoclast formation and function. Both committed osteoblasts and the numerous stromal cells in bone marrow produce a range of proteins both basally and in response to hormones and growth factors, resulting in modulation of the capacity of HSCs to become functional osteoclasts.

Third, cancer cells facilitate their infiltration into the marrow cavity by stimulating osteoclast formation and function. An initial stimulus is PTHrP generation by lung and breast cancer cells [24, 25, 36, 46], thus enhancing mesenchymal production of RANKL and M-CSF, whereas decreasing that of OPG and possibly chemotactic factors. The resulting increase in matrix dissolution releases bone-residing cytokines and growth factors that, feeding back on the cancer cells, increase their growth and/or survival. This loop has been termed "the vicious cycle" [24]. Multiple myeloma seems to use a different but related strategy, namely secretion of MIPa and MCP-1, both of which are chemotactic and proliferative for osteoclast precursors [47, 48]. The latter compound has been reported to be secreted by osteoclasts in response to RANKL and enhances osteoclast formation [2]. It seems likely further future studies experiments will uncover additional molecules mediating bone loss in metastatic disease.

INTRACELLULAR SIGNALING PATHWAYS

The discussions above have not described in detail the intracellular signals by which osteoclasts are formed or those by which they degrade bone. The final major section of this review lays out the important pathways involved. Briefly, three major protein classes are involved: adaptors, kinases, and transcription factors (Fig. 3.3), with one significant exception, RANKL-induced release of Ca^{++}, a pathway that activates the calmodulin-dependent phosphatase calcineurin. NFATlc is a major substrate for this enzyme, resulting in its nuclear translocation and subsequent activation of osteoclast-specific genes. Importantly, the potent immunosuppressive drugs FK506 and cyclosporine inhibit calcineurin activity and therefore may target the osteoclast [49].

The multiplicity of adaptors that link the various receptors to downstream signals precludes providing a meaningful summary, and so we summarize only the modulatory effects of kinases and transcription factors, which together regulate receptor-driven proliferation and/or survival of precursors. Thus, proliferation is mediated by αvβ3 and c-Fms [10, 50]; reorganization of the cytoskeleton by αvβ3, c-Fms, and RANK [2, 10]; differentiation of mature osteoclasts from myeloid progenitors by c-Fms, RANK, TNFRl, and IL-lRl [2, 50, 51], and their function by RANK, TNFRl, and IL-lRl [52, 53]. Not shown is the fact that multiple other cytokines and growth factors, targeting the same or other less prominent pathways, or acting indirectly probably contribute to overall control of bone resorption.

HUMAN GENETICS

The text above might suggest that numerous mutations in many genes linked to the osteoclast are likely to have been discovered in humans. In fact, few such genetic changes have been defined, with more than 50% of those reported being in patients with osteopetrosis caused by defects in the chloride channel that modulates osteoclast acid secretion (Fig. 3.4). Rare reports link deficiencies in RANK, the proton pump, or carbonic anhydrase II to osteopetrosis, whereas decreased cathepsin K function leads to pyknodysostosis. In contrast, RANK activation manifests as osteolytic bone disease, whereas OPG deficiency leads to a severe form of high turnover osteoporosis.

INTRODUCTION

In the adult skeleton, osteocytes make up over 90–95% of all bone cells, compared to 4–6% osteoblasts and approximately 1–2% osteoclasts. These cells are regularly dispersed throughout the mineralized matrix, connected to each other and cells on the bone surface through dendritic processes generally radiating towards the bone surface and the blood supply. The dendritic processes travel through the bone in tiny canals called canaliculi (250–300 nm) while the cell body is encased in a lacuna (15–20 um) (See Figs. 4.1, 4.2, and 4.3). Osteocytes are thought to function as a network of sensory cells mediating the effects of mechanical loading through this extensive lacunocanalicular network. Not only do these cells communicate with each other and with cells on the bone surface, but their dendritic processes extend past the bone surface into the bone marrow. Osteocytes have long been thought to respond to mechanical strain to send signals of resorption or formation, and evidence is accumulating to show that this is a major function of these cells. Recently, it has been shown that osteocytes have another important function: to regulate phosphate homeostasis; therefore, the osteocyte network may also function as an endocrine gland. Defective osteocyte function may play a role in a number of bone diseases, especially glucocorticoid induced bone fragility and osteoporosis in the adult, aging skeleton (for review see Ref. 1).

OSTEOCYTE ONTOGENY

Osteoprogenitor cells reside in the bone marrow before differentiating into plump, polygonal osteoblasts on the bone surface. (For a review of the osteoblast to osteocyte transformation, see Refs. 2 and 3.) By an unknown mechanism, some of these cells are destined to become osteocytes, while some become lining cells and some undergo programmed cell death known as apoptosis [4]. Osteoblasts, osteoid-osteocytes, and osteocytes may play distinct roles in the initiation and regulation of mineralization of bone matrix, but Bordier first proposed that osteoid-osteocytes are major regulators of the mineralization process [5]. Osteoid-osteocytes actively make a matrix while simultaneously calcifying this matrix. The osteoblast cell body reduces in size about 30% at the osteoid-osteocyte stage while cytoplasmic processes are forming and about 70% with complete maturation of the osteocyte (See Figs. 4.1 and 4.2).

Whereas numerous markers for osteoblasts have been identified, such as cbfa1, osterix, alkaline phosphatase, collagen type 1, etc., few markers have been available for osteocytes until recently (for a review, see Ref. 3). In 1996, the markers described for osteocytes were limited to low- or no-alkaline phosphatase, high casein kinase II, high osteocalcin protein expression, and high CD44 as compared to osteoblasts. Osteocyte markers such as E11/gp38, phosphate-regulating neutral endopeptidase

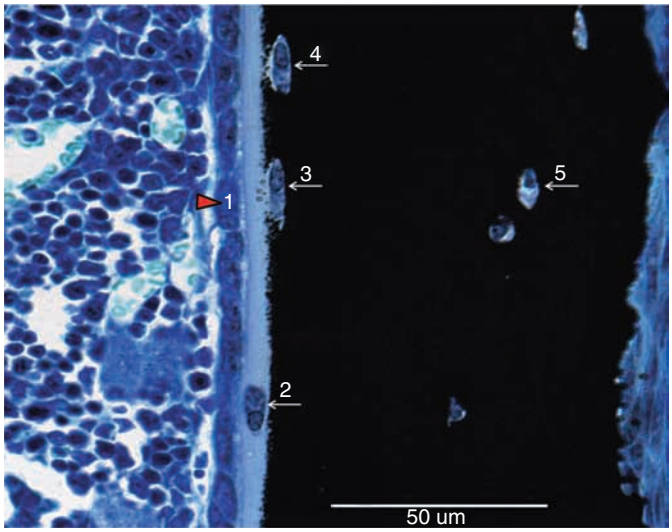

Fig. 4.1. Histological section of tetrachrome stained murine cortical bone showing osteoblast to osteocyte differentiation. 1 = matrix producing osteoblast; 2 = osteoid osteocyte; 3 = embedding osteocyte; 4 = newly embedded osteocyte; 5 = mature osteocyte. From this histological section, one would assume only the lacunae are the porosities within bone. However, as can be seen in Figs. 4.2 and 4.3, the osteocyte canaliculi provide extensive porosities within the mineralized bone matrix.

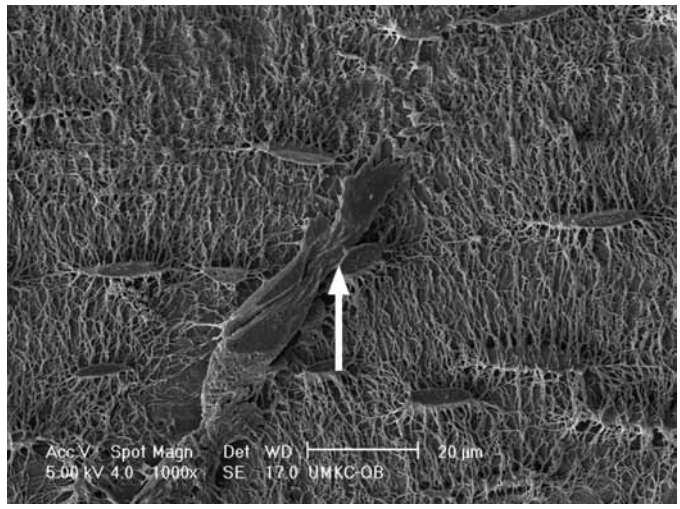

Fig. 4.3. The osteocyte lacunocanalicular network is intimately associated with the blood vessel network in the bone matrix. The white marker points to an osteocyte lacunae intimately associated with the blood vessel.

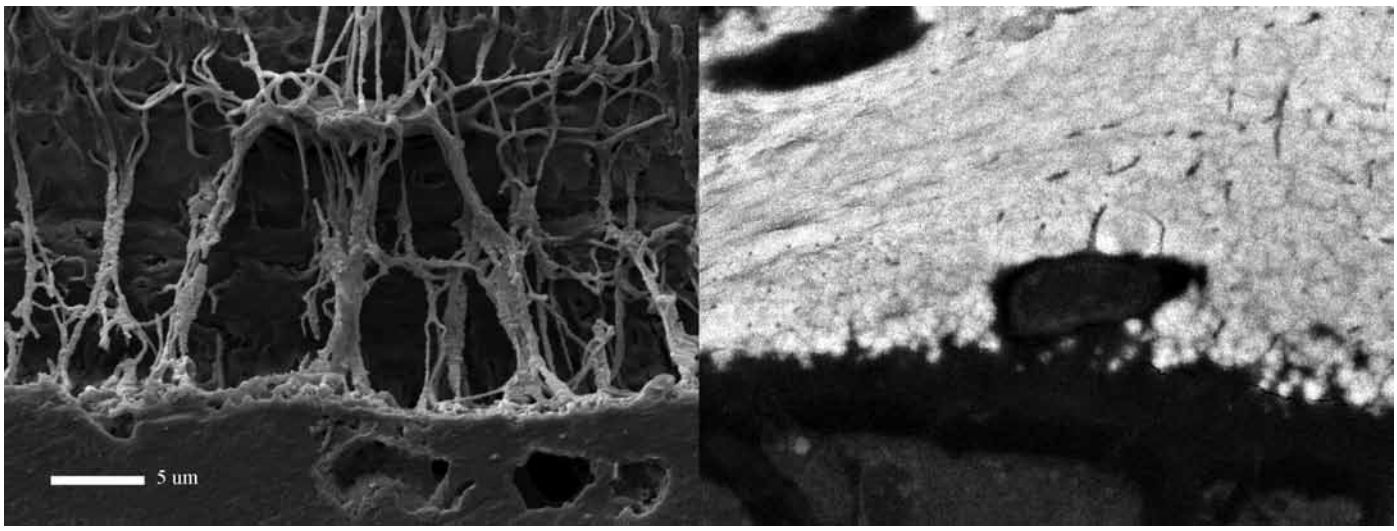

Fig. 4.2. The embedding osteocyte retains its connectivity with cells on the bone surface. The image on the right is of acid-etched plastic embedded murine cortical bone. With this technique, resin fills the lacunocanalicular system, osteoid, and marrow, but cannot penetrate mineral. Mild acid is used to remove the mineral, leaving behind a resin cast relief. Note the canaliculi connecting the lacunae with the bone surface at the bottom of the image. The image on the right is from transmission electron microscopy showing a fully embedded osteocyte and an osteoid-osteocyte becoming surrounded by mineral (white). The osteoid is black and the osteoblasts are at the bottom of the image.

Table 4.1. Osteocyte Markers

Marker	Expression	Function
E11/gp38	Early, embedding cell (Ref. 45)	Dendrite formation (Ref. 45)
CD44	More highly expressed in osteocytes compared to osteoblasts (Ref. 46)	Hyaluronic acid receptor associated with E11 and linked to cytoskeleton (Ref. 47)
Fimbrin	All osteocytes (Ref. 6)	Dendrite branching?
Phex	Early and late osteocytes (Refs. 48, 49)	Phosphate metabolism (Ref. 50)
OF45/MEPE	Late osteoblast through osteocytes (Ref. 51)	Inhibitor of bone formation (Ref. 51)/regulator of phosphate metabolism (Ref. 52)
DMP1	Early and mature osteocytes (Ref. 53) osteocytes (Ref. 53)	Phosphate metabolism and mineralization (Ref. 42)
Sclerostin	Late embedded osteocyte (Ref. 54)	Inhibitor of bone formation (Ref. 55)
FGF23	Early and mature osteocytes (Ref. 43)	Induces hypophosphatemia (Ref. 50)
ORP150	Mature osteocytes (Ref. 9)	Protection from hypoxia (Ref. 9)

on the chromosome X (Phex), dentin matrix protein 1 (DMP1), sclerostin, FGF23, and ORP150 have since then been identified (see Table 4.1). Some of these markers overlap in expression with osteoblasts, but some have been identified for specific stages of differentiation. The identification of these markers has led to identification of osteocyte functions (Table 4.1). The actin-bundling proteins—villin, alpha-actinin, and fimbrin—were shown to be markers for osteocytes with strong signals of fimbrin at branching points in dendrites [6]. It is likely that these actin-reorganizing proteins play a role in osteocyte cell body movement within its lacuna and the retraction and extension of dendritic processes [7, 8]. CapG and destrin have been shown to be more highly expressed in the embedding osteocyte [9].

Promoters for specific markers have been used to drive green fluorescent protein (GFP) to follow osteoblast to osteocyte differentiation *in vivo*. Collagen type 1-GFP is strongly expressed in both osteoblasts and osteocytes, osteocalcin-GFP is expressed in a few osteoblastic cells lining the endosteal bone surface and in scattered osteocytes, and the osteocyte-selective promoter, the 8kb DMP1 driving GFP showed selective expression in osteocytes [10]. A marker for the late, embedded osteocyte is sclerostin, which is coded by the gene *Sost*. This protein is a negative regulator of bone formation, targeting the osteoblast. Inhibition of sclerostin activity leads to increased bone mass; therefore, therapeutics such as neutralizing antibodies or small molecules are now the focus of much research and are being tested clinically (for a review, see Ref. 11).

OSTEOCYTES AS ORCHESTRATORS OF BONE (RE)MODELING

Considerable evidence is mounting that osteocytes can conduct and control both bone resorption and bone formation. Some of the earliest supporting data for the theory that osteocytes can send signals to initiate bone resorption were observations that isolated avian osteocytes can support osteoclast formation and activation in the absence of any osteotropic factors [12], as can the osteocyte-like cell line, MLO-Y4 [13]. It was suggested that expression of the receptor activator of NF-kappaB ligand (RANKL) along exposed osteocyte dendritic processes provides a potential means for osteocytes within bone to stimulate osteoclast precursors at the bone surface.

One of the major means by which osteocytes may support osteoclast activation and formation is through their death. Osteocyte apoptosis, also known as programmed cell death, is an orderly process that can occur at sites of microdamage; it is proposed that dying osteocytes are targeted for removal by osteoclasts. The expression of anti-apoptotic and pro-apoptotic molecules in osteocytes surrounding microcracks was mapped, and it was found that pro-apoptotic molecules are elevated in osteocytes immediately at the microcrack locus, whereas anti-apoptotic molecules are expressed 1–2 mm from the microcrack [14]. Therefore, those osteocytes that do not undergo apoptosis are prevented from doing so by protective mechanisms, while those destined for removal by osteoclasts undergo apoptosis. Targeted ablation of osteocytes by necrosis was performed using the 10kb *Dmp1* promoter to drive expression of the diptheria toxin receptor in mice [15]. Injection of a single dose of diphtheria toxin eliminated approximately 70% of osteocytes in cortical bone in these mice leading to dramatic osteoclast activation. Therefore, viable osteocytes are necessary to prevent osteoclast activation and maintain bone mass (see Fig. 4.4).

The osteocyte-like cell line MLO-Y4 supports osteoclast formation and osteoblast differentiation [16], and surprisingly, mesenchymal stem cell differentiation [17]. It is most likely (but remains to be proven) that primary osteocytes can perform all three functions, therefore possessing the unique capacity to regulate all phases of bone remodeling.

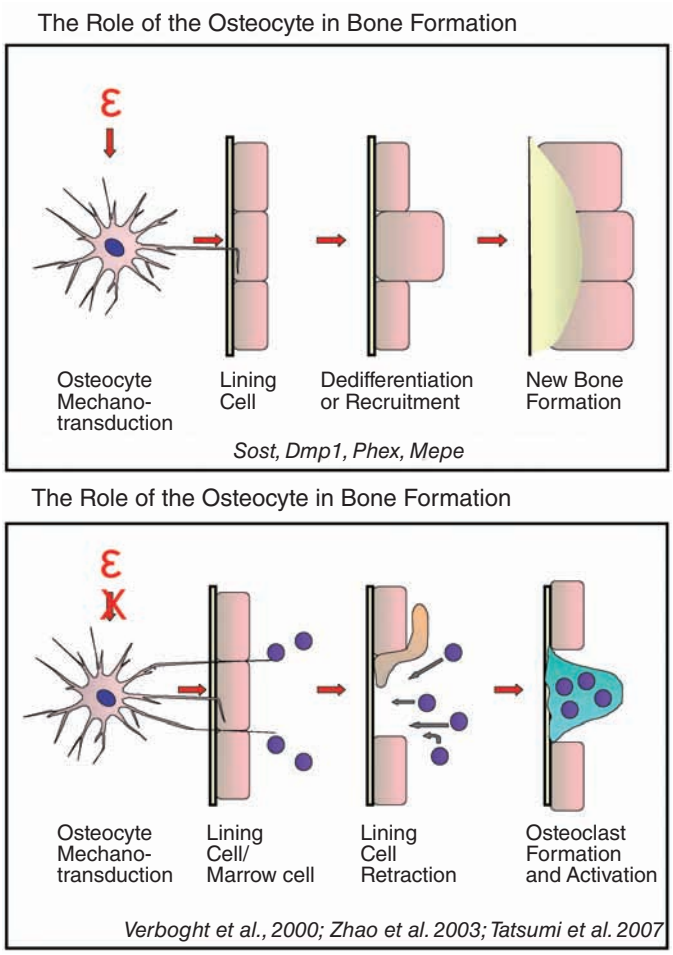

Fig. 4.4. Osteocytes as orchestrators of bone (re)modeling. Osteocytes play a role in bone formation and mineralization as promoters of mineralization through Dmp1 and Phex and inhibitors of mineralization and bone formation, such as Sost/sclerostin and MEPE/OF45, which are highly expressed in osteocytes (top figure). These supporters and inhibitors of bone formation and mineralization are most likely exquisitely balanced to maintain equilibrium in order to maintain bone mass.

Osteocytes also appear to play a major role in the regulation of osteoclasts, by both inhibiting and activating osteoclastic resorption. It has recently been shown that with loading, the osteocytes send signals inhibiting osteoclast activation (bottom figure) (Ref. 15). In contrast, compromised, hypoxic, apoptotic, or dying osteocytes, especially with unloading, appear to send unknown signals to osteoclasts/preosteoclasts on the bone surface to initiate resorption. Therefore, osteocytes within the bone regulate bone formation and mineralization and inhibit osteoclastic resorption, while also having the capacity to send signals of osteoclast activation under specific conditions.

OSTEOCYTE CELL DEATH AND APOPTOSIS

It has been proposed that the purpose and function of osteocytes is to die, thereby releasing signals of resorption. Osteocyte cell death can occur in association with pathological conditions, such as osteoporosis and osteoarthritis, leading to increased skeletal fragility [18]. Such fragility is considered to be due to loss of the ability to sense microdamage and/or to initiate repair. Several conditions have been shown to result in osteocyte cell death, such as oxygen deprivation as occurs during immobilization, withdrawal of estrogen, and glucocorticoid treatment [18]. TNFα and interleukin-1 (IL-1) have been reported to increase with estrogen deficiency and also induce osteocyte apoptosis (for a review, see Ref. 3). Voluntary exercise appears to preserve osteocyte viability and bone strength with ovariectomy [19].

Several agents have been found to reduce or inhibit osteoblast and osteocyte apoptosis. These include estrogen, selective estrogen receptor modulators, bisphosphonates, calcitonin, CD40 ligand, calbindin-D28k, monocyte chemotactic proteins MCP1 and 3, and recently mechanical loading through the release of prostaglandin (for a review, see Ref. 3). Osteocyte viability clearly plays a significant role in the maintenance of bone homeostasis and integrity. However, whereas blocking osteocyte apoptosis may improve diseases such as bone loss due to aging or to glucocorticoid therapy, osteocyte apoptosis may be essential for normal damage repair and skeletal replacement. Any agents that block this process may exacerbate conditions in which repair is required. The death processes, and consequently the resorption signals sent by dying osteocytes in an aging or glucocorticoid treated skeleton may be distinct from those in a normal, healthy skeleton in response to microdamage. It will be important to identify and characterize these differences.

Alternatively, instead of the osteocyte undergoing apoptosis, it can enter a state of self-preservation called autophagy where the cell "eats itself," i.e. "auto-phagy" to maintain viability until a favorable environment returns. Glucocorticoids can induce this state in osteocytes [20], and dose determines whether the osteocyte will undergo apoptosis or autophagy with high or low dose, respectively [21].

OSTEOCYTE MODIFICATION OF THEIR MICROENVIRONMENT

Almost 100 years ago, it was proposed that osteocytes may resorb their lacunar wall under particular conditions [22]. The term "osteolytic osteolysis" was initially used to describe the enlarged lacunae in patients with hyperparathyroidism and later in immobilized rats. "Osteolytic osteolysis" has a negative connotation as it was confused with osteoclastic bone resorption. When resorption "pits" similar to those observed with osteoclasts were not observed with primary avian osteocytes seeded onto dentin slices, it was concluded that osteocytes cannot remove the mineralized matrix. Removal of mineral by osteocytes would not be detectable using this approach as these cells are within a lacuna and do not form the characteristic sealed osteoclast resorption lacuna that rapidly decalcifies bone. In contrast to lacunar

enlargement by the embedded, mature osteocyte, enlarged lacunae in bone from patients with renal osteodystrophy may be due to defective mineralization during embedding of the osteoid-osteocyte during bone formation (for reviews, see Refs. 3, 23–25).

In addition to enlargement of the lacunae, changes can take place in the perilacunar matrix. The term "osteocyte halos" was used to describe perilacunar demineralization in rickets [26] and later to describe periosteocytic lesions in X-linked hypophosphatemic rickets [27]. Glucocorticoids, in addition to having effects on osteocyte apoptosis, also appear to cause osteocytes to not only enlarge their lacunae but also to remove mineral from the perilacunar space, thereby generating "halos" of hypomineralized bone [28]. Glucocorticoid may therefore alter or compromise the metabolism and function of the osteocyte, not just induce cell death.

Over 3 decades ago, it was suggested that the osteocyte not only has matrix-destroying capability but also can form a new matrix [29]. Osteocyte lacunae were shown to uptake tetracycline, called "periosteocytic perilacunar tetracycline labeling," indicating the ability to calcify or form bone. Therefore, the osteocyte may be capable of both adding and removing mineral from its surroundings. The capacity to deposit or remove mineral from lacunae and canaliculi has important implications with regards to (1) mineral homeostasis, (2) magnitude of fluid shear stress applied to the cell, and (3) mechanical properties of bone. The surface area of the osteocyte lacunocanalicular system is several orders of magnitudes greater than the bone surface area; therefore, removal of only a few angstroms of mineral would have significant effects on circulating, systemic ion levels. Enlargement of the lacunae and canaliculi would reduce bone fluid flow shear stress, thereby reducing mechanical loading on the osteocyte. As holes in a material act as stress concentrators, enlargement of lacunae would enhance this effect in bone. Therefore, changes in lacunar size and matrix properties could have dramatic effects on bone properties and quality in addition to osteocyte function.

MECHANOSENSATION AND TRANSDUCTION

Mechanical strain is required for postnatal, but not for prenatal skeletal development and maintenance. The postnatal and adult skeletons are able to continually adapt to mechanical loading by the process of adaptive remodeling, where new bone is added to withstand increased amounts of loading, and bone is removed in response to unloading or disuse. The parameters for inducing bone formation or bone resorption *in vivo* are fairly well known and well characterized. Frequency, intensity, and timing of loading are all important parameters. Bone mass is influenced by peak applied strain [30], and bone formation rate is related to loading rate [31]. When rest periods are inserted, the loaded bone shows increased bone formation rates, compared to bone subjected to a single bout of mechanical loading, and improved bone structure and strength is greatest if loading is applied in shorter vs longer increments [32].

The major challenge in the field of mechanotransduction has been to translate these well-characterized *in vivo* parameters of mechanical loading to *in vitro* cell culture models. Theoretical models and experimental studies suggest that flow of bone fluid is driven by extravascular pressure as well as applied cyclic mechanical loading of osteocytes [33]. Mechanical forces applied to bone cause fluid flow through the canaliculi surrounding the osteocyte inducing shear stress and deformation of the cell membrane. It has also been proposed that mechanical information is relayed by the primary cilium, a flagellar-like structure found on every cell [34, 35]. Osteocytes may use a combination of means to sense mechanical strain [36]. Theoretical modeling predicts osteocyte wall and membrane shear stresses resulting from peak physiologic loads *in vivo* to be in the range of 8 to 30 dynes/cm^3 [33]. Recently *in vivo* experiments have been performed showing an estimated 5 Pa, which is within the 8 to 30 dynes/cm^3 peak shear stress along the osteocyte membrane [37], validating the use of this magnitude of strain *in vitro*.

ROLE OF GAP JUNCTIONS AND HEMICHANNELS IN OSTEOCYTE COMMUNICATION

A means by which osteocytes communicate intracellularly is through gap junctions, transmembrane channels that connect the cytoplasm of two adjacent cells, through which molecules with molecular weights less than 1 kD$_a$ can pass. Gap junction channels are formed by members of a family of proteins known as connexins, and Cx43 is the major connexin in bone cells. Much of mechanotransduction in bone is thought to be mediated through gap junctions.

Primary osteocytes and MLO-Y4 osteocyte-like cells [38] express large amounts of Cx43, suggesting that Cx43 has another function in addition to being a component of gap junctions. Recently, it has been shown that connexins can form and function as unapposed halves of gap junction channels called hemichannels. Hemichannels directly serve as the pathway for the exit of intracellular PGE_2 in osteocytes induced by fluid flow shear stress [39] and function as essential transducers of the anti-apoptotic effects of bisphosphonates [40]. Hemichannels are now one of several types of openings or channels to the extracellular bone fluid that also includes channels such as calcium, ion, voltage, stretch activated channels, and others (for a review, see Ref. 41). Therefore, gap junctions at the connecting tips of dendrites appear to mediate a form of intracellular communication, and hemichannels along the dendrite (and perhaps the cell body) appear to

mediate a form of extracellular communication between osteocytes.

THE POTENTIAL ROLE OF OSTEOCYTES IN BONE DISEASE

Osteoid osteocytes play a role in phosphate homeostasis. Once the osteoblast begins to embed in osteoid, molecules such as Dmp1, Phex, and Mepe are elevated (See Table 4.1). Autosomal recessive hypophosphatemic rickets in patients is due to mutations in *Dmp1* [42]. *Dmp1* null mice have a similar phenotype to Hyp mice carrying a Pex mutation, that of osteomalacia and rickets due to elevated FGF23 levels in osteocytes [42, 43]. The osteocyte lacunocanalicular system should be viewed as an endocrine organ regulating phosphate metabolism. The unraveling of the interactions of these molecules should lead to insight into diseases of hyper and hypophosphatemia (See the chapter on Phex/FGF23).

The connectivity and structure of the osteocyte lacunocanalicular system most likely play a role in bone disease. Osteocyte dendricity may change with static and dynamic bone formation and has been shown to be disrupted in bone disease [44]. In osteoporotic bone there is disorientation of the canaliculi, as well as a marked decrease in connectivity, which increases in severity of disease. In contrast, in osteoarthritic bone, a decrease in connectivity is observed, but orientation is intact. In osteomalacic bone, the osteocytes appear viable with high connectivity, but the processes are distorted and the network chaotic [44]. Variability in complexity and number of dendrites and canaliculi could have a dramatic effect on osteocyte function and viability and on the mechanical properties of bone.

Osteocyte cell death may be responsible for some forms of osteonecrosis. Osteonecrosis is "dead" bone containing empty osteocyte lacunae that does not remodel but can remain in the bone for years. As reviewed above, viable osteocytes are necessary to send signals of (re)modeling. Early proposed mechanisms responsible for osteonecrosis include: the "mechanical theory," where osteoporosis and the accumulation of unhealed trabecular microcracks result in fatigue fractures; the "vascular theory" where ischemia is caused by microscopic fat emboli; and a newer theory, where agents induce osteocyte cell death, which results in dead bone that does not remodel [18]. Osteocyte health, compromised status, and viability and capacity to regulate its own death most likely play a highly significant role in the maintenance and integrity of bone. Bone loss in osteoporosis may be due in part to pathological and not physiological osteocyte cell death [4]. It will be important to develop therapeutics that maintain both osteocyte viability and physiological osteocyte cell death that leads to normal bone repair.

In conclusion, it is most likely that osteocytes utilize undiscovered specific molecules to regulate bone (re) modeling. With the dramatic increases or maintenance of bone mass being observed with neutralizing antibody to sclerostin, an osteocyte selective marker [11], greater effort is being made to identify additional markers and to unravel the mysteries surrounding osteocyte function. It is also likely that new functions will be discovered for these cells, making them a target of investigation, not only to understand basic bone physiology but also to understand and treat bone disease.

INTRODUCTION

Different connective tissues perform different physiological functions. In order to perform these different functions, connective tissue cells secrete distinct sets of extracellular matrix (ECM) proteins that are arranged within the individual connective tissue in discrete patterns. The relative abundance of ECM proteins within a tissue and the histological patterns in which these proteins are organized endow connective tissues with their specific developmental, physiological, and homeostatic properties. For example, in bone, type I collagen is the most abundant ECM protein constituent, and type I collagen fibers are organized in long, thick bundles that are consistent with the mechanical properties required of bone.

The contributions of ECM proteins such as collagens and proteoglycans to the mechanical properties of cartilage and bone are better understood today than the contributions of many of the minor constituents of the ECM. However, recent and emerging knowledge of the function of a fibril-forming ECM protein named "fibrillin" [1] indicates important roles for fibrillin microfibrils in the development, growth, and maintenance of skeletal elements. This chapter summarizes current knowledge about fibrillin microfibrils, their molecular partners in the connective tissue, and their relevance to skeletal biology.

THE FIBRILLINOPATHIES

The importance of fibrillin to the skeleton was first appreciated when a mutation in the gene for fibrillin-1 (*FBN1*) was identified as the cause of Marfan syndrome [2]. Individuals with Marfan syndrome (OMIM #154700) display major disease features in the skeleton: tall stature and arachnodactyly, scoliosis and chest deformities, joint hypermobility and muscle wasting, pes planus, and craniofacial abnormalities, including a highly arched palate. Skeletal features of Marfan syndrome are thought to be largely due to the overgrowth of long bones. Multiple features in other organs (cardiovascular, ocular, skin, lung, and central nervous system) also distinguish Marfan syndrome, reflecting the ubiquitous tissue distribution of fibrillin-1 as well as the importance of fibrillin-1 to the affected tissues.

Mutations in the gene for fibrillin-2 *(FBN2)* cause Beals syndrome or congenital contractural arachnodactyly (CCA) [3]. Features of CCA (OMIM #121050) include contractures of the small and large joints, crumpled ears, and arachnodactyly. The more limited nature of disease features caused by mutations in *FBN2* is thought to reflect the low to null expression levels of *FBN2* mRNA in postnatal tissues and the compensatory high levels of *FBN1* mRNA in postnatal tissues.

Mutations in *FBN1* also cause autosomal dominant Weill-Marchesani syndrome [4, 5]. The skeletal features

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

of Weill-Marchesani syndrome are the opposite of those found in the Marfan syndrome. Individuals with Weill-Marchesani syndrome (OMIM #608328) display short stature, brachydactyly, hypermuscularity, and joint stiffness. While these skeletal features are the opposite of Marfan, ectopia lentis (resulting from a weakness in the suspensory ligament of the lens) is typical of both syndromes. Weill-Marchesani syndrome is one of several others grouped together as the acromelic dysplasias. Mutations in *FBN1* have been recently identified in individuals with geleophysic and acromicric dysplasias, two additional syndromes in the acromelic group [6].

These genetic findings demonstrate the pivotal role of fibrillins in controlling bone growth. In particular, it is now clear that disturbances in the fibrillin-1 structure or function can lead to either tall or short bones. Further study of these genetic disorders will reveal the mechanisms by which fibrillin-1 influences bone growth.

FIBRILLIN MICROFIBRILS

Fibrillin was first identified as the major protein component of small (10 nm) diameter microfibrils that are ubiquitous in the extracellular space [1]. At the ultrastructural level, fibrillin microfibrils can be distinguished from collagen fibers by their uniform small diameter and a characteristic beaded or hollow appearance with no periodic banding pattern. Fibrillin microfibrils are often found as bundles of microfibrils and are always present in elastic fibers.

In developing cartilages, fibrillin microfibrils in the perichondrium ring the cartilage matrix and also extend into the cartilage matrix in a chicken-wire pattern. In aging cartilages, fibrillin microfibrils close to the chondrocyte aggregate laterally to form banded thick fibers that can be distinguished from amianthoid fibers [7]. In demineralized bone, fibrillin microfibrils are found in the cement lines, Haversian canals, osteocyte lacunae, canaliculi, and within fibrous structures containing type III collagen [8].

The protein components of microfibrils include fibrillin-1 [1], fibrillin-2 [9], and fibrillin-3 [10]. Interestingly, the expression levels of *FBN2* and *FBN3* mRNA are highly restricted to fetal development, while fibrillin-1 can be found from the time of gastrulation [11] through postnatal life. Microfibrils can be heteropolymers or homopolymers of fibrillins [12]. Gene knockout experiments in mice suggest that fibrillin-2 function is especially important in the interdigital space, since mice null for fibrillin-2 develop syndactyly [13]. Mice null for fibrillin-1 develop postnatal aortic aneurysms and dissection, indicating that fibrillin-1 function is required in the aorta after the second week of life [14].

The fibrillins and the LTBPs (latent TGFβ binding proteins) form a family of structurally related proteins. Each of the three fibrillins is a modular protein composed of tandemly repeated epidermal growth factor (EGF)-like domains of the calcium-binding type (cbEGF). These stretches of cbEGF domains are interspersed by domains that contain 8 cysteines (8-cys) and "hybrid" domains that appear to be similar to both the 8-cys and the cbEGF domains [15]. In addition, each of the fibrillins is flanked by N-terminal and C-terminal domains, and each contains a special region that is either proline-rich, glycine-rich, or proline- and glycine-rich [10]. While the fibrillins are homologous in primary structure, overall domain structure, and size, LTBPs vary in size and in primary structure but retain an overall similarity in domain organization. LTBPs are composed of the same types of modular domains as the fibrillins. One of the three 8-cys domains present in LTBP-1 was shown to bind covalently to LAP, the latency associated propeptide of TGFβ-1 and to facilitate the secretion of latent TGFβ complexes [16]. Hence, 8-cys domains are also referred to as TB (TGFβ-binding) domains. LTBP-1 was immunolocalized to fibrillin microfibrils in perichondrium and osteoblast cultures [17, 18], and direct binding of the C-terminal regions of LTBP-1 and -4 to fibrillin-1 was demonstrated [19].

Other proteins associated with fibrillin microfibrils include elastin, the fibulins [20, 21], MAGPs [22], perlecan [23], versican [24], decorin [25], and biglycan [26]. These associated proteins establish connective tissue pathways that extend from the fibrillin microfibril networks to basement membranes (through perlecan interactions) and from proteoglycan shells around the microfibrils to hyaluronan and to collagen. These connective tissue pathways integrate fibrillin microfibril networks into the histological patterns of specific organs (cartilage and bone compared with muscle and skin) and into the mechanical and physiological properties of specific organs. In addition, these connective tissue pathways serve to integrate growth factor signaling into the mechanical and physiological functions of specific organs.

REGULATION OF GROWTH FACTORS BY FIBRILLIN MICROFIBRILS

A working model for the extracellular regulation of the large latent TGFβ complex by fibrillin microfibrils was proposed, based on the demonstration that LTBPs interact directly with fibrillin-1 [19]. According to this model, LTBPs target latent TGFβ complexes to the extracellular matrix, where the large LTBP/TGFβ complex is stabilized through C-terminal interactions of LTBPs with fibrillin [19] and N-terminal interactions with other matrix components, possibly fibronectin [16]. Mutant fibrillin-1 (for example, in Marfan syndrome) or absent fibrillin-1 (in fibrillin-1 deficient mice) was expected to destabilize LTBP/TGFβ complexes. This hypothesis was tested in mouse models of deficient and mutant fibrillin-1, and activation of TGFβ signaling was found in the lung [27], mitral valve [28], and aorta [29].

Additional support that activation of TGFβ signaling underlies aortic dissection and aneurysm, the major life-threatening feature of Marfan syndrome, comes from genetic evidence in humans. Mutations in the receptors for TGFβ cause a Marfan-related disorder [30] that has been named Loeys-Dietz syndrome [31, 32]. The major phenotypic features of Loeys-Dietz syndrome (OMIM #609192) include aortic aneurysm and dissection, hypertelorism, bifid uvula and/or cleft palate, arterial tortuosity, and sometimes craniosynostosis and mental retardation. Dolichostenomelia, a feature shared in common with Marfan syndrome, was reported in less than 20% of individuals with Loeys-Dietz [32].

All together, the genetic evidence in humans and mice demonstrates that TGFβ signaling and fibrillin-1 share common pathways, at least in the aorta. However, skeletal features in Loeys-Dietz syndrome are not major, compared with those found in Marfan syndrome, suggesting that additional signaling mechanisms may be modulating skeletal phenotypes in these two genetic disorders. In *Fbn1* mutant mice, analyses of skeletal phenotypes may be precluded by early postnatal death in homozygotes [14, 33, 34]. Skeletal features (mainly kyphosis and overgrowth of the ribs) were noted in heterozygous C1039G *Fbn1* mutant mice [34] and in a hypomorphic *Fbn1* deficient mouse [35], but it has not been reported whether activation of TGFβ signaling is associated with these phenotypes. The tight skin (Tsk) mouse *(Fbn1Tsk)*, which harbors a large in-frame duplication within the *Fbn1* gene [36], demonstrates skin fibrosis as well as excessive long bone growth, but it is unknown whether TGFβ signaling is associated with Tsk skeletal phenotypes.

Another related mechanism that may be involved in the pathogenesis of phenotypic features in Marfan syndrome is the interaction between fibrillin and bone morphogenetic proteins (BMPs). Fibrillin-1 binds to the propeptide of BMP-7, and antibodies specific for BMP-7 propeptide and growth factor can be immunolocalized to fibrillin microfibrils [37]. BMP-7 propeptide and the BMP-7 propeptide/growth factor complex bind to fibrillin microfibrils isolated from tissues [38]. Studies of additional members of the TGFβ superfamily indicate that the propeptides of BMP-2, -4, -5, and -10, and GDF-5 also interact with fibrillin and that these growth factor complexes may utilize this interaction as a mechanism for proper and effective positioning of growth factors in the extracellular space [39]. The specificity of these interactions is supported by the findings that propeptides of TGFβs bind to LTBPs but not to fibrillins [40], that the propeptide of BMP-7 binds to fibrillin but not to LTBP-1 [37], and that the propeptide of myostatin (GDF-8) does not bind to fibrillin [39] but may interact with LTBP-3 [41].

In vivo evidence that fibrillin-2 affects BMP-7 signaling and limb patterning was demonstrated when fibrillin-2 was knocked out in mice [13]. *Fbn2* null mice were born with bilateral syndactyly of the forelimbs and hindlimbs. Complete fusion or close apposition of the cartilage elements of digits 2 and 3 or 2, 3, and 4 were observed, along with fewer apoptotic signals in the interdigital spaces. Expression of BMP-4 and responsiveness to BMP-loaded beads were retained in the *Fbn2* null autopods, demonstrating that loss of fibrillin-2 in the interdigital space was sufficient to dysregulate the BMP signaling required for proper formation of the cartilage elements and regression of interdigital tissue. Furthermore, compound heterozygous mice *(Fbn2+/-; Bmp-7+/-)* were both polydactylous and syndactylous (features of the single nulls, but not of the single heterozygous mice), indicating that both genes are in the same pathway that controls digit formation.

Fibrillin-1 and fibrillin-2 protein localization is non-overlapping in the interdigital space of the developing autopod: Fibrillin-1 is located mostly at the boundaries or edges of the cartilage elements whereas fibrillin-2 forms abundant rays extending through the interdigital space to connect the cartilage elements to the ectoderm [42]. These tissue-specific differences in the fibrillins may explain why BMP signaling is dysregulated in the developing autopod but apparently not in other tissues, where it is presumed that fibrillin-1 compensates for the loss of fibrillin-2.

MOLECULAR MECHANISMS ORCHESTRATED ON A MICROFIBRIL SCAFFOLD

In the TGFβ complex, the propeptides of TGFβs confer latency to the growth factor dimer, and the propeptides are disulfide-linked to LTBPs. Therefore, in order to initiate TGFβ signaling, the TGFβ growth factor dimer must first be released from this large latent complex. BMPs, on the other hand, are not believed to require activation. BMP-9 propeptide/growth factor complex has been shown to be as active as BMP-9 growth factor, using *in vitro* cell-based assays [43]. Similarly, BMP-7 propeptide/growth factor complex is as active as BMP-7 growth factor [44]. In solution, type II BMP receptors can outcompete BMP-7 propeptides for interaction with the BMP-7 growth factor dimer and displace the propeptides from the propeptide/growth factor complex, indicating that unlike TGFβ propeptides BMP-7 propeptide does not block receptor binding and does not confer latency to the growth factor [44].

Although these growth factors are similar in structure, extracellular mechanisms that control signaling are clearly different. Whereas TGFβ requires activation by proteolytic or dissociative mechanisms and also requires cofactors like thrombospondin, endoglin, or betaglycan to facilitate signaling, BMPs can activate signaling simply by binding to its receptors, and instead of activators, BMPs require inhibitors like noggin (and several others) to control the amount of extracellular presentation. The role of the matrix as a physical scaffold important in regulating extracellular signaling is only now becoming

appreciated. However, the mechanisms involved in matrix regulation of extracellular signaling are largely unknown.

Direct interactions of fibrillins with BMPs and LTBPs with TGFβs have been documented. Nevertheless, it is not clearly understood whether interactions between these proteins, and with the microfibril scaffold composed by these proteins, sequester and store growth factors in the connective tissue or target and concentrate growth factors for immediate use. It is not known how other interactions (e.g., fibrillin/fibulin interactions) mediated by the microfibril scaffold affect these matrix/growth factor interactions. However, since both TGFβ and BMP signals are associated with the same microfibril scaffold, it may be predicted that the matrix scaffold physically integrates these disparate, and sometimes opposing, signals. Since perlecan binds to fibrillin [23], it is also possible that the microfibril scaffold helps to integrate FGF signals with BMP and TGFβ signals. The roles of heparan sulfate proteoglycans in the regulation of fibroblast growth factor (FGF) signaling and skeletal biology have been extensively reviewed [45, 46].

Knockouts of the genes encoding LTBP-2, LTBP-3, and LTBP-1L, and an LTBP-4 hypomorphic mouse have been described. Only *Ltbp3* null mice demonstrated skeletal phenotypes (craniofacial abnormalities, kyphosis, osteosclerosis of the long bones and vertebrae, and osteopetrosis). Many of the phenotypes found in these mutant mice were reported to be consistent with loss of TGFβ activity, indicating that LTBPs are required in specific tissues for appropriate TGFβ function. However, none of these mouse models phenocopies *Tgfb1*-null mice, suggesting functional redundancies among the four LTBPs and/or additional tissue-specific functions of the individual LTBPs [16].

An interesting study of LTBP-4 deficient lung fibroblasts revealed that BMP-4 signaling is enhanced and that expression of gremlin, an inhibitor of BMP signaling, was decreased [47]. These findings, which were confirmed in lung tissue, were within the context of loss of LTBP-4 and consequent impaired activation of TGFβ. This study directs attention to the unknown mechanisms by which BMP and TGFβ signals may be integrated across the microfibril scaffold.

Many genes that encode other proteins that interact with fibrillin microfibrils have also been knocked out in mice. Mice null for each of the five fibulin genes have been reported. Skeletal phenotypes have not been reported. However, disturbed TGFβ signaling was found associated with aneurysm formation in a fibulin-4 hypomorphic mouse [48]. In humans, mutations in *FBN4* can result in skeletal features (arachnodactyly) as well as aneurysm and cutis laxa [49], suggesting that defects in fibulin function may perturb pathways common to fibrillin microfibrils.

Biochemical results have also identified proteoglycans as potential interactors on the microfibril scaffold. Versican [24], perlecan [23], and decorin [25] bind to fibrillin, and biglycan binds to elastic fiber components [26]. Perlecan null *(Hspg2-/-)* mice have defective cartilage formation, possibly due to both structural effects and dysregulated FGF signaling, and die in the perinatal period [50]. Decorin binds to the TGFβ growth factor [51], and biglycan modulates BMP-4 signaling to osteoblasts [52]. More investigation is required in order to understand how these associated proteoglycans may cooperate with the microfibrillar scaffold in the extracellular regulation of growth factor signaling.

SUMMARY

Human genetic disorders have pointed to important functional roles of fibrillins in skeletal biology. Fibrillin-1 controls long bone growth, and mutations in *FBN1* can lead either to tall stature and arachnodactyly (in Marfan syndrome) or to short stature and brachydactyly (in Weill-Marchesani syndrome). Fibrillins also control joint function, since mutations in *FBN1* or *FBN2* can result in either joint hypermobility, joint contractures, or stiff joints. Recent advances have demonstrated that mutations in fibrillin genes result in dysregulated TGFβ and BMP signaling, and have led to the concept that the microfibrillar scaffold, together with its extended partners in specific connective tissue pathways, regulate TGFβ and BMP signaling.

According to this concept of extracellular regulation by the microfibrillar scaffold, growth factor signaling is "fine-tuned" [42], and resulting perturbations in signaling can lead to a broad range of pathologies. These pathologies may bear only limited resemblance to phenotypes that result from the complete loss of function mouse models of growth factor signaling. More sophisticated mouse models are required in order to dissect the mechanisms by which the microfibril scaffold regulates growth factor signaling and by which human pathologies are produced.

A model for the extracellular regulation of TGFβ and BMP signals is depicted in Fig. 5.1(A). Cells secrete the large latent TGFβ complex and BMP complexes. Through interactions with LTBPs, which target the latent TGFβ complex to the matrix, and with the propeptides of BMP complexes, fibrillins position and concentrate growth factor signals. Cells may activate or inhibit growth factor signals as they come into contact with the microfibril scaffold. These choices may be regulated by positional information contained in the microfibrils themselves or in associated proteins, some of which are shown in Fig. 5.1(B). In addition, the associated proteins may themselves regulate growth factor signaling by competitive mechanisms (for example, LTBPs and fibulins may compete for the same binding site on fibrillin) or by differential or sequential interactions with the growth factors themselves. In this manner, the microfibril scaffold may work as a well-oiled machine [53] to regulate growth factor signaling.

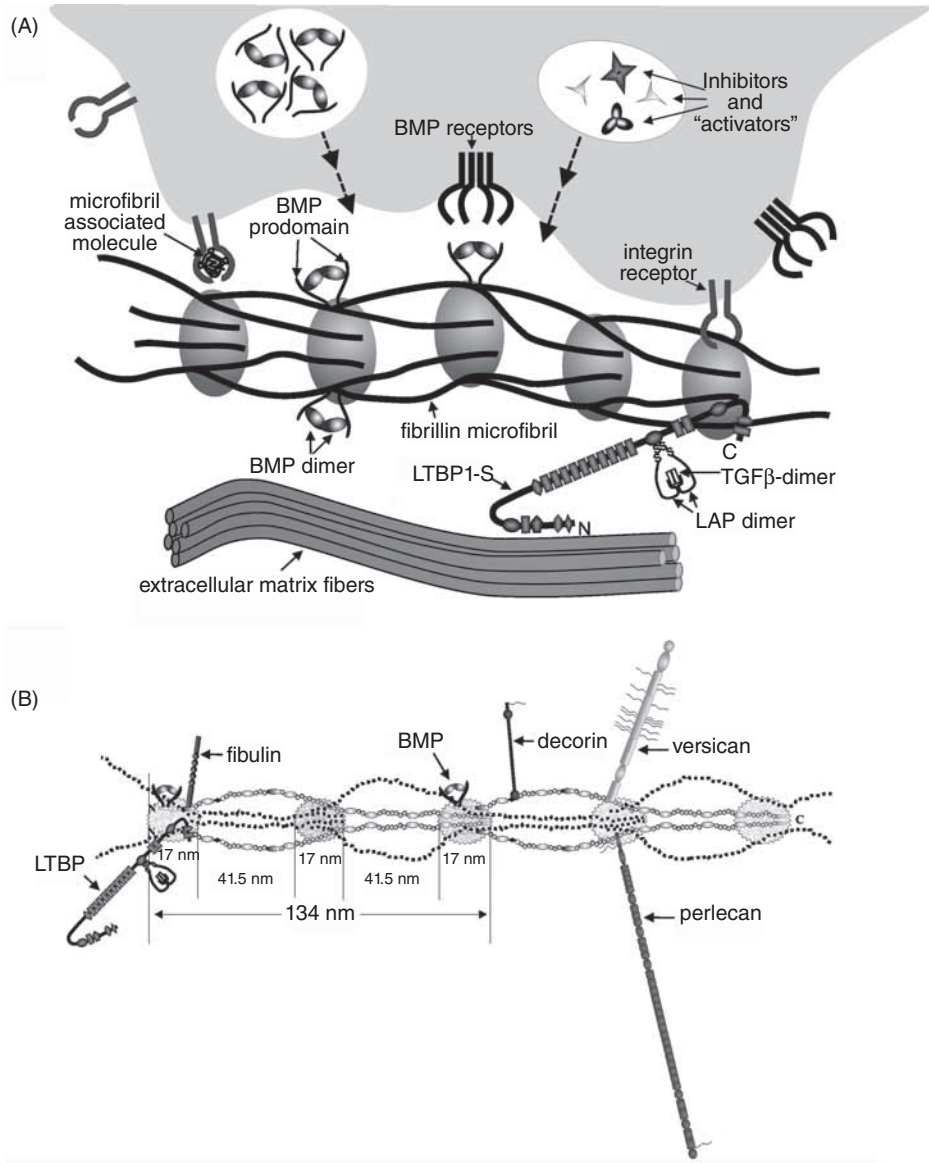

Fig. 5.1. Microfibril regulation of TGFβ and BMP signals.

ABBREVIATIONS

8-cys:	8-cysteine domain
BMP:	bone morphogenetic protein
cbEGF:	calcium-binding epidermal growth factor like
CCA:	congenital contractural arachnodactyly
ECM:	extracellular matrix
FBN:	fibrillin gene
GDF:	growth and differentiation factor
LTBP:	latent TGFβ binding protein
MAGP:	microfibril associated glycoprotein
TGF:	transforming growth factor
Tsk:	tight skin

INTRODUCTION

Bone comprises the largest proportion of the body's connective tissue mass. Unlike most other connective tissue matrices, bone matrix is physiologically mineralized and is unique in that it is constantly regenerated throughout life as a consequence of bone turnover. Bone as an organ is made up of the cartilaginous joints, the calcified cartilage in the growth plate (in developing individuals), the marrow space, and the cortical and cancellous mineralized structures. Bone as a tissue consists of the mineralized and nonmineralized (osteoid) components of the cortical and cancellous regions of long and flat bones. There are three cell types on (and in) bone tissue: (1) the bone-forming osteoblasts, which when engulfed in mineral become (2) osteocytes, and (3) the bone-destroying osteoclasts. Each of these cells communicates with one another by either direct cell contact or through signaling molecules, and they respond to each other. The detailed properties of these cells have been discussed in numerous publications; see for example the excellent chapter by Lian and Stein [1]. This chapter focuses on the extracellular matrix, which is synthesized primarily by osteoblasts but also contains proteins adsorbed from the circulation. The preponderance of bone is extracellular matrix (ECM). Information on the gene and protein structure and potential function of bone ECM constituents has exploded during the past two decades. This information has been described in great detail in several recent reviews [2,3], to which the reader is referred for specific references; these are too numerous to be listed adequately here. Below is a summary of the composition of bone and the salient features of the classes of bone matrix proteins. The tables list specific details for the individual ECM components.

THE COMPOSITE

Bone is a composite material whose extracellular matrix consists of mineral, collagen, water, noncollagenous proteins, and lipids in decreasing proportion (depending on age, species, and site). These components have both mechanical and metabolic functions. Understanding of some of the biological functions of these components has come from mouse models and analyses of healthy and diseased human tissues, and from cell culture studies.

The mineral

The mineral phase of bone is a nanocrystalline, highly substituted analog of the naturally occurring mineral, hydroxylapatite [$Ca_{10}(PO_4)_6(OH)_2$]. The major substitutions are with carbonate, magnesium, and acid phosphate, along with other trace elements, the content of which depends on diet and environment. Although the precise chemical nature of the initial mineral formed has

Table 6.1. Characteristics of Collagen-Related Genes and Proteins Found in Bone Matrix

Protein/Gene	Function	Disease/Animal Model/Phenotype
Type I—17q21.23, 7q21.3-22 [$\alpha1(I)_2\alpha2(I)$] [$\alpha1(I)_3$]	Serves as scaffolding, binds and orients other proteins that nucleate hydroxyapatite deposition	Human mutations: Osteogenesis imperfecta (OMIM 166210; 166200; 610854; 259420; 166220) Mouse models: oim mouse; mov 14 mouse; brittle mouse, mechanically weak, mineral crystals small, some mineral outside collagen
Type X—6q21-22.3 [$\alpha1(X)_3$]	Present in hypertrophic cartilage of the growth plate but does not appear to regulate matrix mineralization	Human mutations: Schmid metaphyseal chondrodysplasia (OMIM 120110); knockout mouse: no apparent skeletal phenotype, may have hematopoietic phenotype
Type III—2q24.3-31 [$\alpha1(III)]_3$	Present in bone in trace amounts, may regulate collagen fibril diameter, paucity in bone may explain the large diameter size of bone collagen fibrils	Human mutations in type III: different forms of Ehlers-Danlos syndrome (OMIM 130050)
Type V—9q34.2-34.3;2q24.3-31, 9q34.2-34.3 [$\alpha1(V)_2\alpha2(V)$] [$\alpha1(V)$ $\alpha2(V)$ $\alpha3(V)$]	Present in bone in trace amounts, may regulate collagen fibril diameter, paucity in bone may explain the large diameter size of bone collagen fibrils	Mutations in type V $\alpha1$ and $\alpha2$ (OMIM 120215; 120190) Mouse model: disrupted fibril arrangement

been debated [4, 5], it is well accepted that the majority of the "biomineral" present in the bones during development is apatitic. The physical and chemical properties of this mineral have been determined by a variety of techniques including chemical analyses, X-ray diffraction, vibrational spectroscopy, energy dispersive electron analysis, nuclear magnetic resonance, small angle scattering, and transmission and atomic force microscopy [6].

The functions of the mineral are to strengthen the collagen composite, providing more mechanical resistance to the tissue, and also to serve as a source of calcium, phosphate, and magnesium ions for mineral homeostasis. For physicochemical reasons, usually it is the smallest mineral crystals that are lost during remodeling; thus, in osteoporosis, it is not surprising that the larger more perfect crystals persist within the matrix [7] contributing to the brittle nature of osteoporotic bone. When remodeling is impaired, as in osteopetrosis, the mineral crystals remain small relative to age-matched controls [7].

Collagen

The basic building block of the bone matrix fiber network is type I collagen, which is a triple-helical molecule containing two identical αl(I) chains and a structurally similar, but genetically different α2(I) chain [8]. Collagen α chains are characterized by a Gly-X-Y repeating triplet (where X is usually proline, and Y is often hydroxyproline) and by several post-translational modifications including: (1) hydroxylation of certain lysyl or prolyl residues; (2) glycosylation of the hydroxylysine with glucose or galactose residues, or both; (3) addition of mannose at the propeptide termini; and (4) formation of intra- and intermolecular covalent cross-links that differ from those found in soft connective tissues. Measurement of these bone-derived collagen cross-links in urine has proven to be good measures of bone resorption [9]. Bone matrix proper consists predominantly of type I collagen; however, trace amounts of type III, V, and fibril-associated collagens (Table 6.1) may be present during certain stages of bone formation and may regulate collagen fibril diameter.

NONCOLLAGENOUS PROTEINS

Noncollagenous proteins (NCPs) comprise 10–15% of the total bone protein content. NCPs are multifunctional, having roles in organizing the extracellular matrix, coordinating cell-matrix and mineral-matrix interactions, and regulating the mineralization process. Knowledge of these functions have come from studies of the isolated proteins in solution, from analyses of mice in which the proteins are ablated (knocked out), or overexpressed, characterization of human diseases in which these proteins have mutations, and studies using appropriate cell cultures. The tables summarize the gene and protein structures, and the functions of these proteins are associated with each discussion of the protein families.

Serum-derived proteins

Approximately one-fourth of the total NCP content is exogenously derived (Table 6.2). This fraction is largely composed of serum-derived proteins, such as albumin

Table 6.2. Gene and Protein Characteristics of Serum Proteins found in Bone Matrix

Protein/Gene	Function	Disease/Animal Model/ Phenotype
Albumin—2q11-13 69 kd, non-glycosylated, one sulfhydryl, 17 disulfide bonds, high affinity hydrophobic binding pocket	Inhibits hydroxyapatite crystal growth	
α2HS glycoprotein—3q27-29 Precursor protein of fetuin, cleaved to form A and B chains that are disulfide linked, Ala-Ala and Pro-Pro repeat sequences, N-linked oligosaccharides, cystatin-like domains	Promotes endocytosis, has opsonic properties, chemoattractant for monocytic cells, bovine analog (fetuin) is a growth factor; inhibits calcification	Knockout mouse: adult ectopic calcification

and α_2-HS-glycoprotein, which are acidic in character and bind to bone matrix because of their affinity for hydroxyapatite. Although these proteins are not endogenously synthesized, they may exert effects on matrix mineralization and bone cell proliferation. For example, α_2-HS-glycoprotein, the human analog of fetuin, when ablated in mice causes ectopic calcification [10] suggesting that the protein is a mineralization inhibitor. The remainder of the exogenous fraction is composed of growth factors and a large variety of other molecules present in trace amounts, which influence local bone cell activity [1, 2].

On a mole-to-mole basis, bone-forming cells synthesize and secrete as many molecules of NCPs as of collagen. These molecules can be classified into four general (and sometimes overlapping) groups: (1) proteoglycans, (2) glycosylated proteins, (3) glycosylated proteins with potential cell attachment activities, and (4) γ-carboxylated (gla) proteins. The physiological roles for individual bone protein constituents are not well defined; however, they may participate not only in regulating the deposition of mineral but also in the control of osteoblastic and osteoclastic metabolism.

Proteoglycans

Proteoglycans are macromolecules that contain acidic polysaccharide side chains (glycosaminoglycans) attached to a central core protein, and bone matrix contains several members of this family [11] (Table 6.3).

During the initial stages of bone formation, the large chondroitin sulfate proteoglycan, versican, and the glycosaminoglycan, hyaluronan (which is not attached to a protein core), are highly expressed and may delineate areas that will become bone. With continued osteogenesis, versican is replaced by two small chondroitin sulfate proteoglycans—decorin and biglycan—composed of tandem repeats of a leucine-rich repeat (LRR) sequence. Decorin has been implicated in the regulation of collagen fibrillogenesis and is distributed predominantly in the ECM space of connective tissues and in bone, whereas biglycan tends to be found in pericellular locales. A heparan sulfate proteoglycan, perlecan is involved in limb patterning and is found surrounding chondrocytes in the growth plate, whereas the glypican family of cell surface associated heparan sulfate proteoglycans also affect skeletal growth. In addition, there are other small leucine-rich proteoglycans (SLRPs) in bone, including osteoglycin (mimecan), keratocan [12], osteoadherin, lumican, asporin, and fibromodulin [13]. Although their exact physiological functions are not known, these proteoglycans are assumed to be important for the integrity of most connective tissue matrices. Deletion of the *biglycan* gene, for example, leads to a significant decrease in the development of trabecular bone, indicating that it is a positive regulator of bone formation [2]. Deletion of the *epiphican* gene, or the *epiphican* and *biglycan* genes together causes shortening of the femur during growth, and early onset osteoarthritis [14]. Other functions might arise from the ability of these proteoglycans to bind and modulate the activity of the growth factors in the extracellular space, thereby influencing cell proliferation and differentiation [1].

Glycosylated proteins

Glycosylated proteins with diverse functions abound in bone. One of the hallmarks of bone formation is the synthesis of high levels of alkaline phosphatase (Table 6.4).

Alkaline phosphatase, a glycoprotein enzyme, is primarily bound to the cell surface through a phosphoinositol linkage, but is cleaved from the cell surface and found within a mineralized matrix. The function of alkaline phosphatase in bone cell biology has been the subject of much speculation and remains undefined. Mice lacking tissue nonspecific alkaline phosphatase have impaired mineralization, suggesting the importance of this enzyme for mineral deposition [15].

Table 6.3. Gene and Protein Characteristics: Glycosaminoglycan-Containing Molecules in Bone

Protein/Gene	Function	Disease/Animal Model/Phenotype
Aggrecan—15q26.1 ~2.5 × 10^6 kd intact protein, ~180–370,000 core, ~100 CS chains of 25 kd, and some KS chains of similar size, G1, G2, and G3 globular domains with hyaluronan binding sites, EGF and CRP-like sequences	Matrix organization, retention of water and ions, resilience to mechanical forces	Human mutation: Spondyloepiphyseal dysplasia (OMIM 155760; 608361) Mouse models: brachymorphic mouse, accelerated growth plate calcification; cartilage matrix deficiency mouse-shortened stature Nanomelic chick (mutation)—abnormal bone shape
Versican (PG-100)—5q12-14 ~1 × 10^6 kd intact protein, ~360 kd core, ~12 CS chains of 45 kd, G1 and G3 globular domains with hyaluronan binding sites, EGF and CRP-like sequences	Regulates chondrogenesis; may "capture" space that is destined to become bone	Human mutation: Wagner syndrome (an ocular disorder) (OMIM 143200)
Decorin (Class 1 SLRP)—12q13.2 ~130 kd intact protein, ~38-45 kd core with 10 leucine rich repeat sequences, 1 CS chain of 40 kd	Binds to collagen and may regulate fibril diameter, binds to TGF-β and may modulate activity, inhibits cell attachment to fibronectin	Knockout mouse: no apparent skeletal phenotype although collagen fibrils are abnormal, DCN/BGN double knockout—progeroid form of Ehler's–Danlos syndrome
Biglycan (Class 1 SLRP)—Xq27 ~270 kd intact protein, ~38-45 kd core protein with 12 leucine rich repeat sequences, 2 CS chains of 40 kd	Binds to collagen, TGF-β, and other growth factors; pericellular environment, a genetic determinant of peak bone mass	Knockout mouse: osteopenia; thin bones, decreased mineral content, increased crystal size; short stature
Asporin (Class 1 SLRP)—9q21.3 67 kd, most likely no GAG chains	Regulates collagen structure	Human polymorphism associated with osteoarthritis (OMIM 608135)
Fibromodulin (Class 2 SLRP)—1q32 59 kd intact protein, 42 kd core protein, one N-linked KS chain	Binds to collagen, may regulate fibril formation, binds to TGF-β	Fibromodulin/biglycan double knockout mice: joint laxity and formation of supernumery sesmoid bones
Osteoadherin (Class 2 SLRP) 85 kd intact protein, 47 kd core protein, RGD sequence	May mediate cell attachment	
Lumican (Class 2 SLRP)—12q21.3-q22 70-80 kd intact protein, 37 kd core protein	Binds to collagen, may regulate fibril formation	Lumican/fibromodulin double knockout mouse: has ectopic calcification and a variant of Ehler's—Danlos syndrome (OMIM 130000)
Perlecan- 1p36.1 Five domain heparan sulfate proteoglycan, core protein 400 kd	Interacts with matrix components to regulate cell signaling; cephalic development	Transgenic mice with mutated perlecan: Schwartz-Jampel syndrome (OMIM 142461): impaired mineralization and mis-shapen skeletons and joint abnormalities Knockout mice: phenotype resembling thanatophoric dysplasia (TD) type I
Glypican-3 –Xq26 Lipid-linked heparan sulfate proteoglycan, 65 kd core protein, 14 conserved cysteine residues	Regulates BMP-SMAD signaling Regulates cell development	Human mutation: Simpson-Golabi-Behmel Syndrome (OMIM 300037) Knockout mouse: delayed endochondral ossification and impaired osteoclast development
Keratocan (Class 2 SLRP)—12q22 60–200 kDa intact protein, 52 kDa core protein with 6–10 LRRs, multiple keratan sulfate side chains	Regulates osteoblast differentiation	Knockout cells show delayed mineralization
Osteoglycin/Mimecan (Class 3 SLRP)—9q22 299 aa precursor, 105 aa mature protein, no GAG in bone, keratan sulfate in other tissues	Binds to TGF-β Regulates collagen fibrillogenesis	
Hyaluronan—Multi-gene complex Multiple proteins associated outside of the cell, structure unknown	May work with versican molecule to capture space destined to become bone	

Table 6.4. Gene and Protein Characteristics of Glycoproteins in Bone Matrix

Protein/Gene	Function	Disease/Animal Models/Phenotype
Alkaline Phosphatase (bone-liver-kidney isozyme)—1p34-36.1 Two identical subunits of ~80 kd, disulfide bonded, tissue specific post translational modifications	Potential Ca^{++} carrier, hydrolyzes inhibitors of mineral deposition such as pyrophosphates, increases local phosphate concentration	Human mutations: hypophosphatasia (OMIM 171760) (decreased activity) TNAP knockout mouse: growth impaired; decreased mineralization
Osteonectin—5q31.3-q32 ~35–45 kd, intramolecular disulfide bonds, α helical amino terminus with multiple low affinity Ca^{++} binding sites, two EF hand high affinity Ca^{++} sites, ovomucoid homology, glycosylated, phosphorylated, tissue specific modifications	Regulates collagen organization, may mediate deposition of hydroxyapatite, binds to growth factors, may influence cell cycle, positive regulator of bone formation	Knockout mouse: severe osteopenia, decreased trabecular connectivity; decreased mineral content; increased crystal size
Periostin—13q13.3 90 kd disulfide linked protein, homology to BIGH3, promotes cell attachment	Regulates collagen organization and response to mechanical signals	Knockout mouse: periodontal and vascular calcification
Tetranectin—3p22-p21.3 21 kd protein composed of four identical subunits of 5.8 kd, sequence homologies with asialoprotein receptor and G3 domain of aggrecan	Binds to plasminogen, may regulate matrix mineralization	Knockout mouse: no long bone phenotype, spinal deformity, increased mineralization in implant model
Tenascin-C—9q33 Hexameric structure, six identical chains of 320 kd, Cys rich, EGF-like repeats, FN type III repeats	Interferes with cell-FN interactions	Knockout mouse: no overt bone phenotype
Tenascin-X—6p21.3 Hexameric with 5 N-linked glycosylation sites and multiple EFG and 40 fibronectin type III repeats	Regulates cell-matrix interactions	Human mutation: Ehlers-Danlos II phenotype (OMIM 600985)
Secreted phosphoprotein 24—2q37 24 kd secreted phosphoprotein, shares sequence homology with members of the cystatin family of thiol protease inhibitors	Associates with regulators of mineralization in serum, regulates BMP mediated bone turnover	

The most abundant NCP produced by bone cells is osteonectin, a phosphorylated glycoprotein accounting for approximately 2% of the total protein of developing bone in most animal species. Osteonectin is transiently produced in non-bone tissues that are rapidly proliferating, remodeling, or undergoing profound changes in tissue architecture, and is also found constitutively expressed in certain types of epithelial cells, cells associated with the skeleton, and in platelets. Osteonectin, along with thrombospondin-2 (TSP-2) and periostin are members of the class of "matricellular proteins," each of which has a role in bone cell proliferation and differentiation, with some role in regulating mineralization [16]. Tetranectin (which is important for wound healing) [2], tenascin (which regulates the organization of the extracellular matrix) [17], and secreted phosphoprotein 24 (which regulates bone morphogenetic protein expression) along with periostin [18] are other glycoproteins found in the bone matrix.

Small integrin-binding ligand, N-glycosylated protein, and other glycoproteins with cell attachment activity

All connective tissue cells interact with their extracellular environment in response to stimuli that direct or coordinate (or both) specific cell functions, such as migration, proliferation, and differentiation (Tables 6.5 and 6.6). These particular interactions involve cell attachment through transient or stable focal adhesions to extracellular macromolecules, which are mediated by cell surface receptors that subsequently transduce intracellular signals. Bone cells synthesize at least 12 proteins that may mediate cell attachment: members of the small integrin-binding ligand, N-glycosylated protein (SIBLING) family (osteopontin, bone sialoprotein, dentin matrix protein-1, dentin sialophosphoprotein, and matrix extracellular phosphoprotein), type 1 collagen, fibronectin,

Table 6.5. Gene and Protein Characteristics of SIBLINGs (Small Integrin-Binding Ligands, N-Glycosylated Proteins)

Protein/Gene	Function	Disease/Animal Models/Phenotype
Osteopontin—4q21 ~44-75 kd, polyaspartyl stretches, no disulfide bonds, glycosylated, phosphorylated, RGD located 2/3 from the N-terminal	Binds to cells and collagen, may regulate mineralization, may regulate cell proliferation, inhibits nitric oxide synthase, may regulate resistance to viral infection	Knockout mouse: decreased crystal size; increased mineral content; not subject to osteoclastic remodeling
Bone Sialoprotein—4q21 ~46–75 kd, polyglutamyl stretches, no disulfide bonds, 50% carbohydrate, tyrosine-sulfated, RGD near the C-terminus	Binds to cells, may regulate bone remodeling, may initiate mineralization	Knockout mouse: impaired osteoblast and osteoclast function
DMP-1—4q21 513 amino acids predicted; serine-rich, acidic, RGD 2/3 from N-terminus	Regulator of biomineralization; regulates osteocyte function	Human mutation: dentinogenesis imperfecta and hypophosphatemia (OMIM 600980) Knockout mouse: undermineralized with craniofacial and growth plate abnormalities and defective osteocyte function
Dentin sialophosphoprotein—4q21.3 Gene produces three proteins: dentin sialoprotein, dentin phosphophoryn, and dentin glycoprotein. All have RGD sites; dentin phosphophoryn is highly phosphorylated	Regulation of biomineralization	Human mutations: dentinal dysplasias and dentinogenesis imperfecta; no bone disease (OMIM 125485) Knockout mouse: has thinner bones at 9 months, no significant other bone phenotype, and severe dentin abnormalities
MEPE—4q21.1 525 amino acids, 2 N-glycosylation motifs, a glycosaminoglycan-attachment site, an RGD cell-attachment motif, and phosphorylation motifs	Regulation of biomineralization; regulation of PHEX (phosphaturic hormone) activity	Humans: association with oncogenic osteomalacia Knockout mouse: increased bone mass and resistance to ovariectomy-induced bone loss
Other Siblings: Enamelin—4q21	Regulates enamel mineralization	Human mutations: amelogenesis imperfecta (OMIM 104500, 204650)

Table 6.6. Gene and Protein Characteristics of Other RGD-Containing Glycoproteins

Protein/Gene	Function	Disease/Animal Models
Thrombospondins (1-4, COMP)—15Q-1, 6q27, 1q21-24, 5q13, 19p13.1 ~450 kd molecules, three identical disulfide linked subunits of ~150–180 kd, homologies to fibrinogen, properdin, EGF, collagen, von Willebrand, *P. falciparum* and calmodulin, RGD at the C terminal globular domain	Cell attachment (but usually not spreading), binds to heparin, platelets, types I and V collagens, thrombin, fibrinogen, laminin, plasminogen and plasminogen activator inhibitor, histidine rich glycoprotein	Human mutation in COMP: pseudoachondroplasia (OMIM 600310) TSP-2 knockout mouse: large collagen fibrils, thickened bones; spinal deformities
Fibronectin—2q34 ~400 kd with 2 nonidentical subunits of ~200 kd, composed of type I, II, and III repeats, RGD in the 11th type III repeat 2/3 from N-terminus	Binds to cells, fibrin, heparin, gelatin, collagen	Knockout mouse: lethal prior to skeletal development
Vitronectin—17q11 ~70 kd, RGD close to N-terminus, homology to somatomedin B, rich in cysteines, sulfated, phosphorylated	Cell attachment protein, binds to collagen, plasminogen and plasminogen activator inhibitor, and to heparin	
Fibrillin 1 and 2—15q21.1, 5q23-q31 350 kd, EGF-like domains, RGD, cysteine motifs	May regulate elastic fiber formation	Human fibrillin 1 mutations: Marfan's syndrome (OMIM 134797) Human fibrillin 2 mutations: congenital contractural arachnodactyly (OMIM 121050)—.

thrombospondin(s) (predominantly TSP-2 with lower levels of TSP1, 3, and 4, and COMP), vitronectin, fibrillin, BAG-75, and osteoadherin (which is also a proteoglycan). Many of these proteins are phosphorylated and/or sulfated, and all contain RGD (Arg-Gly-Asn), the cell attachment consensus sequence that binds to the integrin class of cell surface molecules. However, in some cases, cell attachment seems to be independent of RGD, indicating the presence of other sequences or mechanisms of cell attachment [2]. Thrombospondin(s), fibronectin, vitronectin, fibrillin, and osteopontin are expressed in many tissues. Whereas certain types of epithelial cells synthesize bone sialoprotein, it is highly enriched in bone and is expressed by hypertrophic chondrocytes, osteoblasts, osteocytes, and osteoclasts. In bone, the expression of bone sialoprotein correlates with the appearance of mineral [19]. The bone sialoprotein knockout (KO) has impaired osteoblast and osteoclast function, although the precise mechanism of action of bone sialoprotein is not known [20]. In solution, bone sialoprotein can function as an hydroxyapatite nucleator [2], it is found in association with bone acidic glycoprotein-75 in mineralization foci [21], and it is upregulated during mineralization in culture [22].

Both osteopontin and bone sialoprotein are known to anchor osteoclasts to bone, and in addition to supporting cell attachment, they bind Ca^{2+} with extremely high affinity through polyacidic amino acid sequences. Each SIBLING protein regulates hydroxyapatite formation in solution, and their KOs have phenotypes that can be correlated with these *in vitro* functions [2]. It is not immediately clear why there are such a plethora of RGD-containing proteins in bone; however, the pattern of expression varies from one RGD protein to another, as does the pattern of the different integrins that bind to these proteins. This variability indicates that cell-matrix interactions change as a function of maturational stage, suggesting that they also may play a role in osteoblastic maturation [2]. Their post-translational modifications also vary, suggesting that these modifications may also determine their *in situ* functions [17, 23, 24].

Gla-containing proteins

Four bone-matrix NCPs, matrix gla protein (MGP), osteocalcin [bone gla protein (BGP)], and periostin (also a bone matrix glycoprotein), all of which are made endogenously, and protein S (made primarily in the liver but also made by osteogenic cells) are post-translationally modified by the action of vitamin K-dependent γ-carboxylases (Table 6.7) [2]. The dicarboxylic glutamyl (gla) residues enhance calcium binding. MGP is found in many connective tissues, whereas osteocalcin is more bone specific [2] and periostin is made in all connective tissues that respond to load [25]. The physiological roles of these proteins are still under investigation; MGP,osteocalcin and periostin may function in the control of mineral deposition and remodeling. MGP-deficient mice develop calcification in extraskeletal sites such as the aorta [26], implying that it is an inhibitor of mineralization. Expression of MGP in blood vessels prevents calcification, whereas expression in osteoblasts prevents mineralization [27]. Osteocalcin seems to be involved in regulating bone turnover. Osteocalcin-deficient mice are reported to have increased BMD compared with normal [28] but with age, the mineral properties did not show the changes that occurred in age-matched controls [29], which suggests a role for osteocalcin in osteoclast recruitment. In human bone, osteocalcin is concentrated in osteocytes, and its release may be a signal in the bone turnover cascade. Osteocalcin measurements in serum have proved valuable as a marker of bone turnover in metabolic disease states [9]. In contrast, uncarboxylated osteocalcin was reported to be a hormone involved in the regulation of energy and glucose metabolism in mice [30] but was not found to have this

Table 6.7. Gene and Protein Characteristics of Gamma-Carboxy Glutamic Acid-Containing Proteins in Bone Matrix

Protein/Gene	Function	Disease/Animal Model/Phenotype
Matrix Gla Protein—12p13.1 ~15 kd, five gla residues, one disulfide bridge, phosphoserine residues	May function in cartilage metabolism, a negative regulator of mineralization	Human mutations: Keutel syndrome (OMIM 245150), excessive cartilage calcification Knockout mouse: excessive cartilage calcification
Osteocalcin—1q25-31 ~5 kd, one disulfide bridge, gla residues located in α helical region	May regulate activity of osteoclasts and their precursors, may mark the turning point between bone formation and resorption, suggested to be a hormone	Knockout mouse: osteopetrotic, thickened bones, decreased crystal size, increased mineral content
Periostin—13q13.3	Regulates response to load	Knockout mouse: vascular calcification and periodontal calcification
Protein S—3p11-q11.2 ~72 kd	Primarily a liver product, but may be made by osteogenic cells	Human mutations: protein deficiency with osteopenia (OMIM 076080)

Table 6.8. Effects of Bone Matrix Molecules on Mineralization *In Vitro*

Promote or Support Apatite Formation	Inhibit Mineralization	Dual Function (Nucleate and Inhibit)	No Effect	Data not available
Type I collagen	Aggrecan	Biglycan	Decorin	Thrombospondin
Proteolipid (matrix vesicle nucleational core)	α2-HS glycoprotein	Osteonectin		Osteoadherin
BAG-75	Matrix gla protein (MGP)	Fibronectin		Lumican
Alkaline phosphatase	Osteocalcin	Bone sialoprotein		Mimecan
		Osteopontin		Tetranectin
		MEPE		Periostin
				Keratocan

function in human studies [31]. Periostin senses load and regulates periodontal and vascular calcification [32]. Periostin-deficient mice also have increased vascular calcifications.

OTHER COMPONENTS

The sections above summarize the major components of bone ECM, but there are other minor components that affect the properties of the tissue. For example, there are numerous enzymes that are important for processing the extracellular matrix components. Some of these are cell associated, and some are found in the ECM. Readers are referred to other reviews [2, 23, 33–35] for more details. Growth factors sequestered in bone regulate cell-matrix interactions and cell function [1]. Water accounts for approximately 10% of the weight of bone, depending on species and bone age. Water is important for cell and matrix nutrition, for control of ion flux, and for maintenance of the collagen structure because type I collagen contains the bulk of the tissue water.

Lipids make up less than 2% of the dry weight of bone; however, they have some significant effects on bone properties [36]. This is illustrated by a few recent examples including the neutral sphingomyelinase-deficient mouse that has a dwarfed phenotype [37], the fro/fro mouse that mimics severe osteogenesis imperfecta and has a chemically induced mutation in sphingomyelinase [38], the caveolin-deficient mouse that has altered mechanical properties [39], and the report that phospholipase D is involved in the initial formation of bone during embryogenesis [40].

Each of the components in the organic matrix of bone influences the mechanism of mineral deposition. Some promote mineralization; some inhibit the formation and/or growth of mineral crystals; and some are multifunctional, promoting in some cases and inhibiting in others. The known effects on hydroxyapatite formation in solution for each of the components discussed in this chapter are summarized in Table 6.8.

INTRODUCTION

Rodent models are crucially important research tools for investigating the musculoskeletal system. Analysis methods that are able to accurately distinguish bone mass and structure can help to determine the effects of aging or disease, as well as changes in skeletal morphology due to dietary, genetic, pharmacologic, or mechanical interventions. Until recently, quantitative histological techniques were the standard for assessing trabecular and cortical bone architecture. However, these techniques are limited with respect to assessment of trabecular microarchitecture since structural parameters are derived from analysis of a few two-dimensional (2D) sections, interpolating three-dimensional (3D) structure based on stereologic models [1]. Although histological analyses continue to provide unique information on cellularity and dynamic indices of bone remodeling, the use of 2D histological analysis to determine trabecular bone structure is now an antiquated technique that has largely been replaced by imaging techniques that are able to directly measure 3D bone structure.

Several imaging modalities are currently available for the assessment of skeletal morphology in animal models, offering a variety of costs and benefits for every application. Some imaging techniques, such as radiographs and peripheral dual-energy X-ray absorptiometry (pDXA) provide relatively inexpensive and fast assessments of bone mass and gross morphology *in vivo*, but have poor spatial resolution and are limited to planar images. In comparison, 3D imaging techniques such as microcomputed tomography (μCT) are able to directly measure bone microarchitecture without relying on stereologic models, but at a higher financial cost and greater scan time. Cutting-edge 3D imaging techniques are able to distinguish bone structure at extremely high resolutions (less than 1 micron), allowing for the imaging of bone nanostructure such as osteonal networks and cortical porosity, but with costly and difficult preparation techniques, and imaging systems that are not widely available.

In this chapter, we review the imaging techniques commonly used to assess bone mass and microarchitecture in rodents, paying particular attention to their advantages and disadvantages, as well as technical challenges associated with each technique.

RADIOGRAPHS

Though they are most likely underutilized, 2D radiographs can be useful tools for evaluating gross skeletal morphology both *in vivo* and *ex vivo*. For example, radiographs are commonly used to assess fracture healing [Fig. 7.1(a)] and have been used to assess limb development and range of motion in mouse models of injury [Fig. 7.1(b)] [2]. Radiographs are produced by the summation of attenuation along a single scan direction. The advantage to planar

radiographs is the rapid, relatively inexpensive visualization of skeletal morphology; however, they are limited to qualitative or semi-quantitative 2D evaluations.

PERIPHERAL DUAL-ENERGY X-RAY ABSORPTIOMETRY

Peripheral dual-energy X-ray absorptiometry (pDXA) is commonly used to measure bone mineral content (BMC, g), areal bone mineral density (BMD, g/cm^2), and body composition (percentage fat, lean tissue mass) of small animals both *in vivo* and *ex vivo*. DXA imaging uses a compact X-ray source to expose an animal to two X-ray beams with different energy levels. The ratio of attenuation of the high- and low-energy beams allows the separation of bone from soft tissue, as well as lean tissue from fat. A typical pixel size for pDXA measurement in mice and rats is 0.18×0.18 mm. *In vivo* pDXA measurements have been widely used to demonstrate the skeletal changes following estrogen deficiency [3], dietary and pharmacologic interventions [4, 5], as well as mouse strain-related differences in bone mass and body composition [6, 7].

Generally, pDXA provides highly reproducible measures of whole-body bone mass and body composition, with precision errors for whole body measurements less

than 2% [8, 9] with relatively short scan times (less than 5 min). Due to the relatively large pixel size of DXA imaging, the precision of bone measurements at individual skeletal sites, such as the lumbar spine or distal femur, is much worse due to the challenges of consistently identifying the region of interest. Additionally, measurements of body composition suffer from poor accuracy, with general underestimation of lean tissue mass and overestimation of fat mass [8, 10, 11]. These errors can largely be eliminated with careful calibration of the DXA system to body fat content measured by carcass analysis [10, 11], though few investigators take the time to do this. DXA has relatively limited spatial resolution and assesses areal (i.e., 2D) images; therefore, it is not an appropriate imaging method for distinguishing cortical and trabecular bone compartments or for the assessment of trabecular microarchitecture.

PERIPHERAL QUANTITATIVE COMPUTED TOMOGRAPHY

Peripheral quantitative computed tomography (pQCT) is used for 3D assessment of bone geometry, bone mineral content (BMC), and volumetric bone mineral density (vBMD) in small animal studies, both *in vivo* and *ex vivo*. Commercially available pQCT scanners achieve a nominal voxel size of approximately 70 µm. The ability to measure bone mass and morphology *in vivo* makes pQCT useful for longitudinal assessment of the skeletal response to aging, disease, and/or interventions. The resolution of commercially available pQCT scanners does not allow for effective imaging of trabecular architecture, but they can be used to analyze compartment-specific changes in vBMD.

Many studies have used pQCT in rats to monitor changes in cortical bone geometry along with cortical and trabecular vBMD following pharmacologic [12, 13] or mechanical [14] interventions, or to monitor fracture healing [15]. Peripheral QCT has also been used to quantify bone density and geometry in mice [16, 17]. It has been suggested that this imaging method yields satisfactory *in vivo* precision and accuracy in skeletal characterization of mice [18]. However, the voxel size of pQCT (approximately 70 µm) is relatively large compared to the cortical thickness of mouse long bones (100–300 µm); therefore, this imaging method may have significant errors due to partial volume averaging (described below in the section "Voxel Size and Image Resolution"). Because of this, the accuracy of pQCT for assessment of compartment-specific bone parameters in mice is questionable.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) uses a powerful magnetic field and radio frequency fields to image the soft tissues of the body. A few studies have used high-resolution MRI to assess trabecular and cortical bone in small animals (Fig. 7.2) [19–21], although this technique

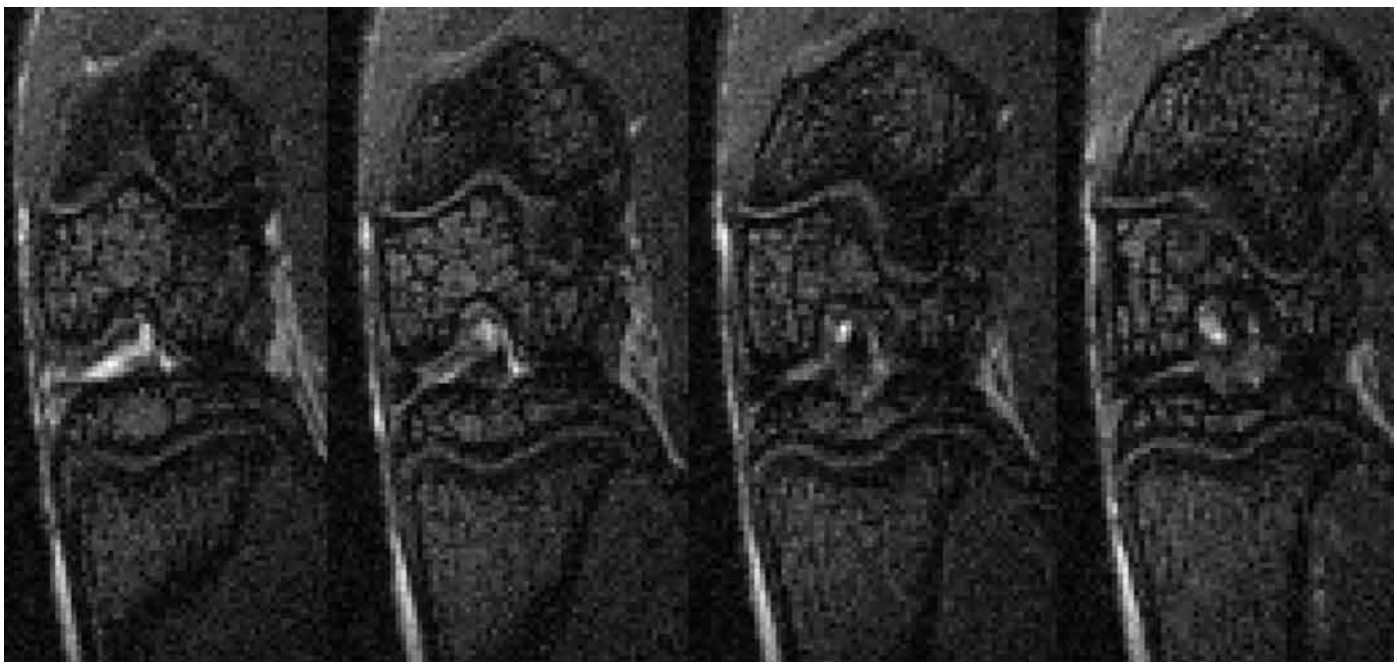

Fig. 7.2. Magnetic resonance imaging (MRI) of mouse knees. In MRI images, bone appears black because bone mineral lacks free protons and generates no MR signal, whereas soft tissues contain abundant free protons and give a strong signal. Typical voxel size for MRI images is 39–137 µm, making this imaging technique more suitable for use in humans or large animal models.

is more widely used for assessment of soft tissues. This is because bone mineral lacks free protons and generates no MR signal, whereas soft tissues contain abundant free protons and give a strong signal. The contrast between bone and the surrounding soft tissue allows for segmentation and quantification of bone architecture, which can yield results that are highly correlated with those obtained from 2D histology [19]. However, no information about the mineralization of bone tissue (BMD) can be obtained from MRI scans. Additionally, MRI systems with sufficiently powerful magnets to distinguish trabecular microstructure in small animal models are not widely available (typical voxel size is 39–137 µm), making this imaging technique more suitable for use in humans or large animal models [22].

MICROCOMPUTED TOMOGRAPHY

Microcomputed tomography (µCT) has become the gold standard for evaluation of bone morphology and microarchitecture of animal models. Microcomputed tomography uses X-ray attenuation data taken from multiple viewing angles to reconstruct a 3D representation of the specimen characterizing the spatial distribution of material density (Fig. 7.3). Current µCT scanners can achieve a nominal voxel size of 5 µm or less, which is sufficient for investigating structures such as mouse trabeculae that have widths of approximately 20 to 50 µm [23]. Microcomputed tomography allows for rapid and nondestructive 3D measurement of trabecular morphology, allowing samples to be used for subsequent analyses such as histology or mechanical testing. µCT scans can also provide an estimate of bone tissue mineralization on a voxel-by-voxel basis by comparing material attenuation to that of known standards, though this must be done with care given the constraints of the scan resolution and the polychromatic X-ray source [24].

Fig. 7.3. Three-dimensional reconstruction of a mouse proximal tibia and distal femur scanned by µCT. Typical skeletal sites of interest for trabecular bone analysis in mice and rats are the proximal tibia epiphysis or metaphysis, distal femur epiphysis or metaphysis, and vertebral bodies of lumbar vertebrae.

Microcomputed tomography has been used for a wide range of studies of bone mass and bone morphology, including the analysis of growth and development [25], skeletal phenotypes in genetically altered mice, and animal models of disease states such as postmenopausal osteoporosis and renal osteodystrophy. Additionally, µCT has been used to assess the effects of pharmacologic interventions [26], as well as mechanical loading [27] and unloading [28]. Furthermore, µCT has been used to image macrocracks in cortical bone [29], evaluate fracture healing [30], and has also been used in combination with a perfused contrast agent to assess 3D vascular architecture [31].

All current µCT systems allow for *ex vivo* analysis of bone samples, with some systems providing the additional functionality of *in vivo* scanning. *In vivo* µCT provides the high resolution of µCT while allowing for longitudinal studies of morphological changes (Fig. 7.4). *In vivo* µCT is an ideal strategy for tracking bone changes that occur on a time scale of weeks or months, such as bone loss associated with disuse or ovariectomy [32, 33], or increased bone mass due to pharmacological or mechanical intervention [34–36]. By registering 3D images against images from previous time points, it is possible to determine the precise locations of bone formation or resorption [32, 37]. Altogether, the ability to perform longitudinal assessments of bone microstructure has the potential to reduce the number of animals needed in a given study and provide novel information about skeletal development, adaptation, repair, and response to disease or therapeutic interventions.

Despite the clear advantages of *in vivo* µCT, there are also several concerns about this method of imaging. First, there are concerns about the amount of ionizing radiation delivered during the *in vivo* µCT scan, particularly when animals are scanned multiple times throughout an experimental period. This radiation may introduce unwanted effects on the tissues or processes of interest, or on the animals in general. Young, growing animals and proliferative biologic processes, such as fracture healing or tumor growth, may be particularly susceptible to radiation exposure. It has previously been reported that weekly scans (8 weeks) have no effect on trabecular bone structure or bone marrow cells in the irradiated limbs of rats [38], while others have reported 8–20% decreases in trabecular bone volume (BV/TV) in irradiated limbs compared to nonirradiated limbs following weekly scans (5

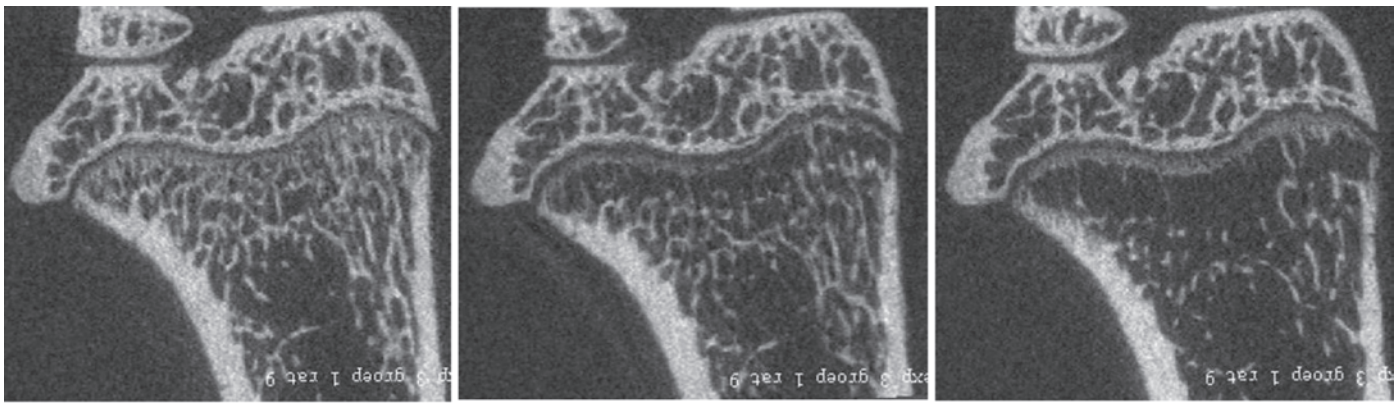

Fig. 7.4. *In vivo* longitudinal μCT images of the proximal tibia of a 30-week-old Wistar rat at baseline and then 2 and 4 weeks after ovariectomy. Note the marked deterioration of trabecular bone in the metaphysis, particularly adjacent to the growth plate, in comparison with little change in the epiphysis. (Image courtesy of J.E.M. Brouwers, Eindhoven University of Technology.)

weeks) in mice and rats [39]. Additional studies are needed to determine the potential effects of repeated *in vivo* μCT scans.

NANOCOMPUTED TOMOGRAPHY

Nanocomputed tomography (nCT) refers to the imaging of bone tissue at resolutions below 1 micron. This was first achieved by systems utilizing synchrotron radiation. Synchrotron radiation systems utilize a high photon flux monochromatic X-ray beam that is extracted from a synchrotron source, rather than the polychromatic X-ray source used for standard desktop μCT imaging systems. The use of a monochromatic X-ray beam eliminates beam-hardening artifacts and allows for accurate assessment of tissue mineral density [40]. Several commercially available imaging systems are also able to achieve submicron nominal voxel sizes without the use of a synchrotron radiation source.

The high spatial resolution associated with nCT systems allows for extremely precise assessment of trabecular bone architecture [23] and may be particularly useful for assessment of small-scale bone structures in young animals [41, 42], or ultrastructural properties of cortical bone (i.e., vascular canals and osteocyte lacunae; Fig. 7.5) [43, 44]. Although nCT imaging is typically performed on excised specimens, Kinney and colleagues [45] have used synchrotron radiation imaging *in vivo* in the rat proximal tibia to show the early deterioration in trabecular architecture following estrogen deficiency.

Altogether, nCT offers extremely high resolution imaging of microstructure and mineral density in excised bone specimens. The disadvantages of the technique are its high cost and limited availability, relatively small volume of tissue examined, and technical expertise needed to acquire and analyze the measurements.

IMAGING CONSIDERATIONS

There are several common issues associated with imaging of bone that must be considered in order to ensure the accuracy and reproducibility of measurements. Structural measurements obtained from μCT or other 3D imaging techniques are strongly dependent on a number of technical issues associated with the analysis, including (1) the scan resolution (voxel size), (2) the segmentation algorithm and threshold used to delineate soft tissue from bone, (3) the skeletal site(s) and volumes of interest, and (4) calibration of the system using density phantoms. These considerations are presented here in the context of μCT imaging but are also applicable to other 3D imaging techniques.

Voxel size and image resolution

A voxel, or volumetric pixel, is a 3D volume representing two dimensions within a reconstructed image and the slice thickness. Typically, voxels from μCT images have all three dimensions equal and therefore are described as isotropic voxels. Ideally, the smallest voxel size (i.e., highest scan resolution) available should be used for all scans; however, higher-resolution scans are more expensive with respect to scan time and memory requirements; therefore, the trade-off between image resolution and scan time/file size should be considered carefully. Differences in voxel size have little effect on the evaluation of structures with high relative thickness (i.e., 100–200 μm),

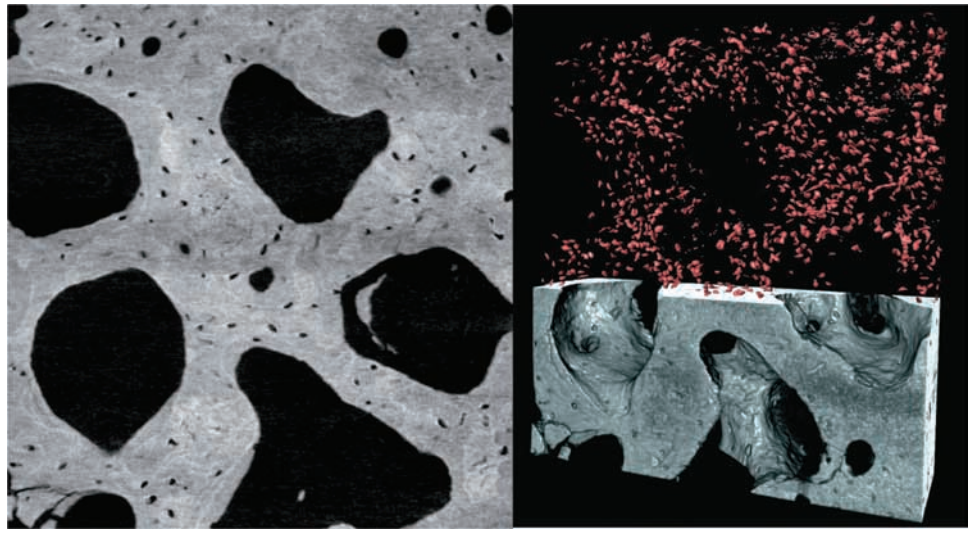

Fig. 7.5. Nanocomputed tomography allows for high-resolution imaging of cortical or trabecular bone with nominal voxel sizes below 1 micron. This enables research into the complex hierarchical structures of bone, including microstructure (e.g., 50–200μm osteons and trabeculae) and fine structure (e.g., 10–25-μm canal networks, and 3–15-μm osteocyte lacunae). (Images courtesy of Xradia and T.J. Wronski, University of Florida.)

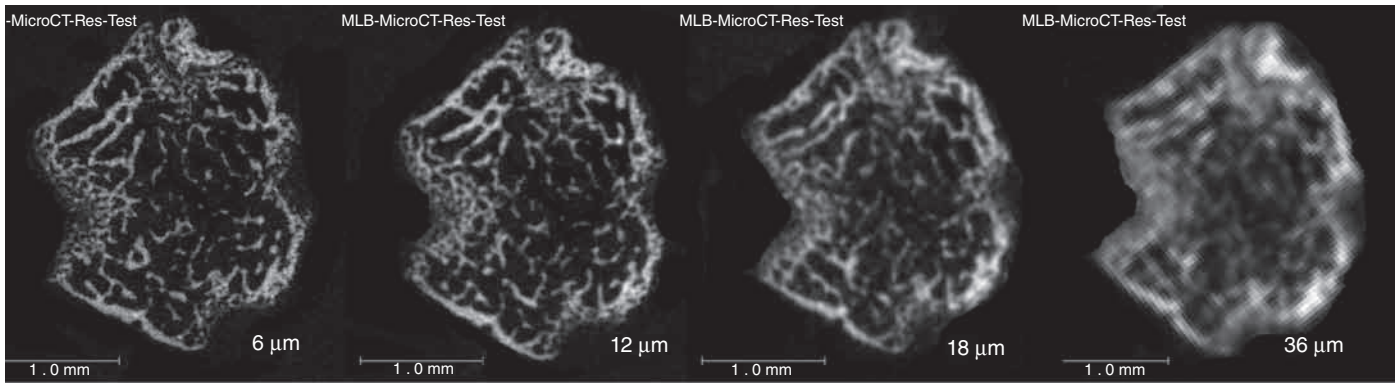

Fig. 7.6. Effect of voxel size on image quality. 2D gray-scale images of the distal femur of an adult mouse scanned with nominal voxel size of 6μm, 12μm, 18μm, and 36μm. Images acquired at 70kVp, 114mA, and 200-ms integration time. [Images courtesy of Rajaram Manoharan, Beth Israeal Deaconess Medical Center, and reprinted with permission from Bouxsein, Boyd, Christiansen et al. (Ref. 57).]

such as cortical bone or trabeculae in humans or large animal models. However, when analyzing smaller structures such as mouse or rat trabeculae with approximate dimensions of 20–60μm, voxel size can have significant effects on the results (Fig. 7.6) [46]. Scanning with low resolution (large voxel size) relative to the size of the structure of interest can cause an underestimation of bone mineral density owing to partial-volume averaging effects, in which a CT voxel samples a region containing two materials with different densities (bone and soft tissue). Depending on segmentation methods, partial volume averaging errors typically cause overestimation of cortical or trabecular thickness and underestimation of BMD. This has been confirmed in mouse femora as well as similarly sized aluminum tubes, where an object thickness to voxel size ratio of 9:1 or less was associated with errors of at least 15% in density measurements [47]. Generally, as the ratio of voxel size to object size decreases, so does the measurement of error regardless of scale (i.e., from mouse to human). The minimum ratio of voxels to object size is 2, but this is associated with substantial local errors (albeit smaller when averaged over an entire structure). Ideally, the ratio should be much higher for accurate morphological measurements.

Segmentation

The segmentation process involves separating the mineralized and nonmineralized structures (bone and non-

bone) for subsequent quantitative analysis. The goal of selecting a threshold is to obtain results that are physiologically accurate (i.e., similar to those that would be obtained using 2D histology) [48]. However, this "physiologically accurate" threshold value depends on many factors, including the scan resolution, the bone volume fraction (BV/TV), and the mineral density of the bone in the volume of interest. The simplest approach to segmentation is to use a global threshold that extracts all voxels from the μCT data exceeding a given CT value (density). The advantage of using a global threshold is that it is efficient and requires setting only one parameter. In most studies, using a single global threshold for all scans is possible, ensuring that differences between study groups are due to experimental effects rather than image-processing effects. Yet there is no consensus on a threshold that should be used for all studies, and extreme care must be taken when selecting a threshold in studies where bone mineralization may not be constant for all groups (i.e., during growth and development or fracture healing) or when there are extreme ranges of bone volume fraction among groups [49, 50], in which case a single global threshold may not be adequate. Thus, in some cases, it is necessary to use more sophisticated segmentation tools, including specimen-specific thresholds [51, 52], and/or local segmentation methods, where the inclusion of each voxel is based on its local neighborhood. Examples include using the local neighborhood histogram to account for image inhomogeneities owing to beam hardening [53] or using the magnitude of the local image gradient (Sobel operator) to identify bone marrow edges for limited resolution images [54]. No matter what segmentation routine is applied, slice-wise 2D comparisons between the original and segmented scan must be performed to ensure accuracy of the segmentation (Fig 7.7).

Skeletal site and volume of interest

Skeletal sites of interest must be carefully selected depending on the specific research question. For trabecular

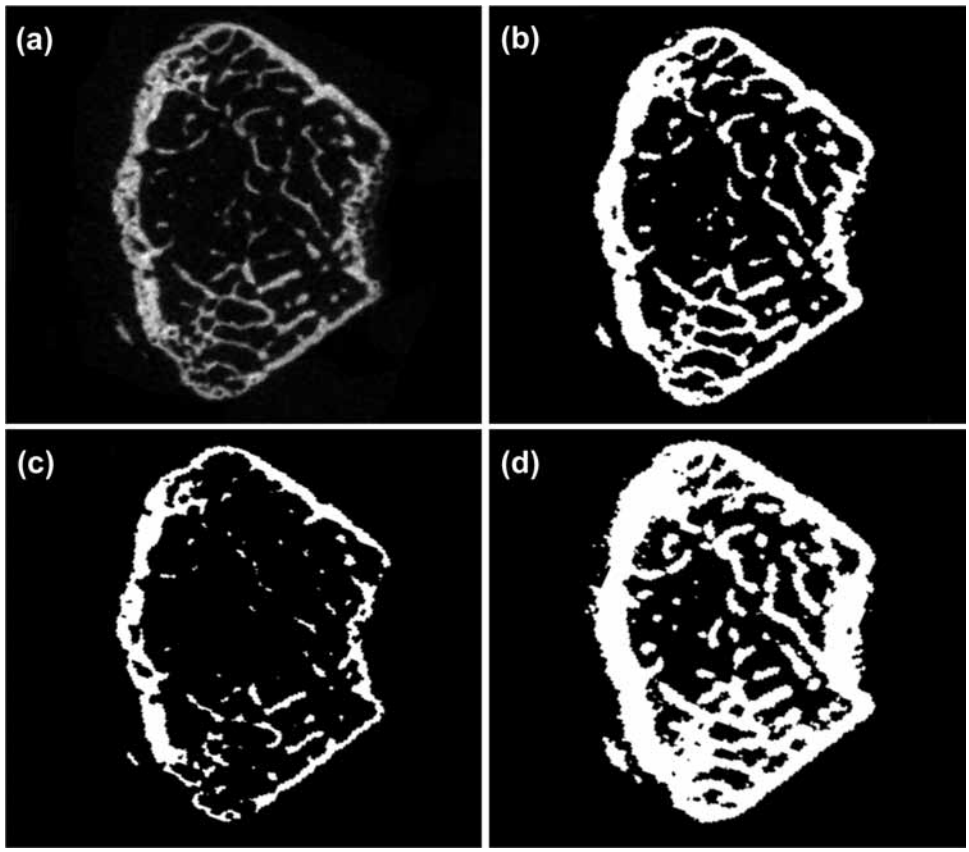

Fig. 7.7. Effect of different thresholds on image segmentation. (a) Original, unsegmented image of mouse distal femur. (b) Correctly segmented image showing reasonable binarization of bone structure. (c) Image segmented with too high a threshold such that key bone structures are missing and/or thinned relative to the original, unsegmented image. (d) Image segmented with too low a threshold such that bone structures appear too thick relative to the original, unsegmented image. Proper segmentation requires visual inspection and comparison of 2D and 3D binarized images with original gray-scale image. [Images courtesy of Rajaram Manoharan, Beth Israeal Deaconess Medical Center, and reprinted with permission from Bouxsein, Boyd, Christiansen et al. (Ref. 57).]

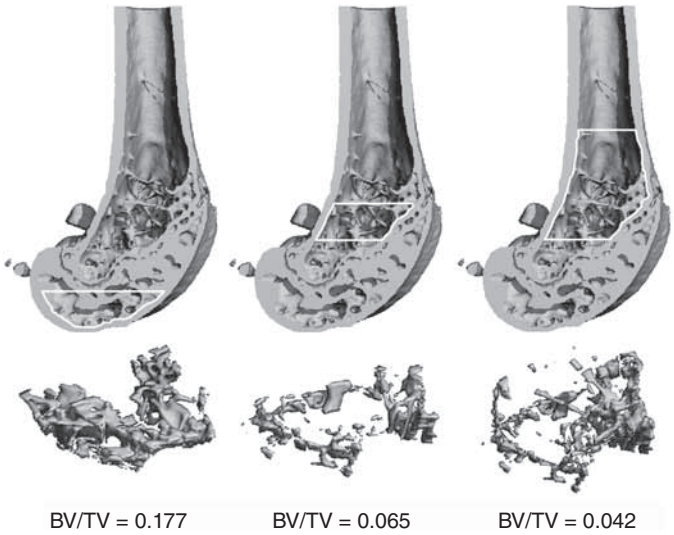

Fig. 7.8. Influence of the volume of interest on trabecular BV/TV at the distal femur of a 24-week-old female C57BL/6 mouse. Evaluation of epiphyseal trabecular bone (left) typically will yield a much higher BV/TV than evaluation of metaphyseal trabecular bone (center, right). Likewise, a volume of interest limited to the metaphyseal trabecular bone close to the growth plate (center) will yield a higher BV/TV than a larger volume of interest that includes a large amount of "empty space" in the diaphysis that contains few trabeculae (right).

bone analysis of mice or rats, the sites most often investigated are the proximal tibia, distal femur, and vertebral bodies. It is also often desirable to analyze more than one skeletal site, since heterogeneity of skeletal sites has been reported [28, 49]. For samples that will be mechanically tested, quantifying cortical bone (of the diaphysis for long bones) is critical, since the cortical bone bears the majority of the load during typical mechanical testing.

Similarly, selecting volumes of interest (VOIs) at a particular skeletal site is an important issue. Assessing trabecular bone requires a suitable VOI, and particular consideration should be paid to the distance that the VOI extends into the diaphysis of long bones. Extension of the VOI too far into the diaphysis will decrease the mean bone volume fraction relative to a VOI that is contained in the metaphyseal region (Fig. 7.8). To represent trabecular bone architecture accurately, the VOI should contain at least three to five intertrabecular lengths [55]. At the mid-diaphysis, 3D cortical thickness measurements must be based on a VOI that is longer than the cortex is thick; otherwise, the thickness will be underestimated.

Calibration

A calibration phantom is necessary to related CT values to a mineral-equivalent value, normally expressed in milligrams per cubic centimeter (mg/cm^3) of calcium hydroxyapatite (HA) from a solid-state phantom. Owing to the excellent linearity of modern μCT systems, calibration is possible with only two points, although some manufacturers use up to five points, covering a range from 0 up to 1,000 mg/cm^3 HA [56]. Many factors (e.g., beam-hardening correction, nominal voxel size, etc.) can influence density results, and absolute differences between scanners cannot be eliminated; however, with care, good relative measures can be made within any given study. Calibration should be performed routinely according to the manufacturer's recommendations.

Other considerations

Several other factors relating to image acquisition, image processing, and analysis can affect the ultimate outcomes of a scan. These factors include sample preparation and positioning, scanning medium, scan energy and intensity, beam-hardening adjustments, and image filtration. These factors have been reviewed previously, along with guidelines for reporting scan parameters and results from μCT analysis [57].

CONCLUSIONS

Assessment of skeletal mass and morphology in rodents via nondestructive imaging is an important component of current investigations aimed at improving our understanding of musculoskeletal development, growth, adaptation, and disease. Currently, several different imaging modalities aimed at whole animal, organ, tissue, and cellular levels are available, and will be increasingly used to study bone structure and adaptation.

INTRODUCTION

Genetically manipulated mice have contributed enormously to our identification of genes controlling skeletal development and to the clarification of their mechanisms of action. Techniques are available to examine the effects of loss-of-function, gain-of-function, and altered structure of gene products. The ability to introduce defined mutations has facilitated the production of animal models of human diseases, cell lineage studies, examination of tissue-specific functions, and dissection of distinct gene functions at specific stages of differentiation within a single cell lineage.

OVEREXPRESSION OF TARGET GENES

The first widely used approach to study gene function *in vivo* was to produce transgenic mice that overexpress target genes. This requires the full-length coding sequence (cDNA) of a gene to be cloned downstream of a promoter. There are severa1 promoters that have been well characterized and used to drive gene expression in skeletal tissues. In the following sections, promoters that have been used to drive transgene expression directly are described. The use of these and other promoters to enable overexpression or underexpression of target genes using Cre recombinase is discussed in a separate section.

Chondrocytes

The most widely used cartilage-specific promoter is derived from the mouse pro aI(II) collagen gene (*Col2al*). This promoter drives high levels of expression beginning after the condensation stage in appendicular elements, and prior to condensation in axial elements in the sclerotomal compartment [1]. The *Col11a2* promoter has also been used to overexpress genes in chondrocytes, although some of these promoters also drive expression in perichondrium and osteoblasts [2, 3]. Overexpression in prechondrogenic limb mesenchyme has been achieved using the *Prxl* promoter [4]. Promoters that drive high levels of expression in hypertrophic chondrocytes have not been described. Chicken and mouse *Col10a1* promoters allow transgene expression in hypertrophic chondrocytes at low to moderate levels; however, expression is not seen in all hypertrophic chondrocytes and is weak [5]. The recent development of *Col10a1-Cre* knock-in mice, when used in conjunction with Cre-inducible transgenic lines (see below) [6] may permit high levels of gene expression in these cells.

Osteoblasts

Several promoters allow overexpression of genes in osteoblasts. The most frequently used is a 2.3-kb fragment from the rat or mouse *Col1a1* proximal promoter (*2.3Col1a1*). Strong and specific activity is seen in fetal and adult mature osteoblasts and osteocytes [7]. A second 2.*3Col1a1* promoter has been described [8]; this promoter shows similar activity in bone, but expression in brain has recently been noted [9]. The 3.6-kb proximal *Col1a1* promoter drives strong gene expression at an earlier stage of differentiation (preosteoblasts), but it is also expressed in nonosseous tissues, including tendon, skin, muscle, and brain [8, 9]. The 1.7-kb mouse *Osteocalcin (OC; Bglap)* promoter has been used to express genes in mature osteoblasts. However, this promoter is expressed in a low percentage of osteoblasts and at a relatively low level. Consistent with this, the 1.7-kb *OC* promoter is unable to drive Cre recombinase expression at effective levels [7]. On the other hand, 3.5- to 3.9-kb human *OC* promoter fragments drive osteoblast-specific expression in a large proportion of mature osteoblasts and osteocytes [10]. Osteocyte-specific promoters have not been widely used, although osteocyte-specific transgene everexpression can potentially be achieved using *Dmpl*-Cre mice (see below) [11].

Tendon and ligament

Tendon patterning and differentiation are seldom studied genetically because of the lack of tissue-specific markers. *Scleraxis* (*Scx*) encodes a transcription factor expressed in developing tendons and ligaments and their progenitors. The development of *Scx-Cre* mice [12] provides a potential strategy for inducing expression of Cre-inducible transgenes (see below).

Osteoclasts

There are a variety of promoters that drive high levels of gene expression in osteoclasts and their progenitors. These include *CDllb*, expressed in monocytes, macrophages, and along the osteoclast differentiation pathway from monoculeated progenitor cells and into mature osteoclasts [13], and *TRACP*, expressed in mature osteoclasts and their precursors [14].

Advantages and disadvantages of overexpression approaches

The major advantages of the transgenic approach are that it is straightforward and inexpensive, high levels of gene expression can potentially be achieved, and transgenic mice often show obvious phenotypes. Furthermore, transgenic strains in which marker genes such as *LacZ*, *GFP*, and/or *ALP* are expressed under the control of tissue-specific promoters allow easy visualization of specific cell types *in vivo* and may permit their isolation with a resolution not possible using other methods. Other methods for detecting specific lineages based on site-specific recombination systems are discussed in a separate section.

A major caveat of the transgenic approach is that constitutive overexpression models often yield nonphysiological levels of protein expression, and this will confound interpretation of the role of the normal gene. Modified transgenic approaches can overcome some of this uncertainty. These include the use of transgenes encoding dominant negative variants or natural antagonists. These approaches lead to loss of function and thus target pathways in their normal physiological context.

The site of transgene integration can have major consequences on tissue specificity and levels of expression. This can be exploited to examine dose-dependent effects, but care must be taken to assess not only levels of expression but also sites of transgene expression, making comparisons of multiple transgenic lines potentially difficult to interpret.

Finally, overexpression of genes that have profound effects in skeletal tissues may confer embryonic lethality, precluding the establishment of stable transgenic lines. By the same token, transgenic lines that can be established overexpress genes only to an extent compatible with survival to sexual maturity. Several bigenic systems address this issue to permit establishment of lines that overexpress genes at levels that confer lethality. One uses the tetracycline (tet) responsive transactivator [15]. This system permits tissue-specific tet-responsive gene expression. A transactivator (tTA) whose activity is modified by tet or the tet analog doxycline (dox) is expressed under the control of a tissue-specific or ubiquitous promoter. The second component is a strain expressing the gene of interest under the control of the operator sequences of the tet operon (tetO). Depending on whether the transactivator is induced (tTA: tet-on) or repressed (rtTA: tet-off) by dox, expression of target genes can be induced or repressed. A second bigenic strategy uses the GAL4/UAS system. This uses one transgenic strain expressing the GAL4 transactivator under a tissue-specific or inducible promoter and a second transgenic strain expressing the gene of interest under the control of the UAS sequence, which requires GAL4 binding for activity. These systems have been used to develop transgenic lines that permit activation of genes in cartilage and bone [16, 17].

GENE TARGETING

The most widely used technique for genetic manipulation is gene targeting in mouse embryonic stem (ES) cells. Briefly, a targeting construct contains a portion of the gene of interest, along with a modification that renders the gene product inactive or modifies its activity.

Gene targeting in ES cells can also be used to generate knock-in models. In these, a locus of interest is modified such that it encodes a gene product with altered activity. A major application of this technology has been to generate mouse models of human genetic diseases.

The ability to eliminate or alter the structure of defined genes is possible in the mouse because of the unique properties of ES cells. These can be genetically manipulated in culture yet retain the ability to colonize the germline when injected into a mouse blastocyst. Once incorporated, they can give rise to germ cells, permitting the establishment of mouse strains carrying the modified gene. ES cells from the 129 strain were the first to be derived and are the most frequently used. However, 129 mice are poor breeders and exhibit abnormal immunological characteristics [18]. Germline competent ES cell lines from 129, C57Bl/6, and C3H are available commercially from multiple sources. These strains have different bone mineral density (BMD) profiles [19] that must be taken into consideration when interpreting skeletal phenotypes.

Germline-competent ES cells carrying defined mutations in many genes are now readily available. These can be found by searching the Mouse Genome Informatics website (www.informatics.jax.org). The most time-consuming step in gene targeting is the introduction of modified ES cells into the germline. This is most commonly done by blastocyst injection, resulting in an F_0 animal that is partially derived from the modified ES cells. These chimeric mice are bred to obtain F_1 mice that are heterozygous for the defined mutation. There are many university core facilities and commercial groups that routinely perform blastocyst injections.

Advantages and disadvantages of gene targeting

Phenotypes caused by loss of function provide direct insight into the physiological roles of the ablated gene product. Moreover, novel actions of targeted genes can emerge because, unlike transgenic models, global knockout models are not limited to a particular tissue or system.

A complication of the global knockout approach is that the deletion of genes essential for early development may preclude analysis of the roles of these genes in skeletal tissues. On the other hand, many knockout strains do not exhibit obvious phenotypes because of functional redundancy; the creation of double or even triple knockouts may be necessary. Another consideration is that global knockout strains usually contain a modified allele in which the selectable cassette used to screen the ES colonies is retained in the locus of interest. On occasion, this leads to effects on neighboring genes. These effects can be shown by comparing phenotypes of mice carrying null alleles in which the selection cassette is left in place with those in which it has been removed. This is discussed below in the context of tissue-specific knockouts.

TISSUE-SPECIFIC AND INDUCIBLE KNOCKOUT AND OVEREXPRESSION

The ability to achieve site-specific recombination has revolutionized analysis of gene action in skeletal cells. Tissue-specific recombination circumvents the early lethality associated with global knockout or overexpression. Tools are available that allow researchers to ablate or express genes in specific types of skeletal cells at specific stages of commitment and differentiation.

Several methods can be used to achieve tissue-specific gene knockout or activation; these rely on site-specific recombinases derived from bacteriophage (Cre) or yeast (Flp) [20]. Cre and Flp recombine DNA at specific target sites. Depending on the orientation of the sites, the recombinase catalyzes excision or inversion of DNA flanked by the sites. Two mouse lines are required. For the Cre-*loxP* system, these are the "floxed" strain, in which the region of the gene targeted for deletion is flanked by *loxP* sites, and a second transgenic mouse line in which Cre recombinase is expressed under the control of an inducible and/or tissue-specific promoter. In mice carrying both the floxed gene and the Cre transgene, Cre deletes the sequence flanked by *loxP* sites. The *loxP* sites are usually placed in introns and generally do not interfere with the normal function of the gene. Hence, the floxed target gene usually functions normally except in tissues where Cre is expressed.

This technology is most commonly used to inactivate genes in which a critical exon is flanked by loxP sites. However, it has also been used to achieve site-specific inducible overexpression. In this case, a transgene is often generated under the control of a strong ubiquitious promoter such as *CAG* [21]. The expression of the transgene is prevented by placing a strong transcriptional stop signal, flanked by *loxP* sites. The gene is activated when Cre catalyzes excision of the stop signal [22]. Engin et al. [23] provide an example of this approach in osteoblasts.

Most studies have used constitutively active forms of Cre. However, ligand-regulated forms enable temporal control of gene activity. The most popular strategy uses fusions of Cre to a ligand binding domain from a mutant estrogen receptor (ER) [24]. The ER domain recognizes the synthetic estrogen antagonist 4-OH tamoxifen (T), but is insensitive to endogenous β-estradiol. In the absence of T, the Cre-ER(T) fusion protein is retained in the cytoplasm. Binding of T to the ER domain induces a conformational change that permits the fusion protein to enter the nucleus and catalyze recombination. Many Cre strains have been developed that are suitable for analysis of skeletal tissues. A complete list of published Cre lines can be found on the Mouse Genome Informatics site (www.informatics.jax.org/recombinases). A few of the

most widely used, and some promising newcomers, are discussed below.

Uncondensed mesenchyme, mesenchymal condensations, and neural crest

Prxl-Cre drives expression in early uncondensed limb and head mesenchyme [4]. *Dermo1-Cre* expresses Cre in mesenchymal condensations [25]. Sox9 is also expressed in mesenchymal condensations. A *Sox9-Cre* knock-in strain drives Cre-mediated excision in precursors of osteoblasts and chondrocytes in these condensations [26]. The *Wnt1-Cre* transgene drives expression in the migrating neural crest and can be used to ablate genes in all chondrocytes and osteoblasts derived from this source [27].

Cartilage

The most widely used Cre strain for cartilage is *Col2a1-Cre* [1]. The activity of this promoter seems to be restricted to chondrocytes in the majority of studies, but there appears to be a brief window during chondrogenesis when *Col2a1-Cre* is expressed in the perichondrium [28]. Hence, controls should be performed to determine the extent to which Cre is expressed in the perichondrium in specific experiments. To date, no published Cre lines exhibit sufficient robustness to permit gene deletion in hypertrophic chondrocytes, but several groups are working on this.

The development of tools that permit inducible recombination in postnatal cartilage has been a challenge. Several groups have generated transgenic lines using CreER(T) fusion proteins under the control of the *Col2al* promoter. These strains permit ablation in articular chondrocytes if T is administered within 2 weeks after birth [28–30]. However, expression of *Col2a1* is known to be low in adults, and although not all of these lines have been tested for in adults, in the one study examining this, the efficiency of recombination was very low [28]. A major breakthrough has been the development of *Aggrecan-CreERT2* mice, in which CreERT2 has been knocked into the *Aggrecan (Acan)* locus [31]. These mice exhibit robust Cre expression in the adult growth plate and articular cartilage, as well as in fibrocartilage.

Osteoblasts

The transcription factor *Osterix* (*Osxl*) is expressed in osteoblast precursors. A Cre-GFP fusion protein has been inserted into the *Osxl* locus on a BAC transgene [32]. This construct allows the targeting of osteoblast precursors. Several transgenic lines in which Cre is expressed under the control of the *Col1a1* promoter permit excision of genes in osteoblasts. A 3.6-kb *Col1a1* promoter drives high levels of Cre expression in osteoblasts but, as discussed above, also targets tendon and fibrous cells types in the suture, skin, and several organs [8, 9]. *Col1a1-Cre* lines (2.3 kb) show more restricted expression to mature osteoblasts, but ectopic expression in the brain is noted in some lines [9]. *Osteocalcin-Cre* drives excision in mature osteoblasts but is not activated until just before birth [10]. Few inducible Cre transgenic strains have been developed for bone. An inducible 2.3 *Col1a1-ERT* strain has been described [33].

Osteoclasts

Several Cre strains permit ablation in myeloid cells. These include *LysMcre* mice, in which Cre has been introduced into the *M Lysozyme* locus [34], and a strain in which the *CDllh* promoter drives Cre expression in macrophages and osteoclasts [35]. Strains permitting Cre-mediated recombination in mature osteoclasts include a Cre knock-in into the *Cathepsin K (Ctsk)* locus [35] and transgenic lines expressing Cre under the control of the *TRAPC* and *Ctsk* promoters [36].

Considerations when using inducible knockouts

The most significant advantage of the Cre-*loxP* system is its flexibility, permitting exploration of gene function in multiple tissues at multiple time points. However, there are some caveats. It may be difficult to find a promoter that drives Cre expression with sufficient activity to result in complete excision of the target gene; this is highly dependent on the floxed allele. Moreover, Cre transgenic strains based on identical promoters but generated in different laboratories can exhibit different specificities and efficiencies. For this reason, every study should include controls to verify the extent of Cre-mediated recombination of the floxed line of interest. Floxed genes also vary with respect to the kinetics of Cre-mediated recombination. This must be borne in mind when attempting to compare phenotypes caused by excision of different genes using the same Cre transgenic line.

The presence of the drug selection cassette in a floxed gene can have a major effect on expression levels of the targeted allele even in the absence of the Cre transgene. Prominent examples include a floxed *Fgf8* strain in which retention of the neo cassette leads to a hypomorphic (reduced function) phenotype [37], and *Scleraxis* knockouts, in which the presence of the drug selection cassette led to embryonic lethality by day 9.5 of gestation [38]. In striking contrast, mice homozygous for a *Scleraxis* null allele in which the drug selection cassette was removed are viable as adults [39]. Another important consideration is that in some cases, Cre itself may confer a phenotype due to toxicity. This is especially true if the Cre is expressed as a fusion with GFP [40].

With respect to inducible Cre models, the inducer may have a significant impact on the phenotype. Both doxy-

cycline and tamoxifen can have profound effects on cartilage, bone, and osteoclasts independently of target gene deletion. Even the low doses of tamoxifen used to catalyze Cre-ER(T)-mediated excision may have effects on bone [41]. Thus, a control group of Cre-negative mice treated with the inducer may need to be included to examine the impact of this variable on the mutant phenotype under study.

LINEAGE TRACING AND ACTIVITY REPORTERS

Genetically modified mice have permitted the determination of cell lineage relationships and the relative contributions of cells from various sources to a given organ with unprecedented resolution. These studies rely on strains that carry a floxed reporter gene, such as *LacZ* or *GFP*. For example, the *R26R* strain carries a floxed *LacZ* cassette introduced into the *ROSA26* locus [42]. When bred to a Cre-expressing strain, all cells in which Cre is expressed, and all of their descendants, express LacZ. *R26R* mice have been used to test the specificity and efficiency of Cre-expressing transgenic lines, although use of this strain in bone is limited by the fact that osteoblasts express endogenous LacZ.

Major insights have been made using *R26R* to study osteoprogenitors. For example, *Wntl-Cre;R26R* mice revealed that frontal bones are derived from the neural crest, but parietal bones are derived from mesoderm [43]. A second example is the demonstration that immature osteoblasts move into developing bone along with invading blood vessels [44]. Most recently, lines have been generated that permit live imaging of the expression of fluorescent proteins in specific organelles (cell membrane, nucleus, etc.) in a tissue-specific and inducible manner; this system was used to mark sites of *Sox9-Cre* expression in skeletal tissues [45].

Transgenic reporter lines can also be used to monitor signaling pathway activity. For example, Wnt pathway activity has been monitored *in vivo* using TOPGAL mice to track β-catenin activity during endochondral bone formation [46]. Tools are also available to monitor canonical bone morphogenetic protein (BMP) pathway activity *in vivo* [47, 48].

FUNCTIONAL GENOMICS

Functional data are available for nearly 14,000 of the estimated 25,000 mouse genes. This information can be accessed through the Phenotype/Alleles project in Mouse Genome Informatics (www.informatics.jax.org/phenotypes). However, fewer than 4,000 of the annotations relate to gene function in skeletal tissue. Thus, there is much work remaining to be done. The International Mouse Knockout Consortium (IMKC) was established in 2007 to coordinate international efforts to generate conditional alleles for all mouse genes. As of 2011, ES cells carrying conditional alleles in nearly 8,000 genes have been generated. Mutant Mouse Regional Resource Centers (http://www.mmrrc.org) have permitted the acquisition and storage of another 320 strains developed in individual laboratories. A second major effort is the use of gene trapping, a high-throughput mutagenesis strategy. Progress on these and other mutagenesis efforts can be found on the Mouse Genome Informatics and IMKC websites [49, 50].

GENERAL CONSIDERATIONS

With all of the successes in genetic manipulation, the real bottleneck is phenotyping. Phenotype is dependent on genetic and environmental factors. As discussed, inbred strains vary considerably in their peak BMD. Moreover, housing conditions and food intake can have a significant impact on metabolic parameters and BMD [51, 52]. Hence, even genetically identical mice can have different phenotypes in different facilities. It is important to assess phenotypes at different ages because effects present at early stages may be compensated for later on. An example of this can be seen in matrix metalloproteinase (MMP)-9-deficient mice [53]. These exhibit prenatal expansion of the hypertrophic zone but are normal within a few weeks of birth. In contrast, other phenotypes manifest only in late stages or when a metabolic stress is applied.

Caution must be taken when extrapolating findings in mouse models to functions in humans. Biomechanical loading and hormonal effects on bones are clearly different in mice and humans. Moreover, linear growth in humans ceases after epiphyseal closure, whereas in mice the growth plate does not fuse. Nonetheless, similarities outweigh the differences by far, and genetic models are likely to play an increasingly prominent role in every aspect of research in skeletal biology.

INTRODUCTION

There is a large body of work studying the impact of allelic variation on skeletal phenotypes in mice, but it is beyond the scope of this brief review to provide encyclopedic coverage of this literature. Rather, examples will be used to illustrate specific aspects of the investigations. The review will encompass two broad areas. First, the phenotypes studied in mice will be described. Second, general themes emerging from the data will be summarized. Finally, expected directions for future work will be explored.

It is important for readers who are not familiar with laboratory mice to recognize that there are many specialized genetic resources available for mouse work. The material below assumes cursory familiarity with specially bred mouse strains. I have previously reviewed these and genetically engineered mice for the nonspecialist [1]. It is also important to note at the outset that the emphasis here is on the variations that exist within established mouse strains and stocks, not the rapidly growing collection of knockout and knock-in mice with interesting skeletal phenotypes. These are obviously of great importance, but beyond the scope of this review.

PHENOTYPES

Most phenotypes of interest to bone biologists are "complex traits." By complex traits, we mean properties that are determined by the combined influence of multiple genes and environmental conditions. Often, but not invariably, complex traits are also quantitative, meaning that there is a continuum of possible trait values rather than a categorical classification of the trait. Genetic loci contributing to quantitative traits are called quantitative trait loci (QTL). Two properties of traits make them attractive objects of genetic study. The first is that they be highly heritable, or that much of the variation in the trait can be attributed to genetics. In human studies, this is determined by twin studies and recurrence rates. In mouse studies, this is determined in backcrosses, intercrosses, or analysis of specially bred mice such as recombinant inbred lines. The second criterion is that the assay used for phenotyping is precise, i.e., highly reproducible. Less precise assays, although not precluding study, make it more difficult because larger sample sizes are needed to distinguish the genetic signal from the noise attending a less precise, "sloppy" phenotyping assay. Another desirable, but not essential, property is that phenotyping be quick and technically easy to perform, as genetic mapping studies require large samples. In addition to the genetic desiderata for phenotypes, it is also important to consider their potential utility in guiding interpretation of the biology. Thus, phenotypes that are difficult to measure reliably may still be worth pursuing if they provide insight that can't be gained otherwise.

Bone Mineral Density (BMD): The contemporary era of mouse bone genetics began with the demonstration that inbred mouse strains differ in apparent volumetric BMD, using peripheral quantitative computed tomography (pQCT) scanning [2]. Subsequent studies [3, 4] have

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

used both pQCT and dual energy X-ray absorptiometry (DXA) technologies to map quantitative trait loci for volumetric and areal BMD in mice, respectively.

Trabecular Structure: Improvements in microcomputed tomography (micro-CT) technology have allowed trabecular structure, a phenotype previously assayable only by histomorphometry, to be studied with sufficiently high throughput for genetic analyses [5]. While micro-CT makes it feasible to analyze hundreds of specimens for trabecular structure, in practice these phenotypes have been studied primarily to characterize congenic mice bred on the basis of another phenotype, as these investigations require far smaller sample sizes.

Dimensions: Both lengths and cross-sectional dimensions of long bones have been widely studied in mice [6–9], using a variety of methods. Measurement of bone geometry greatly enhances interpretation of biomechanical tests, and therefore is included in virtually all studies that include biomechanical phenotypes. It is worth noting that the robustness of the genetic signals obtained for bone geometry typically exceeds those for any other class of traits, manifested by higher linkage statistics for bone dimensions than for bone density or mechanical performance.

Mechanical Performance: The ability to perform mechanical tests represents one of the great advantages of the mouse model system. Various aspects of mechanical performance have been widely studied [7, 9–12]. There are several distinct aspects of mechanical performance, and while each has been mapped successfully, the robustness of these for genetic analysis varies. In general, both strength (yield or maximum load or stress) performs best among these, reflecting its better reproducibility relative to displacement (or strain) or energy (or toughness) [13]. It is important to recall that the domains of mechanical performance are distinct and that each is important to function *in vivo*.

Gene Expression: Relatively inexpensive microarrays allow genome-wide measurement of message abundance. The abundance of a specific message may itself be considered a phenotype, and mapped genetically [14]. When considered in conjunction with pleiotropic traditional phenotypes, expression QTLs (eQTLs) offer the promise of improved identification of the gene underlying the QTL [15]. Expression QTLs typically explain a larger fraction of the genetic variance in gene expression than phenotypic QTLs do, in some cases approaching 50%. Chief among the possible reasons for eQTLs impressive performance is that the phenotype being assessed—gene expression—is far less removed physiologically from the causative variant than is the case for a "clinical" or physiological phenotype, thus the influences of adaptation and feedback are restricted.

Dynamic Phenotypes: All the phenotypes considered above are "snapshots" obtained at a single time. It is also possible to map genes for change in a trait, either as a consequence of time or in response to an intervention. In mice, this has been done for postmaturity change in BMD [16] and modeling in response to mechanical loading [17].

Principal Components and Other Composite Phenotypes: The phenotypes considered above are not independent, as each has some biological overlap with at least one other trait, and it is useful to attempt to extract the unique information from each. One approach to this challenge is to apply principal component (PC) analysis to the data [18]. PC analysis transforms the original phenotypes into an equal number of orthogonal PCs, each defined as a specific linear combination of the original phenotypes. While PCs have been used to study bone phenotypes in mice [7, 19], they suffer from two important limitations. First, as they are linear combinations of directly measured phenotypes chosen algorithmically, they defy intuitive biological interpretation. Second, because the PCs are dependent on the specific phenotypes contributing to them, PCs studied by different investigative teams can't readily be compared.

The genetics of other composite phenotypes have been studied as well. A particularly interesting example is mandibular shape [20]. The method used in this study employs software that converts the positions of multiple anatomical landmarks to normalized distances from the corresponding mean landmark positions. This approach allows a useful mathematical framework for comparing morphological differences independently of size.

THEMES OF EXISTING DATA

Heritability: It has long been recognized that inbred mouse strains have distinctive, reproducible phenotypes. This is true for volumetric BMD [2], areal BMD [4], architectural features [21], various aspects of biomechanical performance [21, 22], and responsiveness to mechanical loading and unloading [23, 24]. In mice, all of these traits are highly heritable, a prerequisite for successfully mapping the responsible genes.

Covariation: Bone properties are interrelated. Larger bones are stronger bones, more heavily mineralized bones are stiffer bones, and areal BMD is dependent on both bone size and mineralization. It is natural to ask which traits used in mapping are more "important" or "informative." There is no simple answer to the question, and several research groups have studied the interrelationship among bone phenotypes in detail [12, 25, 26]. The simplest way to gauge the interdependence of phenotypes is to construct a correlation matrix, in which the correlation of each trait with every other trait is tabulated. These uniformly reveal that some traits are largely redundant with each other, e.g., stiffness and maximum load, and therefore provide largely overlapping information. This redundancy is a motivation for performing PC analysis, as discussed above. More interesting from a biological perspective is the observed negative correlation between mineralization and long bone cross-sectional size [12, 26]. The relationship provides powerful evidence supporting the mechanostat model of the skeleton [27, 28].

Pleiotropy: Pleiotropy is the property of a single genetic locus affecting multiple traits. Unsurprisingly, many bone genes and loci identified in mouse experiments display pleiotropy. Pleiotropy is best appreciated in experiments that have studied multiple traits in the same population. Pleiotropy is commonly observed among mechanical and geometric phenotypes at a single site [6, 29], as well as between measures of the same phenotype at different anatomical sites [8, 30].

One possible interpretation of the data is that the observed pleiotropy reflects covariation among the traits, as discussed in the previous section. The extreme version of this view implies that the traits being studied are only approximations of an underlying, fundamental set of traits that can't be measured directly with current assessment methods, but can be approximated by existing phenotyping assays.

An alternative interpretation instead focuses on the large mechanistic gap that exists between most phenotypes and the proteins encoded by the QTLs. According to this formulation, a primary task for bone biologists is to fill in how differences in the level of expression or activity of specific protein cascades through integrative physiology to impact the skeleton. This is a daunting task, which entails detailed studies of protein function in multiple tissues in isolation, and, additionally, of dissecting the cross-talk among tissues to understand the whole-organism physiology.

The fraction of variance explained by allelic variation serves as a rough surrogate for the extent to which the physiologic impact of the polymorphism can be buffered by compensatory mechanisms. As a trivial example, consider a polymorphism that affects the activity of albumin transcription. Such a polymorphism would be expected to have a large impact on the abundance of albumin mRNA, a lesser effect on serum albumin concentration, even lesser impact on serum calcium, and negligible impact on serum phosphate. At each step in this hierarchy, additional regulatory feedback loops contribute to the ultimate phenotype.

Clustering: QTLs identified in intercrosses of inbred mouse strains, while accounting for much phenotypic variability, are only imprecisely located. The next step in identifying the responsible gene(s) is often construction of nested congenic strains, in which a donor chromosome segment is crossed into a recipient strain. In this way, the phenotypic consequence of substituting only a short genomic region can be assessed independently of the genetic contributions of other QTLs. Recombination, or crossing over, within the donor segment allows more precise chromosomal localization of the QTL. The result of several such experiments [30–32] has been that the donor segment contained not one, but multiple, closely linked QTLs for bone phenotypes. Physical linkage of genes contributing to a common set of functions is an evolutionary mechanism for keeping compatible alleles together (for a review, see Ref. 33). This mechanism is believed to underlie the emergence of sex chromosomes and may be operating with regard to the skeleton as well.

Sex Limitation: Multiple research groups have reported QTLs that affect only males, only females, or have significantly greater effects in one sex than the other [9, 32, 34]. The most important implication of these findings is that the genes underlying such QTLs are involved in pathways that are include sex hormone signaling or that display cross-talk with sex hormone signaling pathways. The additional mechanistic insight arising from sex specificity is a powerful tool for identifying the causative gene and an equally powerful tool for investigating the more general question of how sex hormones act on the skeleton.

Intersite Discordance: One of the most important insights gained from mice is that the genetic bases of cortical and trabecular bone properties are distinct [5], even though some QTLs affect both the cortical and trabecular compartments. In contrast, long bone length QTLs tend to affect multiple sites similarly [8]. This finding demonstrates that cortical bone and trabecular bone are subject to different physiological feedback. A common interpretation is that cortical bone is more responsive to regulation related to mechanical loading, while trabecular bone is more responsive to metabolic signals.

Concordance with Human Data: Not only are the sequences of genes conserved across species, but so are linkage relationships. Therefore, it has been possible to develop a detailed comparative genetic map of the human and the mouse. If one knows the location of a gene in one organism, then its position is also known in the other. Armed with this knowledge, it is possible to ask whether the genes that contribute to bone properties in one species also have an impact in the other. There is substantial overlap between mouse and human genes for BMD [35]. This analysis did not include any of the BMD-related phenotypes that have also been studied in mice, as most of these have not been amenable to measurement in humans.

The mouse data and the human data are complementary in important ways. The human data allow identification of specific DNA sequence variants that are associated with BMD, either because they have a functional significance themselves or because they are in linkage disequilibrium with functional variants. However, the analysis is limited to common sequence variants, so that the contribution of rare variants to BMD is not addressed. Consequently, human studies account for only a very small fraction of the phenotypic variability. In mice, the fraction of the variance explained is about five- to tenfold greater than in humans, but the localization of the responsible loci is much less precise than in humans. Moreover, the genetic linkage studies in mice are performed in experimental crosses in which only a small number of alleles are considered. The greater fraction of the variance explained in the mouse studies is likely due in part to the capturing of all the contributions of genetic differences to the phenotype, unlike the situation in the human studies. In addition, since the mouse linkage peaks include a greater fraction of the genome, they may

also contain multiple genes, as discussed above. Nevertheless, the high concordance between the human and mouse QTL for BMD is a critical validation of the mouse as a model organism for studying bone genetics.

The above notwithstanding, it is important to recognize that mice are not a perfect model, as differences of body size and other features result in important differences between humans and mice. One obvious consequence of the body size difference is the absence of Haversian systems in mouse cortical bone. Thus, there are aspects of human bone architecture that can't be studied in mice.

FUTURE DIRECTIONS

In addition to the recognized limitations of mice in reproducing human bone biology, it is also important to recognize that there are important genetic limitations that attend the use of mouse models. These include the extent to which studies have been performed in highly inbred animals, the limited genetic variation being studied, and the poor genetic resolving power achievable in most experimental crosses, which only extend two or three generations.

In order to overcome these limitations, the collaborative cross is an ongoing effort produce a mouse resource for genetic mapping that overcomes the genetic limitations of currently available mouse resources [36]. The objective is to generate a large series of eight progenitor recombinant inbred strains. The progenitors are chosen to capture more than 80% of the known interstrain allelic diversity among present inbred mouse strains. F1 animals produced from such strains are isogenic, outbred, and possess haplotype blocks whose length approaches those of natural outbred populations. Combinational mating among these inbred strains will allow enough distinct genotypes to apply genome-wide association methods as are used in human studies. The short haplotype blocks will allow localization of functionally important genetic variation to short genomic segments. Thus, the advantages of isogeneity will be maintained, including the need to perform genotyping only once and the ability to estimate phenotype from the pooling of multiple animals sharing a common genotype. The first collaborative cross RI strains have been bred, and hundreds more are approaching completion. These strains will provide a powerful resource for future mouse studies of bone.

Another approach to the limited resolving power of short mouse breeding experiments is to study advanced intercross mice [37]. With every generation of breeding, additional recombination, or crossing over, occurs. This shortens the lengths of chromosome segments that have been inherited from a specific ancestor. For this reason, advanced intercross lines have improved genetic resolving power relative to F2 mice, with genetic resolving power increasing as a function of the number of generations of breeding. The challenge of using advanced intercross mice, however, is that statistical analysis of the data requires accounting for family structure, and is therefore more computationally difficult than for F2 or backcross experiments. Some work using advanced intercross populations to study skeletal phenotypes have already been published [30]. These will no doubt increase in frequency in the years ahead.

Of course, the usefulness of mouse models in advancing the study of bone genetics in the future will depend most on the ability to integrate functional, structural, and mechanical elements in innovative experiments. The genetic tools available in the mouse will allow resourceful investigators to continue to learn new biology that can be applied to improving the human condition.

INTRODUCTION

Bone remodeling, the process whereby bone is constantly renewed during adulthood, is a prototypical homeostatic process in which the destruction of bone by osteoclasts is followed by *de novo* bone formation by osteoblasts to maintain bone mass. Given its importance, it is no surprise that this physiological function is regulated by local, endocrine, and neuronal factors. This review will detail the mechanisms underlying the central control of bone mass.

AN ADIPOCYTE-DRIVEN CENTRAL CONTROL OF BONE MASS

Many observations suggest a link between food, i.e., energy intake, and bone mass, as well as between reproduction and bone mass. For instance, obese patients are protected from osteoporosis, and osteoporosis typically follows gonadal deficiency. Faced with these and other observations, we hypothesized that there is a coordinated regulation, endocrine in nature, of bone mass, energy metabolism, and reproduction [1]. Since the regulation of reproduction and body weight include a central component, this hypothesis implied from its inception the existence of a central control of bone remodeling. Again, the homeostatic nature of bone remodeling adds conceptual credence to this hypothesis since the regulation of most homeostatic functions includes a central component.

Our working hypothesis was verified by showing that mice lacking leptin (*ob/ob* mice), an adipocyte-derived hormone that inhibits appetite, exhibited increased energy expenditure and bone mass along with enhanced reproduction. [1] Moreover, intracerebroventricular (ICV) infusion of leptin into the third ventricle of *ob/ob* mice corrected fully their bone phenotype and established the existence of a central control of bone mass. This experiment is particularly telling because of its genetic nature. In effect, leptin was reintroduced, in the brain only, into animals that were lacking it. At no point could leptin be detected in the blood of these animals, yet their high bone mass was completely corrected. Because this ICV infusion corrected fully the high bone mass phenotype of the *ob/ob* mice, this experiment not only established the existence of a leptin-dependent central regulation of bone formation but also showed that leptin had no other mechanism of regulating bone formation *in vivo;* otherwise, the rescue would never have been complete. This latter point was also established genetically. Indeed,

mice lacking the signaling form of the leptin receptor in osteoblasts have a normal bone mass, whereas mice lacking this receptor in neurons only have a high bone mass [2]. Soon after this initial discovery was made in mice, the existence of a central control of bone mass was extended to rats, sheep, and humans [1, 3, 4]. In line with this work, the increased bone density and decreased fracture risk associated with obese patients is explained by the fact that obesity is a state of leptin resistance.

ANATOMICAL, CELLULAR, AND MOLECULAR BASES OF THE CENTRAL CONTROL OF BONE MASS

It is fair to say that the notion that bone mass was regulated centrally was unexpected. As a result, it was important to establish firm molecular bases for it. The questions to address here were: Where does leptin act in the brain? What is (are) the mediator(s) linking leptin signaling in the brain to bone cells?

Studies performed in wild-type (WT) and *ob/ob* mice, in which specific neuronal populations were lesioned and followed by leptin ICV infusions, identified the ventromedial hypothalamic (VMH) neurons as constituting a major leptin-sensitive central center regulating bone mass [5]. Destruction of VMH neurons (that highly express *ObRb*) indeed recapitulated the high bone formation/high bone mass phenotype of the *ob/ob* mice, and leptin ICV infusion could no longer rescue the high bone mass phenotype of VMH-lesioned *ob/ob* mice. Remarkably, genetic cell-specific ablation of *ObRb* in VMH neurons did not affect bone mass nor did it affect appetite or reproduction [6]. These observations suggested that leptin requires the integrity of VMH neurons to achieve its functions on bone but needs not to bind to them. In other words, leptin must act elsewhere in the brain to regulate the synthesis of neuromediator(s) that will then act in the hypothalamus.

BRAINSTEM-DERIVED SEROTONIN CONTROLS BONE FORMATION

Serotonin, an indoleamine produced by tryptophan hydroxylase 1 (*Tph1*) in enterochromaffin cells of the duodenum and by tryptophan hydroxylase 2 (*Tph2*) in serotonergic neurons of the brainstem, does not cross the blood–brain barrier. Hence, it is *de facto* a molecule with two distinct functional identities depending on its site of synthesis: a hormone when made in the gut and a neurotransmitter when made in the brain. Besides its well-known role in influencing cognitive functions, brainstem-derived serotonin emerged recently as a regulator of three homeostatic functions: bone remodeling, appetite, and energy expenditure. Lack of brain serotonin in $Tph2^{-/-}$ mice induced a low bone mass phenotype without any change in serum serotonin level, indicating that brainstem-derived serotonin is a major central stimulator of bone formation. Brain-derived serotonin is the first, and so far the only, neuropeptide regulating bone mass; indeed all other molecules incriminated (see below) can cross the blood–brain barrier.

Further studies indicated that *Tph2*-expressing neurons express *ObRb* and that leptin significantly decreases *Tph2* expression and action potential frequency in serotonergic neurons of WT mice, but not in serotonergic neurons of mice lacking *ObRb* in *Tph2*-expressing neurons ($ObRb_{SERT}^{-/-}$ mice). Accordingly, $ObRb_{SERT}^{-/-}$ mice lacking *ObRb* in serotonergic neurons of the brainstem developed a high bone mass phenotype. Axon guidance experiments showed the existence of a connection between VMH and brainstem neurons and the analysis of genetic mouse models in which *Htr2c*, the gene encoding the most highly expressed serotonin receptor in VMH neurons, was deleted, showed that brainstem-derived serotonin acts on VMH neurons via *Htr2c*, to favor bone mass accrual [7]. In VMH neurons, brain-derived serotonin uses a calmodulin kinase (CaMK) cascade involving CaMKKb and CaMKIV to phosphorylate the transcription factor CREB (cAMP response element binding protein) [8]. Together, these studies demonstrate that in order to regulate bone mass accrual, appetite, and energy expenditure, leptin needs to inhibit the synthesis and release of serotonin by *Tph2*-expressing neurons of the brainstem. They also establish that the serotonergic neuronal circuitry exerts a more fundamental influence on several homeostatic functions than previously thought.

THE SYMPATHETIC NERVOUS SYSTEM IS A PERIPHERAL MEDIATOR OF LEPTIN SIGNALING IN THE BRAIN

The nature of the downstream mechanism whereby brainstem and hypothalamic neurons regulate the activity of distant cells, such as osteoblasts and osteoclasts, has been determined through genetic and pharmacological approaches. Early on, a key experiment for the field pointed toward a neuronal mediation of leptin central regulation of bone mass. This experiment is a parabiosis, which consists of surgically connecting the blood circulations of two ob/ob mice. In one of them, leptin was then infused centrally at a dose known to not cross the blood–brain barrier. This mouse became the control of the experiment and the question was: Does the contralateral mouse lose bone? It actually did not, thus pointing toward a neural relay of leptin action. This experiment—and the fact that patients with reflex sympathetic dystrophy, a disease characterized by focal high sympathetic tone, associated with bone loss—led us to hypothesize that the sympathetic nervous system, whose activity is

regulated by leptin, could be this neural mediator. Analysis of mice with autonomic dysfunction confirmed the existence of a sympathetic link between the brain and osteoblasts. For instance, mice lacking dopamine beta-hydroxylase (*Dbh*), the enzyme generating norepinephrine (NE), display a late onset increase in bone mass, indicating that the sympathetic nervous system inhibits bone formation [5]. Supporting this result, mice and rats treated with the nonselective beta-adrenergic receptor (AR) blocker propranolol exhibit a high bone mass, whereas mice treated with the nonselective beta-agonist isoproterenol or the beta2AR-selective agonists clenbuterol or salbutamol exhibit a low bone mass [5, 9–12]. More to the point, mice lacking *Adrβ2* (the gene encoding the beta2AR) globally or selectively in mature osteoblasts, display an increase in bone formation and a decrease in bone resorption, leading to a high bone mass phenotype [13, 14]. Similarly, mice lacking adenylyl cyclase 5, a downstream mediator of beta2AR signaling, display positive changes in bone mass and biomechanical properties [15]. Importantly, leptin ICV infusion failed to decrease bone mass in beta2AR-deficient mice, demonstrating not only that the sympathetic nervous system (SNS), via the beta2AR, mediates leptin regulation of bone formation, but also that there is no other mediator of this function [13, 14].

The increased number of osteoblasts and increased bone formation rate observed in beta2AR-deficient mice suggested that the autonomic nervous system inhibits osteoblast proliferation and function. Surprisingly, studies of mice lacking, in osteoblasts only, critical determinants of the clock machinery, including *Per1* and *-2* or *Cry1* and *-2-*, revealed that peripheral clock genes mediate the effect of the sympathetic nervous system on osteoblast proliferation [16]. These studies indicated that osteoblasts express peripheral subordinate clock genes that mediate leptin-dependent sympathetic inhibition of bone formation by suppressing the expression of *G1 cyclin*s and their proliferation. Further studies revealed that osteoblastic clock genes are under the control of beta2AR signaling and uncovered that leptin and sympathetic signaling exert a countervailing and stimulatory effect on osteoblast proliferation through the AP-1 family of transcription factors [16]. These results are in agreement with the known daily variation in bone marrow cell proliferation, collagen synthesis, and turnover markers [17, 18]. More recently, the analysis of osteoblast-specific mutant mice indicated that CREB and cMyc are two major transcription factors mediating the effect of beta2AR stimulation on osteoblast proliferation [14].

Although osteoclasts express the beta2AR [19], the effect of the sympathetic nervous system on osteoclast differentiation is indirect and mediated by osteoblasts, via beta2AR and stimulation of the expression of the osteoclastogenic factor receptor activator of nuclear factor-κB ligand (RANKL) [13]. The transcription factor ATF4, involved in osteoblast differentiation [20], was identified as a target of beta2AR signaling. ATF4 becomes phosphorylated by PKA following beta2AR stimulation and directly binds to the *Rankl* promoter to activate *Rankl* transcription [13, 14] (Fig. 10.1).

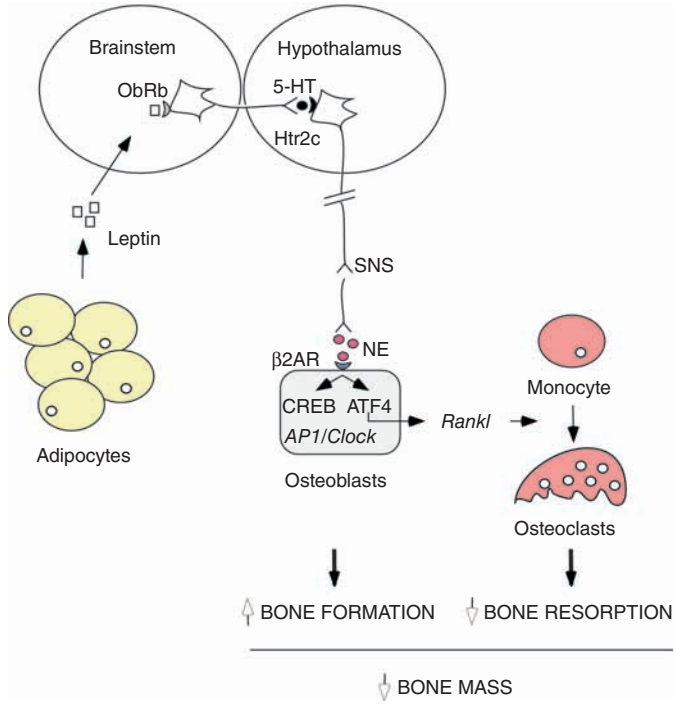

Fig. 10.1. Bone remodeling is under the control of brainstem and hypothalamic serotonergic neurons. Leptin-responsive (ObRb+) neurons in the brainstem, via serotonin signaling in hypothalamic centers, modulate sympathetic outflow to the skeletal system. Norepinephrine (NE) released by sympathetic nerve signals, via the beta2AR in osteoblasts, stimulates bone formation and indirectly inhibits bone resorption. This occurs by controlling AP1/Clock and Rankl expression in a CREB and ATF4-dependent manner, respectively.

Is the leptin-dependent anti-osteogenic function of the sympathetic nervous system on bone remodeling conserved between mice and humans? To put this question in an evolutionary perspective, it is important to state that no molecule identified as a hormone in mice has lost this characteristic in humans. What has been established is that leptin is a negative independent predictor of bone mineral density (BMD) in adults [21]. Likewise, the majority of the available retrospective studies suggests a protective effect of beta-blockers on fracture risk, in agreement with the mouse and rat data [22–26]. Some reports, however, did not find any significant relationship between beta-blocker users and fracture risk [27, 28]. Therefore, long-term prospective randomized studies will be required to demonstrate unequivocally a potential protective effect of beta-blockers on fracture risk in humans. Another question is whether regulatory endogenous mechanisms that involve sympathetic signaling are in play in known pathological bone diseases. Sympathetic activation during aging or chronic stress and severe depression, for instance, might contribute to changes in

bone mass observed under these conditions [29–34]. The response of osteoblasts to sympathetic signals might also be relevant to such conditions, as suggested by the stimulatory effect of glucocorticoids on beta2AR signaling [35].

CART IS A MEDIATOR OF LEPTIN REGULATION OF BONE MASS

An approach based on a screening for genes whose expression is regulated by leptin but that do not regulate appetite or reproduction led to the discovery that *Cart* (cocaine and amphetamine-regulated transcript) mediates leptin inhibition of bone resorption [13]. CART is a neuropeptide broadly expressed in the central nervous system (CNS), including hypothalamic neurons, as well as in peripheral tissues such as the pancreas [36]. The importance of CART in regulating bone remodeling and the hypothalamic nature of this regulation is supported by animal models characterized by low or high hypothalamic *Cart* expression and significant bone phenotypes. Low *Cart* expression in *ob/ob* mice accompanies the increased bone resorption observed in these mice, whereas increased hypothalamic *Cart* expression in obese and hyperleptinemic *Mc4r*-deficient mice correlates with their low bone resorption and high bone mass [13]. Furthermore, lack of one *Cart* copy in *Mc4r*-deficient mice rescues their resorption phenotype, indicating that an increased level of *Cart* in *Mc4r*-deficient mice causes their high bone mass phenotype [37]. The observation that an increase of CART serum concentration causes a high bone mass and rescues the low bone mass of $Cart^{-/-}$ mice suggests that CART regulates bone remodeling as a circulating molecule rather than a central neuropeptide. Regardless of its mode of action, this CART-mediated regulatory loop of bone resorption is conserved in humans, as individuals lacking *MC4R* have increased CART serum levels and increased BMD associated with decreased bone resorption [13, 37, 38]. The molecular mode of action of CART on bone resorption is not yet defined.

BOTH ARMS OF THE AUTONOMIC NERVOUS SYSTEM CONTROL BONE REMODELING

The crucial role of the sympathetic nervous system (SNS) in the regulation of bone remodeling leads to the question of the possible role that the other arm of the autonomic nervous system, the parasympathetic nervous system (PNS), may have in this context. The main neurotransmitter used by PNS endings is acetylcholine, which binds to five types of muscarinic acetylcholine receptors. Among four receptors tested, the M3 receptor (M3R) was shown to be the only muscarinic receptor subtype influencing bone remodeling [39]. *M3R*-/- mice indeed displayed a low bone mass phenotype with cellular changes similar to those observed in mice with increased SNS activity. The weak expression of this receptor in bone cells, as compared to central neurons, led to the hypothesis that M3R signaling in the CNS regulates bone remodeling, a hypothesis that was confirmed using neuronal and osteoblast-specific inactivation of *M3R*-/-. Furthermore, studies of double mutant mouse strains lacking one copy of *Adrβ2* and *M3R* supported the model whereby M3R fulfills this function by decreasing sympathetic activity. These observations broadened the importance of the autonomic nervous system in the regulation of bone remodeling and suggest that the PNS acts as a break on the SNS to dampen its anti-osteogenic influence on bone remodeling, in a similar fashion to other organs.

THE GROWING LIST OF SKELETOGENIC NEUROPEPTIDES

Neuropeptide Y (NPY) is a well-known target of leptin in the hypothalamus, with the potential to act through at least five Y-receptors (Y1, Y2, Y4, Y5, and Y6) that differ in their distribution in the CNS and the periphery. All of these receptors are expressed in the hypothalamus and several respond to other ligands, including peptide YY and pancreatic polypeptide (PP). Strong expression of NPY is found in the hypothalamic area, where NPY fibers project from the arcuate nucleus. NPY expression is inhibited by leptin, as shown by the high NPY content in the hypothalamus of *ob/ob* mice. Exogenous NPY ICV administration, however, induces bone loss, indicating that leptin and NPY do not antagonize each other's function in the control of bone formation, as they appear to do in the control of body weight [40, 41].

In support of a role of NPY receptor signaling in the regulation of bone formation, mice lacking the Y2 receptor ($Y2^{-/-}$ mice) display an increase in trabecular bone mass that can be phenocopied by hypothalamic-specific deletion of *Y2*, indicating that Y2 signaling in the hypothalamus inhibits bone formation [42, 43]. Interestingly, inactivation of both *Y2* and *Y4* receptors led to a further increase in bone mass compared to *Y2* alone, which was accompanied by reduced serum leptin level, suggesting a *Y4*-mediated additional effect of leptin deficiency on the $Y2^{-/-}$ bone phenotype [44]. Thus, Y2 receptor signaling clearly regulates, via a hypothalamic relay, the bone formation arm of the bone remodeling process. NPY and the Y1 receptor are expressed by bone cells, and lack of Y1R promotes the differentiation of mesenchymal progenitor cells as well as the activity of mature osteoblasts, constituting a likely mechanism for the high-bone-mass phenotype evident in $Y1R^{-/-}$ mice [41, 45, 46]. NPY thus may function as both a central neuromediator and a peripheral autocrine/paracrine factor in bone.

Neuropeptide U (NMU) is another neuropeptide whose expression is regulated by leptin and that may be involved in the regulation of bone remodeling. NMU is expressed in hypothalamic neurons as well as in the small intestine, and its functions include the regulation of appetite and sympathetic activation [47], as demonstrated by the obesity of NMU-deficient mice [48]. These mice display a high-bone-mass phenotype caused by an increase in bone formation [49]. The fact that the receptors for NMU, NMU1R and NMU2R, are not detectable in bone, the absence of effect of NMU treatment on osteoblast differentiation *in vitro*, the expression of NMU2R in hypothalamic neurons, and, most importantly, the rescue of the high bone mass of NMU-deficient mice by ICV infusion of NMU, collectively demonstrate that NMU acts via a central relay to regulate bone remodeling. That NMU ICV infusion could decrease the high bone mass of leptin-deficient mice indicates that NMU acts downstream of leptin to regulate bone formation. Most interestingly, NMU-deficient mice are resistant to the anti-osteogenic effect of leptin and adrenergic agonists. Furthermore, osteoblast number paradoxically increased in NMU-deficient mice treated by leptin ICV, as observed in *Clock*-deficient mice, suggesting that NMU regulates the clock gene's function in osteoblasts (see below). In support of this hypothesis, expression of *Per* genes was downregulated in NMU-deficient bones compared to WT bones.

The endocannabinoid system is involved in the regulation of bone remodeling in a central and peripheral manner as well. The cannabinoid type 1 (CB1) receptor, mostly known for its involvement in psychotropic, analgesic, and orexigenic processes, is expressed in the CNS and PNS, whereas the CB2 receptor is expressed mostly peripherally. The main CB1 and CB2 endogenous ligands are N-arachidonoylethanolamine (AEA or anandamide) and 2-arachidonoylglycerol (2-AG). Interestingly, leptin negatively regulates both 2-AG levels and bone mass, and traumatic brain injury increases both bone formation and central 2-AG production. These observations and the fact that CB1 signaling in peripheral neurons inhibits NE release [50] led several groups to assess the contribution of the cannabinoid system to bone remodeling and to analyze genetic mouse mutants lacking *Cb1* or *Cb2*. Mice lacking *Cb1* exhibit a bone phenotype that is dependent on strain background differences [51–53], indicating that indeed the endocannabinoid system contributes to the regulation of bone remodeling. Prejunctional CB1 stimulation by 2-AG and tonic inhibition of NE release by sympathetic nerves are proposed to suppress the anti-osteogenic effect of the sympathetic nervous system and to contribute to the osteoinductive effect of traumatic brain injury [54]. On the other hand, the CB2 receptor and endogenous cannabinoids produced by bone cells, including osteoblasts, have a stimulatory effect on bone formation [55–57]. Importantly, polymorphisms in *CNR2* are important genetic risk factors for osteoporosis [58], and the peripheral expression of CB2 as well as the availability of nonpsychoactive CB2 agonists position this receptor as an anti-osteoporosis target [59].

In contrast to the endothelial (eNOS) and inducible (iNOS) isoforms of NO synthase that are expressed in bone cells (see Ref. 60 for a review), the neuronal form of NO synthase (nNOS) is not expressed in bone cells under normal conditions [61], but is highly expressed in the CNS. This observation and the high-bone-mass phenotype of nNOS-deficient mice suggest that central NO signaling might also regulate bone mass by a central mechanism [62], although direct evidence for this is still lacking.

WHAT ABOUT SENSORY NERVES?

Although sensory neuropeptides are richly expressed in bones [63–66], the relevance of these nerves in bone remodeling is less well defined. Several studies, however, support the contribution of sensory neurons to this process. First, familial dysautomia is an autosomal recessive disease in which patients suffer from unmyelinated sensory neuron loss, reduced BMD, and frequent fractures [67]; second, destruction of unmyelinated sensory axons by capsaicin induces bone loss in rats, accompanied by reduced expression of substance P and cGRP (a calcitonin gene-related peptide) [68, 69]. Lastly, both *in vitro* and *in vivo* studies have led to the conclusion that cGRP is an anabolic factor that acts on osteoblasts and stimulates their proliferation and function [70, 71]. *In vitro* data also suggest that cGRP may be involved in modulating the proresorptive effect of the sympathetic nervous system by interfering with the action of RANKL [19].

LOOKING FORWARD

What are the implications of this growing body of work? The first and most obvious, given the powerful influence exerted by leptin and serotonin, is that there may still be novel systemic regulators of bone mass to be discovered. The second is that the notion that bone formation and resorption are always regulated in the same direction is erroneous since the sympathetic tone exerts opposite influence on each arm of bone remodeling. A third implication of therapeutic nature is that it may be possible to harness the control of bone mass by the sympathetic tone for clinical purposes.

The Process of Skeletal Healing 90
Conditions That Impair Fracture Healing and Therapeutic Modalities 93
Molecular Therapies to Enhance Bone Healing 94
References 95

The process of skeletal repair is essential for resolution of (1) orthopedic trauma that has caused bony disjunction or (2) surgical interventions that are intended to create bony injury with the aim of inducing a repair response or a therapy. Understanding the cellular and molecular basis of this healing process has been the focus of intense research both in humans and animal models over the past two decades, with this work largely driven by the need to develop therapeutic strategies to enable or enhance healing of fibrous nonunions, critically sized defects, or other situations of impaired healing. Combined, failed, or delayed healing impacts up to 10% of all fracture patients seen clinically [1, 2] and can result from a series of common situations including comminution, inadequate fixation, infection, tumor, hypoxia/poor blood supply, metabolic dysfunction, and other chronic disease [3]. Overall, research efforts have led to a general understanding of the molecular and genetic control over the inflammatory, cellular, and tissue processes that are required for healing, which are generally conserved across species and are not different in structurally distinct skeletal elements. This chapter provides a concise and up-to-date overview of our understanding of the skeletal healing process at the cellular and molecular level, a discussion of a few key situations that complicate healing, and a summary of therapeutic modalities that are either in development or employed clinically to enhance repair or facilitate healing in nonunion situations.

THE PROCESS OF SKELETAL HEALING

The cellular contribution to healing tissues: The fracture healing process requires the coordinated activity of several different cell types, including inflammatory cells, chondro- and osteoprogenitors, chondrocytes, osteoblasts, and osteoclasts. Healing events that occur in various vertebrate species are similar, except that relative to humans the pace of repair is generally accelerated in smaller animals/rodents. Thus, the schematic presented in Fig. 11.1, which presents a pictorial representation of the unique morphogenesis of reparative tissue during the phases of bone fracture healing, provides a benchmark for the description of the healing process in general. This process begins immediately after fracture and usually involves both intramembranous and endochondral ossification (comprehensively reviewed in Refs. 4–6). The trauma that induces the fracture initially results in bleeding and formation of a hematoma at the injury site. Hematoma-associated cytokines including tumor necrosis factor-α (TNF-α) and interleukins (IL) -1, -6, -11 and -18 [5] lead to recruitment and infiltration of inflammatory cells to the fracture site, which themselves potentiate the inflammatory environment and induce the secondary recruitment of key mesenchymal stem cell (MSC) populations. These MSCs may derive from a number of niches, including bone marrow [7, 8], muscle

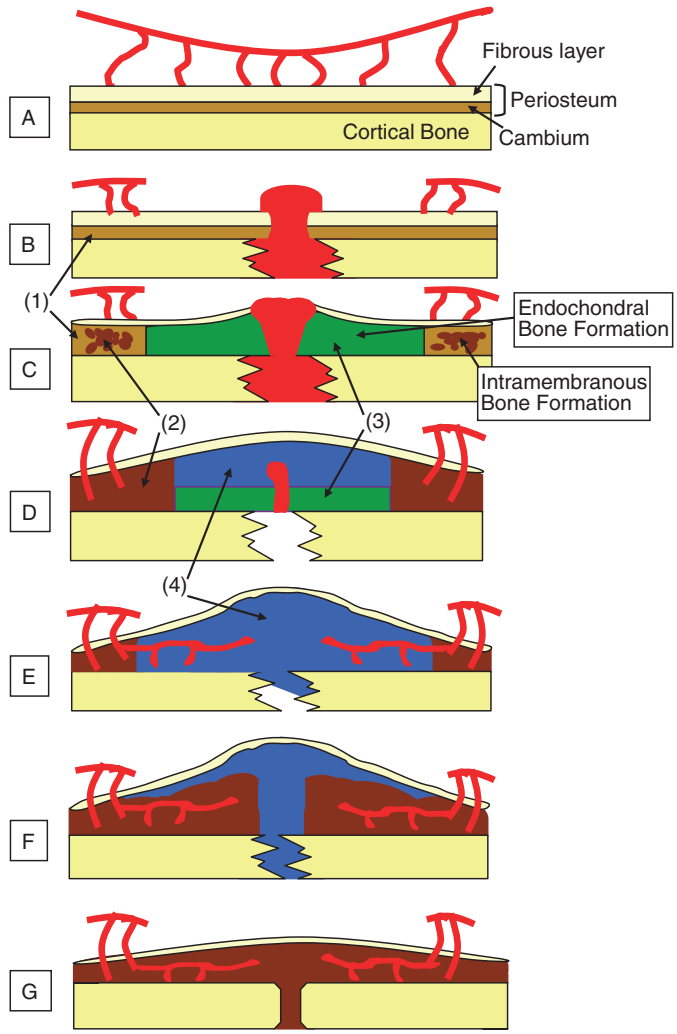

Fig. 11.1. Tissue morphogenesis during bone repair. (A) Periosteum is a well-microvascularized tissue (vessels in red) consisting of an outer fibrous layer and an inner cambium layer. The cambium layer contains abundant stem/progenitor cells that can differentiate into bone and cartilage. (B) Following fracture or osteotomy, blood supply is disrupted at the defect, and a blood clot (hematoma) forms near the disjunction. (C) Progenitor cells residing in the periosteum are recruited to differentiate into osteoblasts to facilitate intramembranous bone formation where intact blood supply is preserved, and into chondrocytes to facilitate endochondral bone formation adjacent to the fracture where the tissue is hypoxic. In this panel, osteogenic tissue is labeled (1), with newly mineralized tissue labeled (2). Tissues supporting chondrogenesis are labeled (3). (D) Intramembranous bone formation proceeds with robust matrix mineralization (1) where blood supply is present distal to the fracture site. Endochondral bone formation proceeds simultaneously with chondrogenic tissue supporting a growing population of chondrocytes that comprise the hypertrophic cartilage, which is labeled (4). (E) Cartilage tissue continues to mature, ultimately encompassing the callus nearest the fracture site. Revascularization of the callus also ensues. (F) Chondrocytes in the hypertrophic cartilage undergo terminal differentiation and the matrix is progressively mineralized expanding the portion of the callus that is comprised of woven bone (brown). (G) The remodeling process proceeds with osteoclasts and osteoblasts facilitating the conversion of woven bone into lamellar bone to ultimately support reestablishment of the appropriate anatomic shape.

[9, 10], periosteum [11, 12], and possibly the general circulation [13, 14]. While there is much debate about which of these populations are the most critical for initiating repair, data suggest that a key participant is the periosteal progenitor cell that responds to the inflammation by entering the osteogenic or chondrogenic lineage [12]. Endochondral bone formation always takes place closest to the fracture site where the oxygen tension is low and vascularity is disrupted. Intramembranous bone formation, on the other hand, always occurs distal to the disjunction where intact vasculature remains present. The mechanical stability of the fractured bone markedly affects the fate of the progenitor cells, with stabilized fractures healing with virtually no evidence of cartilage whereas non-stabilized fractures produce abundant cartilage at the fracture site [15].

Given that the periosteum represents a primary source of MSCs that contribute to bone repair, understanding its structure/function is critical for dissecting the tissue and cellular dynamics of the healing process. Overall, periosteum is a vascularized connective tissue that covers the outer surface of cortical bone. It can be separated into two distinct layers: an outer layer that contains fibroblasts and Sharpey's fibers (which facilitate connection to the underlying cortical bone) and an inner layer referred to as the cambium, which contains multipotent mesenchymal stem cells and osteoprogenitor cells that contribute to normal bone growth, healing, and regeneration [16, 17]. It is known that the cambium layer in children is much thicker and better vascularized than in adults, facilitating faster healing.

Once periosteal MSCs have committed to the chondrogenic or osteogenic lineage, chondrocyte and osteoblast differentiation takes place. Directly overlying the site of the fracture, the ends of the original bone have decreased perfusion due to disrupted vascularity, and necrosis occurs. In this central hypoxic region, MSCs differentiate into chondrocytes, and endochondral bone formation is initiated. This is consistent with the concept that hypoxia is a critical inducer of chondrogenesis [18, 19]. The tissue that forms as the cell population expands is referred to as the callus, and differentiation of MSCs into chondrocytes occurs directionally within the callus, with the process initiating in the most central avascular region. While these centrally positioned MSCs persist in the callus area directly overlying the fracture site, chondrocytes that differentiate radially recapitulate the maturation process that occurs in the growth plate, including phases of proliferation, hypertrophy, and terminal differentiation [5]. The calcified cartilage, which acts a template for primary bone formation, is populated by the most terminally differentiated hypertrophic chondrocytes that are contributing to the mineralization of the tissue. Ultimately, terminally differentiated chondrocytes residing in the calcified cartilage matrix undergo apoptosis, and an initial phase of osteoclast-driven remodeling occurs to remove the remaining cartilage in response to macrophage colony-stimulating factor (M-CSF), receptor activator of nuclear factor-κB (RANK) ligand (RANKL) and osteoprotegerin (OPG) [20]. Maximal resorption occurs when the ratio of OGP to RANKL expression is at its lowest. Distal to the fracture site and flanking the chondrocytes undergoing endochondral ossification is the location where intramembranous ossification occurs. This process, which proceeds in the zone of injury where blood supply has been better preserved, is characterized by the differentiation of periosteal cells into osteoblasts, which directly lay down new mineral without a cartilage intermediate. As mentioned, the better the fracture is fixed (minimizing instability), the greater the ratio of intramembranous to endochondral ossification in the overall healing process.

Fractures are considered healed when bone stability has been restored by the formation of new bone that bridges the area of fracture. However, this initial woven bone matrix is replaced by organized lamellar bone through a second remodeling process that is the critical final step in achieving an anatomically correct skeletal element. Again, this process is governed by osteoclasts, which become dominant in this final stage due to the induction of IL-1 and TNF-α and the subsequent expansion of the functional osteoclast population [21, 22] via RANKL in the remodeling callus [23]. Similarly, the initial cortical bone is remodeled and replaced at the fracture site, where necrosis occurred secondary to loss of vascularization due to the injury. The completion of this final remodeling phase results in an anatomically correct element with biomechanical stability that matches the pre-fracture state.

Gene expression profile during fracture healing: Given that the bone repair process is dependent on a combination of endochondral and intramembranous ossification followed by osteoclast remodeling, the genetic profile of the healing tissue is stage dependent and reflective of the differentiation of these cells. Since the endochondral healing process recapitulates the events that occur during skeletal development, it is no surprise that the genetic profile partially reflects the profile seen in the growth plate chondrocyte hypertrophic program. Overlying this is the genetic profile of osteoblast differentiation that occurs during intramembranous bone formation and in the process of cartilaginous callus conversion into woven bone. Regarding the endochondral process, mesenchymal cell condensation coincides with the expression of early markers of cartilage formation that include Sox-9 and type II collagen [24]. As chondrocyte differentiation ensues, there is a significant increase in cell volume that is associated with the expression of hypertrophy-associated genes that include type X collagen, MMP9 and 13, and osteocalcin [4, 5, 25], as well Indian hedgehog (Ihh) [26]. Partially in response to the upregulation of hypoxia-inducible factor-1α (HIF-1α) [18], terminally mature chondrocytes contribute to revascularization via expression of vascular endothelial growth factor (VEGF) [27] and also may initiate the remodeling process via the induction of osteoclast formation/activity via expression of RANKL [28]. Regarding the intramembranous process, markers of osteoblast differentiation are detected including type I collagen, osteopontin, and osteocalcin. Osteoblasts also contribute to callus revascularization by producing VEGF [29]. The differentiation process in these cells is driven by the expression of Runx2 [30], a transcription factor required for mineralization. By establishing the temporal and regional gene expression pattern during the healing process, a benchmark has emerged that facilitates the monitoring of healing rate that may be delayed or accelerated depending on comorbidities such as aging [31] or diabetes [32], or during therapeutic intervention such as BMP-2 treatment [33, 34].

Molecular control of fracture healing: The molecular signaling pathways involved in the initiation and tissue morphogenesis that occurs during fracture repair are only superficially understood. Although animals and humans have only very limited capacity to regenerate damaged

tissues, it has long been suspected that postnatal bone repair involving endochondral ossification recapitulates some of the essential pathways/factors in limb development [6, 35]. Regarding the developmental process, the most notable regulators are the bone morphogenetic proteins (BMPs) that belong to the transforming growth factor beta (TGF-β) superfamily, Ihh, the mammalian homologs of wingless in *Drosophila* (Wnt) proteins, fibroblast growth factors (FGFs) and insulin-like growth factors (IGFs). Relative to fracture repair, BMP-2 expression has been observed in early periosteal callus just a few days following cortical bone fracture. Most recently, Tsuji et al. demonstrated that elimination of BMP-2 in the limb disrupts the initiation of postnatal fracture healing [33], establishing the essential role of BMP-2 in bone repair. In fact, BMP use has been approved in a number of bone healing situations (reviewed in Ref. 36 and discussed below). Evidence has also emerged indicating that Wnt/β-catenin signaling is required to drive osteoblast differentiation in the fracture callus [37–39], implicating this pathway as an important participant in the callus mineralization process. Hedgehogs are likely important during the cartilage differentiation phase of healing, where Ihh expression is the highest in a rat model of healing [26]. Similarly, FGFs [40] and IGFs [41] have also been implicated to play a role during skeletal healing. Overall, studies are ongoing in the fracture healing field with the aim of fully characterizing the role of these pathways and factors in the adult fracture healing process.

In addition to cell differentiation processes that recapitulate limb development, genes that are involved in injury and inflammatory responses during bone repair have been shown to play key roles in endochondral bone repair [42, 43]. For example, during the inflammatory phase, a constellation of cytokines drive MSC commitment to the chondrogenic and osteogenic lineages [5] as described above. Later, during the endochondral healing phase, a turnover of mineralized cartilage occurs that sets the stage for primary woven bone formation. As mentioned, this initial remodeling process coincides with the upregulation of M-CSF, RANKL, OPG, and TNF-α, implicating these factors as critical for the transition from cartilage to bone [20, 44]. During the second remodeling phase when woven bone is converted into lamellar bone, TNF-α and IL-1 and -6 expression is upregulated, implicating these factors in the recruitment of osteoclasts that are critical for this final remodeling step [21–23, 45]. Supporting this idea, IL-6 knockout mice display delayed callus mineralization and maturation during repair of femoral osteotomy [46]. Thus, there is a clear involvement of pro-inflammatory mediators in the bone repair process.

Several studies have also shown that cyclooxygenase activity is involved in normal bone metabolism and suggest that non-steroidal anti-inflammatory drugs (NSAIDs) have a negative impact on bone repair [47, 48]. The action of aspirin and other NSAIDs is via inhibition of cyclooxygenase (COX), an enzyme that catalyzes the formation of prostaglandins and thromboxanes from arachidonic acid [49]. The most compelling data implicating COX function during skeletal healing comes from genetic models that demonstrate a critical role for COX-2 in the process. While COX-$2^{-/-}$ mice develop normally, bone repair is impaired in adult knockout mice following fracture [50]. Defective healing in this model occurs at the early inflammatory phase and persists into the reparative phase of healing. Histology of fracture callus derived from COX-$2^{-/-}$ mice shows delayed chondrogenesis and persistent mesenchyme at the fracture site. The defective bone healing phenotype coincides with the early induction of COX-2 expression, further demonstrating the requirement of this enzyme in early chondrogenesis in skeletal repair.

Critical to successful bone repair is the revascularization of injured tissues to provide oxygen, facilitate nutrient/metabolic waste management, and deliver a population of precursor cells of hematopoietic origin that may have the potential to contribute to healing. As mentioned previously, support for angiogenesis during the repair process is thought to be modulated by VEGFs and their cognate receptors VEGFR1 and VEGFR2. It has been demonstrated that exogenous administration of VEGF during mouse femur fracture healing enhances vascular ingrowth into the callus and accelerates repair by promoting bony bridging [51]. This has been borne out in allograft bone healing, where VEGF gene therapy likewise enhanced the healing process [52]. While it has been suggested that osteoblasts are the primary regulators of angiogenesis during healing due to their production of VEGF in response to BMPs [53], a contribution of VEGF from hypertrophic cartilage in the callus may also occur [28].

CONDITIONS THAT IMPAIR FRACTURE HEALING AND THERAPEUTIC MODALITIES

The normal progression of the fracture healing process can be significantly compromised by a number of physiologic, pathologic, and environmental factors including aging, diabetes, and cigarette smoking. Clinical data provide evidence for this, and basic research has begun to reveal the details of the underlying biological basis in some cases. Below is a brief discussion of three of the most important conditions that are documented to impair the process of skeletal healing.

Aging: While it has been known for more than 30 years that the rate of fracture healing is reduced with aging, minimal progress has been made toward understanding the mechanisms involved. Studies have suggested that the rate of bone repair is progressively reduced with aging in the pediatric population [54]. Furthermore, numerous studies document that development of nonunion in the aging population is a significant clinical problem [55–57]. Several mechanisms have been proposed to explain reduced/delayed fracture healing in the elderly. Regarding

the potential molecular basis of impaired healing in the elderly, recent work has suggested that reduced expression of COX-2 during the inflammatory phase leads to reduced chondrogenic potential and a truncation of the cartilage phase of healing [31]. Additionally, the normal upregulation of BMP-2 [58], Ihh [59], and various Wnts [60] during chondrocyte maturation and osteoblast differentiation is reduced in aged mice, further impairing the progression of healing in senescence. A reduced number/responsiveness of progenitors [61] enhanced adipogenic potential at the expense of chondrogenesis, and osteogenesis [62] or altered competency to support osteoclastogenesis at various stages of healing [63] may also be involved. There has also been an association between aging and a decrement in endothelial cells and the factors/pathways that modulate them [64, 65], suggesting that impaired blood vessel formation in elderly patients could also affect healing. Ongoing effort aims to address the relative mechanistic contribution of these and other processes to impaired skeletal healing in the elderly.

Diabetes: Documented clinical findings establish that fracture healing is impaired in patients with type 1 diabetes [66, 67]. Consistent with this, animal models of streptozotocin-induced type 1 diabetes show impaired healing evidenced by reduced mesenchymal cell proliferation in the early callus, reduced matrix deposition (collagen), and reduced biomechanical properties in the healed fracture [68, 69]. Additionally, diabetes-related overexpression of TNF-α leads to accelerated loss of cartilage in the callus [70] due to increased chondrocyte apoptosis [71]. While it is not known if the impaired healing is the result of hypoinsulinemia or hyperglycemia/formation of advanced glycation endproducts (AGE), insulin treatment to normalize blood glucose in a diabetic rat bone explant model [72] and a murine femur fracture model [73] has been shown to reverse the deficit in healing. Interestingly, during diabetic bone healing, osteoblast expression of RAGE (cell surface receptors for AGE) is enhanced, possibly facilitating the effects of AGE on reduced bone repair [74]. Lastly, in a diabetic rat fracture model, local intramedullary delivery of insulin to the fracture site, which does not provide systemic management of glucose, reversed the healing deficit at both early (mesenchymal cell proliferation and chondrogenesis) and late (mineralization and biomechanical strength) time points [75]. This supports a novel hypothesis predicting that there is a direct anabolic effect of insulin on cells at the fracture site. It should be noted that in the case of obesity-related type 2 diabetes, clinical data clearly suggest an impairment of fracture healing [76], but the molecular and metabolic basis of the impairment is not currently known. This is likely to be an active area of research given the growing size of the obese and type 2 diabetic population worldwide [77].

Cigarette smoking: Clinically, smoking has been shown to have a negative impact on skeletal healing following long bone fracture [78, 79] and spinal fusion surgery [80]. Little is known about the mechanism underlying these deficits in skeletal repair, with mesenchymal cell condensation and the process of chondrogenesis hypothesized to be important targets of cigarette smoke. This hypothesis is supported by studies demonstrating inhibited cartilage formation during distraction osteogenesis in rabbits [81] and delayed chondrogenesis in a murine tibial fracture model [82]. The most widely studied molecule in the context of smoking and bone healing is nicotine, which has been shown to inhibit distraction osteogenesis [83], spinal fusion [84, 85], and fracture healing in rabbits [86]. Conversely, cigarette smoke, but not nicotine, has been shown to inhibit bone healing around a titanium implant in rabbits [87–89], nor was nicotine found to affect mechanical strength in a rat fracture model [90]. Recently, another class of molecules in cigarette smoke, polycyclic aromatic hydrocarbons, has been implicated in impaired tibial fracture healing in the mouse via activation of the aryl hydrocarbon receptor [91]. In general, however, a full characterization of the healing process in smokers or animal models of smoke exposure is necessary, and work to identify which components of cigarette smoke are responsible for their effects is important if the underlying molecular mechanisms are to be fully understood.

MOLECULAR THERAPIES TO ENHANCE BONE HEALING

Currently, the only FDA-approved molecular therapy for bone healing is BMP-2. As mentioned previously, the underlying rationale for its therapeutic potential is based on the finding that elimination of BMP-2 in the limb disrupts the initiation of postnatal fracture healing [33], establishing its essential role in the process. Thus, it is no surprise that a number of animal studies have identified a positive effect of BMP-2 or activation of its signaling pathway on various bone healing situations. As its use has gained attention, clinical data have emerged that supports the use of BMP-2 in clinical situations. For example, recombinant BMP-2 delivered in a collagen sponge with a cancellous autograft aids in the healing of tibial diaphyseal fractures [92, 93]. Spine fusion patients were also found to have better neck disability and arm pain scores 24 months postoperatively when the INFUSE® bone graft (collagen sponge impregnated with BMP-2) was used [94]. Despite the positive outcomes of these and other studies, it should be noted that the clinical and cost effectiveness of BMP-2 in skeletal repair situations remains an open debate [3, 95].

Recent work has been focused on development of molecular therapies to enhance healing or induce repair in nonunion situations using agents known for their bone-anabolic capability: parathyroid hormone (PTH) and activators of the Wnt/β-catenin pathway. Since PTH is an FDA-approved treatment for enhancing bone mass in osteoporosis patients [96], its repurposing as a candidate

therapy for fracture healing in patients with nonunion has been proposed. In addition to several case reports, recent studies in humans [97] and animals [98–102] show compelling evidence of positive actions of PTH on bone healing. While the mechanism underlying the ability of PTH to enhance healing remains to be determined, recent findings suggest that PTH increases mesenchymal cell proliferation and accelerates chondrogenesis via enhanced upregulation of SOX-9 in rat femur fractures [103]. Regarding the modulation of Wnt signaling, either genetic or molecular (via Wnt3a) enhancement of β-catenin signaling in osteo- and chondroprogenitors has been recently shown to accelerate fracture healing in the mouse [104], suggesting a potential therapeutic strategy involving agonism of this pathway in the treatment of delayed healing [105]. Overall, these recent and novel advances set PTH and Wnt3a treatment on the horizon as important emerging candidate molecular therapies for accelerating healing or alleviating/reversing the development of fracture nonunion.

INTRODUCTION

Fracture healing involves a dynamic interplay of biological processes that when properly executed restore form and function to the injured bone. This chapter presents a biomechanical description of fracture healing, with emphasis on methods of assessing the extent of healing—as defined principally by the extent of the regaining of mechanical function—and on the role of the local mechanical environment. Fracture healing is often classified as either primary or secondary fracture healing, where the former is characterized by direct cortical reconstruction and the latter involves substantial periosteal callus formation. The techniques for assessing healing that are presented in this chapter apply equally well to primary and secondary healing; however, the overviews of the biomechanical stages of fracture healing and the mechanobiology of fracture healing are largely specific to secondary healing. We also note that this chapter does not include a discussion of the biomechanics of fracture fixation, as this topic has been extensively reviewed elsewhere [1–4].

BIOMECHANICAL ASSESSMENT OF FRACTURE HEALING

In the laboratory setting, the mechanical properties of a healing bone are commonly assessed by mechanical tests that load the bone in torsion or in three-point bending. Tension and compression tests are less common. The choice of the type of test is dictated by technical as well as physiological considerations. For example, bending and torsion are logical choices when studying fracture healing in long bones, because these bones experience bending and torsional moments *in vivo*. However, whereas torsion tests subject every cross-section of the callus to the same torque, three-point bending creates a nonuniform bending moment throughout the callus. As a result, failure of the callus during a three-point bend test does not necessarily occur at the weakest cross-section of the callus.

Regardless of the type of mechanical test, the outcome measures that can be obtained are the strength, stiffness, rigidity, and toughness of the healing bone (Fig. 12.1). For torsion tests, an additional parameter, twist to failure, can be used as a measure of the ductility of the callus. Although strength, a measure of the force or moment that causes failure, can only be measured once for a given callus, it is possible to obtain more than one measure of stiffness and rigidity. Multistage testing protocols have been reported that apply nondestructive loads to the callus in planes or in loading modes that are different from those used for the stage of the test in which the callus is loaded to failure. With these protocols, it is possible to quantify the bending stiffness in multiple planes [5] or the torsional as well as compressive stiffness [6].

The mechanical properties illustrated in Fig. 12.1 are structural, rather than material, properties. *Material properties* describe the intrinsic mechanical behavior of

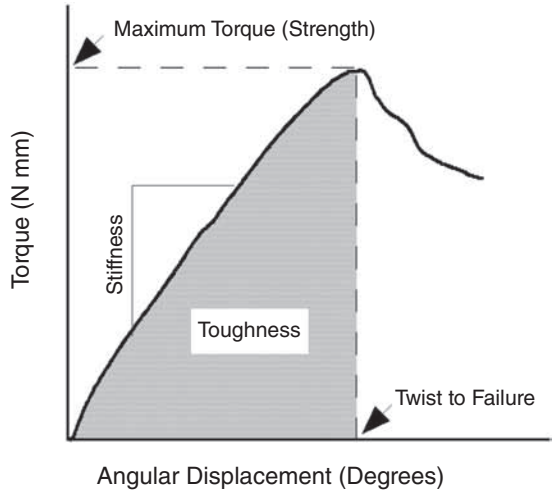

Fig. 12.1. Representative torque-twist curve for a mouse tibia 21 days post fracture. The curve is annotated to show definitions of basic biomechanical parameters. Torsional rigidity is computed by multiplying the torsional stiffness by the gage length. Analogous definitions hold for bending tests.

a particular type of material (tissue), such as woven bone, fibrocartilage, or granulation tissue. The *structural properties* of a fracture callus depend on the material properties of the individual callus tissues as well as the spatial arrangement of the tissues and the overall geometry of the callus. While it is possible to use measurements of callus geometry together with those of structural properties to gain some insight into callus tissue material properties [7], true measurement of these material properties requires direct testing of individual callus tissues [8, 9].

BIOMECHANICAL STAGES OF FRACTURE HEALING

White et al. [10] used the results of torsion tests performed on healing rabbit tibiae at multiple time-points (Fig. 12.2) to define four biomechanical stages of secondary fracture healing. *Stage 1* is characterized by extremely low callus stiffness and strength, and failure during the torsion test occurs at the original fracture line. *Stage 2* corresponds to a notable increase in callus stiffness and, to a lesser extent, strength. However, it is not until *Stage 3* that failure during the torsion test occurs at least partly outside of the original fracture line. This stage is also characterized by an increase in callus strength from Stage 2. Finally, in *Stage 4*, failure during the torsion test occurs in the intact bone rather than through the original fracture line. Although fracture healing is commonly described in terms of four biological phases (inflammation, soft callus formation, bony callus formation, and remodeling), these phases do not map onto the four biomechanical stages in a one-to-one manner. Stage 1 does correspond to the inflammatory phase, yet Stage 2 encompasses the soft callus phase as well as the first part of the bony callus phase. It is the occurrence of bony bridging of the fracture line that is responsible for the increase in stiffness observed in Stage 2. The transition from Stage 3 to Stage 4 roughly corresponds to the start of the remodeling phase.

If the bony callus is sufficiently large, the rigidity and strength of the callus during Stage 3 can exceed that of the intact bone. Even though the callus tissues at this stage are not as rigid or as strong as those of well-mineralized lamellar bone, the larger cross-sectional area and moments of inertia of the callus as compared to the intact bone can overcompensate for the inferior material properties. However, though robust, the callus at this point in the healing progression is also mechanically inefficient. Through remodeling, the callus is able to retain sufficient mechanical integrity with less mass.

Results of several recent studies further illustrate the biomechanical consequences of individual biological phases of healing. For example, intermittent parathyroid hormone (PTH) (1-34) treatment has been shown to increase callus strength [11, 12] primarily as a result of enhanced chondrogenesis [13]. However, while PTH treatment leads to an increase in callus size, a slight decrease in the fraction of the callus that is comprised of mineralized tissue was observed [13], suggesting that the mechanical enhancement results purely from modulation of callus geometry [Fig. 12.3(A)]. The biomechanical importance of the extent of bony bridging (Stage 2), and

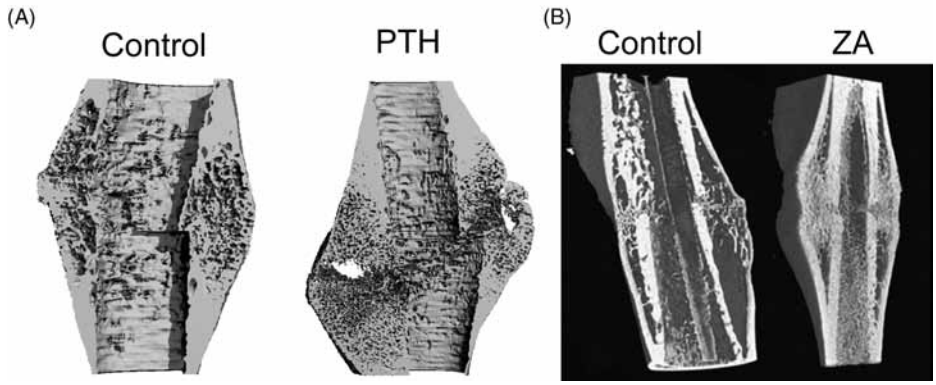

Fig. 12.3. (A) Longitudinal cut-away views of 3D microcomputed tomography reconstructions of representative saline- (control) and PTH-treated murine fracture calluses at 14 days post fracture. (Data from Ref. 13.) (From Ref. 10; images not to scale.)

in particular the extent of outer cortical bridging was demonstrated in a study of the effect of lovastatin treatment on fracture healing [14]. With respect to the later stages of healing, bisphosphonate treatment has been shown to enhance callus strength through inhibition of callus remodeling, resulting in a larger callus and larger proportion of mineralized tissue [Fig. 12.3(B)] [15, 16].

NONINVASIVE ASSESSMENT OF FRACTURE HEALING

While mechanical tests provide the gold-standard measures of healing in laboratory studies of fracture healing, clinical assessment of healing requires noninvasive methods. Multiple noninvasive approaches to measuring callus stiffness, whether in axial loading or bending, have been reported, and the clinical feasibility of several has been demonstrated. Typically, these measurements rely on measuring the displacement across the fracture gap or the pin-to-pin displacement under a known force or bending moment [17–19]. If an external fixator is present, it is necessary to consider only the fraction of the applied load that is borne by the callus as opposed to the fixator. From these approaches, quantitative criteria for healing have been put forth. For example, it has been proposed that a fracture can be considered healed when the bending stiffness (the ratio of the applied bending moment to the angular displacement) exceeds a certain threshold (15 Nm/deg in the case of human tibia fractures) [17], that "healing time" can be defined as the time required to achieve bony bridging of the callus (though assessment of bridging by radiographs is subjective) [20], and that in distraction osteogenesis, external fixation can be removed when the fraction of the axial force borne by the fixator is less than 10% [21].

Other noninvasive methods of assessing healing provide surrogate, rather than direct, measures of callus mechanical properties and include acoustic emission [22], ultrasound [23–28], and computed tomography (CT) imaging. Direct comparisons of CT and standard radiographic analyses have indicated that the former can yield comparable or better predictions of callus compressive strength[29], bending strength[14], and torsional strength and stiffness [30–32], and more definitive diagnoses of healing progression[33] and of nonunions [34]. No consensus currently exists, however, as to which CT-derived measures, or combinations of measures, best predict callus strength and stiffness for a range of types of fractures and/or bony defects.

Importantly, the vast majority of noninvasive approaches to monitoring healing focus on callus stiffness and not callus strength. While noninvasive measures of stiffness may provide valuable information about the healing process, a method to evaluate strength would be more clinically meaningful as it would theoretically provide information regarding the ability to bear weight and carry loads. In this respect, acoustic methods may pose a considerable advantage, as analysis of ultrasonic wave propagation across the fracture gap can be used to detect bony bridging of the gap. Another viable approach is CT-based finite element analysis, in which CT images are used to construct a finite element model of the callus. This approach was demonstrated for estimating callus stiffness [35]; however, this approach requires two key types of input for accurate estimates: (1) the elastic and failure properties of the callus tissues, and (2) the types of loads and/or displacements that the callus is subjected to *in vivo*. As mentioned earlier, direct measurements of the material properties of callus tissues have been reported [9, 36]. Recent studies have also made substantial progress in using techniques such as inverse dynamics analysis to

estimate the loads that bone defects experience during gait [37, 38].

MECHANOBIOLOGY OF FRACTURE HEALING

Fracture healing is one of the most frequently employed scenarios for studies of the effects the local mechanical environment on skeletal tissue differentiation. Mechanical loading of a fracture callus occurs most commonly as a consequence of weight bearing; however, dynamization, or applied micromotion, of the fracture gap has also been investigated. Results of these studies have shown that the effects of loading depend heavily on the mode [39–42], rate [43, 44], and magnitude of loading [45, 46], as well as gap size [45] and the time during healing at which the dynamization is enacted [47–50]. Application of cyclic compressive displacements can enhance healing through increased callus formation and more rapid ossification and bridging [51, 52]. This effect was found to be greatest for an intermediate strain rate (40 mm/s) as opposed to fast (400 mm/s) or slow (2 mm/s) rates [53]. However, the benefits of applied cyclic compressive displacements appear to be limited to displacements that induce an interfragmentary strain (defined as the ratio of applied displacement to the gap size) of 7% or less [39, 45, 54, 55]. Moreover, dynamization of the fracture gap appears to be detrimental in the very early stage of healing [47] yet beneficial during later stages [48–50].

As evidenced by the success of distraction osteogenesis in both experimental and clinical settings, application of successive tensile displacements across an osteotomy gap can also promote bone formation. In contrast to the effects of cyclic compressive loading, however, bone formation in distraction osteogenesis occurs primarily via intramembranous ossification. These characteristics of distraction also appear to hold when the tensile displacements are applied for only 2 days at a time, followed by shortening of the osteotomy gap to its original length [56], but not when the tensile displacements are applied in a true oscillatory manner (e.g.,1–10 Hz frequency) [39]. The effects of shear or transverse movement at the fracture site are controversial, with some studies reporting enhanced bone healing [41, 42] and others reporting increased fibrous tissue formation and delayed bony healing [40, 57]. A series of studies investigating the use of shear movement and also a bending motion to an osteotomy gap reported that these two types of applied motion result in the formation of cartilage rather than bone within the gap [58, 59].

In parallel with some of the earlier experimental investigations summarized above, Perren [60, 61] and Perren and Cordey [43] proposed the interfragmentary strain theory, which states that only tissue that is capable of withstanding the present value of interfragmentary strain can form in the fracture gap. This theory is consistent with observations that granulation tissue forms initially in the gap, followed by cartilage and then bone. The successive formation of each type of tissue further reduces the interfragmentary strain that occurs as a result of the applied load and allows a stiffer tissue to form next.

The interfragmentary strain theory presents an oversimplified description of the mechanical environment within the fracture gap in that it uses one scalar (interfragmentary strain) to describe a multiaxial strain field that varies as a function of position within the gap. More recent models of the mechanobiology of skeletal tissue differentiation have sought to account for this complexity by considering the distributions of local mechanical stimuli present throughout the fracture gap [Fig. 12.4(A)–(C)] [62–64] and the interplay between osteogenesis and angiogenesis [Fig. 12.4(D)] [65, 66]. Carter and colleagues have proposed that different combinations of hydrostatic pressure and tensile strain promote formation of different skeletal tissues [62], while Claes and Heigle have postulated that these two stimuli regulate intramembranous versus endochondral ossification [63]. Prendergast and colleagues have instead proposed that the two key stimuli are shear strain and fluid flow [64, 67]. Direct comparison of these models' predictions to histological analyses of bone healing, and also experimental measurement of local mechanical stimuli such as shear strain within a bone defect, suggests that the most accurate predictions are those based on shear strain and fluid flow [68, 69]. However, each of these theories is unable to predict certain histological features of the fracture healing process [64, 68], indicating that the definitive role of the local mechanical environment in modulating healing has yet to be elucidated fully.

SUMMARY

An essential outcome in fracture healing is restoration of sufficient mechanical integrity to allow weight bearing and activities of daily living. Thus, biomechanical analyses of fracture healing are critical for thorough assessment of the repair process. At present, the biomechanical progression of secondary fracture healing is well characterized, and standardized *in vitro* methods of quantifying the extent of healing have been established. Noninvasive methods of measuring the regain of bone stiffness have also been reported; however, noninvasive methods of measuring the regain of strength are still under development. Studies to date on the effects of mechanical factors indicate that it is possible to augment healing via mechanical loading, and the growing body of literature in this area suggests that further enhancements in healing may be possible. Thus, an understanding of the biomechanics of fracture healing can be applied not only to the assessment of healing but also to development of new repair strategies.

Human Genome-Wide Association (GWA) Studies

Douglas P. Kiel

References 109

Twin and family studies have demonstrated that bone mineral density (BMD), one of the most commonly studied bone phenotypes, is highly heritable, as is bone geometry and bone ultrasound measures [1–3]. Significant heritability of fractures has also been demonstrated for hip fracture occurring at younger ages and most recently for vertebral fractures [4, 5]. The search for genes underlying these skeletal phenotypes has matured over the past decade, beginning with linkage analyses in family-based cohorts [6–10] and candidate gene studies [11–14]. Linkage analyses have not been successful in narrowing quantitative trait loci to specific genes responsible for transmission of the trait through families, and they have relatively low power for complex disorders such as osteoporosis. Candidate gene studies, while meeting with some success in identifying genes related to bone density and geometry, are limited to the study of a set of genes known to be related to bone biology based on existing knowledge. Furthermore, many of the early positive candidate gene studies were not replicated by subsequent work. These early successes and failures set the stage for a more "agnostic" genome-wide search for osteoporosis genes with the advent of improvements in genotyping technology and with the development of computer storage platforms and statistical methods to analyze large amounts of data. Thus within the past five years, the field of skeletal genetics has moved into the era of genome-wide association (GWA) studies [15–17].

Genome-wide association studies use high throughput genotyping of hundreds of thousands and even millions of the most common form of genetic variant, the single nucleotide polymorphism (SNP), and relate these SNPs to various phenotypes. This approach is powerful in that it interrogates the entire genome for associations between the variants and the phenotypes. It has also introduced a considerable number of challenges, especially from a statistical point of view, as the number of associations tested across the genome requires an adjustment for multiple testing. The resulting stringent levels of statistical tests needed to achieve a "significant" association require large sample sizes. Thus, the GWA studies era has spawned a dramatic change in the collaborative efforts across the scientific community. On their own, the individual studies are not sufficiently powered to interrogate so many SNPs across the genome. To achieve the large samples required to perform GWA studies, cohorts across the world have developed consortia that cultivate the necessary trust and collegiality required to undertake large meta-analyses of the GWA studies from individual cohorts.

One of the challenges of these collaborative GWA study efforts includes proper harmonization of phenotypes to minimize measurement heterogeneity. There have been efforts to collect the best phenotypic measures as part of the PhenX project (https://www.phenx.org/). Further efforts to minimize heterogeneity require the standardization of data analysis to account for potential confounding, methods of minimizing the effects of possible population stratification, and appropriate quality metrics for the handling of genotyping data that come from a variety of genotyping platforms.

To combine data across cohorts, studies typically "impute" millions of SNPs that are not actually genotyped on the platforms. Robust methods have emerged

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

allowing for the imputation of genotypes based on work from the HapMap project, which developed a human haplotype map that facilitated the imputation process [18, 19]. This project genotyped millions of SNPs in 270 samples from four populations with diverse geographic ancestry in two phases [20]. Most recently, the 1,000 Genomes Project (http://www.1000genomes.org/) is characterizing over 95% of the variants that are in genomic regions accessible to current high-throughput sequencing technologies and that have allele frequency of 1% or higher in each of five major population groups (populations in or with ancestry from Europe, East Asia, South Asia, West Africa, and the Americas). The 1,000 Genomes Project will also catalog lower frequency alleles in the range of 0.1% frequency because these low frequency alleles are often found in coding regions [21].

All publications of GWA study results are recorded on a website maintained by the National Genome Research Institute of all GWA studies (http://www.ebi.ac.uk/fgpt/gwas/). The field of skeletal genetics has been dominated by a focus on the BMD phenotype, although there has been some evolution from the use of areal BMD using dual energy X-ray absorptiometry (DXA) to volumetric measures of bone density using peripheral quantitative computed tomography (pQCT) and also to the study of fractures. The first GWA study for DXA-derived BMD and hip geometry traits was performed in the Framingham Study using a genotyping platform with only 100,000 SNPs in a sample of only 1,141 men and women, which yielded no genome-wide significant findings using the strict p-value criterion of 5×10^{-8} [22].

The largest meta-analyses to date have been conducted by the Genetic Factors for Osteoporosis (GEFOS) Consortium. The first meta-analysis from the GEFOS consortium included five GWA studies of femoral neck and lumbar spine BMD in 19,195 subjects of Northern European descent [23].

Using DXA-derived BMD phenotypes of the spine and hip, 20 loci reached genome-wide significance (GWS; $P < 5 \times 10^{-8}$), of which 13 mapped to regions not previously associated with BMD. These included 1p31.3 (*GPR177*), 2p21 (*SPTBN1*), 3p22 (*CTNNB1*), 4q21.1 (*MEPE*), 5q14 (*MEF2C*), 7p14 (*STARD3NL*), 7q21.3 (*FLJ42280*), 11p11.2 (*LRP4*, *ARHGAP1*, *F2*), 11p14.1 (*DCDC5*), 11p15 (*SOX6*), 16q24 (*FOXL1*), 17q21 (*HDAC5*), and 17q12 (*CRHR1*).

The other seven loci mapped to genes known to be involved in skeletal metabolism such as 1p36 (*ZBTB40*), 6q25 (*ESR1*), 8q24 (*TNFRSF11B* also known as osteoprotegerin), 11q13.4 (*LRP5*), 12q13 (*SP7* also known as osterix), 13q14 (*TNFSF11* also known as RANKL), and 18q21 (*TNFRSF11A* also known as RANK).

In a second study from the GEFOS consortium using DXA-derived BMD of the hip and spine from 17 GWA studies and 32,961 individuals of European and East Asian ancestry, the top-associated SNPs with BMD at either the femoral neck or lumbar spine were then tested for replication in 50,933 independent subjects [24]. These independent samples for replication came from a previously funded consortium called Genetic Markers for Osteoporosis (GENOMOS), which had produced several of the largest candidate gene meta-analyses prior to the advent of GWA study efforts. The availability of fracture phenotypes in the replication cohorts also permitted the GEFOS meta-analysis to include the testing of the top BMD associations for their association with the for low-trauma fracture in 31,016 cases and 102,444 controls. This meta-analysis identified 56 loci (32 novel) associated with BMD at a genome-wide significant level ($P < 5 \times 10^{-8}$). The overall results of this meta-analysis are displayed in Fig. 13.1 referred to as a "Manhattan" plot, as each tower of points indicate $-\log_{10}$ p-values. Each point represents a p-value for a SNP-phenotype association meta-analysis result. The regional plot of one of these loci, *MEF2C*, is shown in Fig. 13.2. The signal for association is located in the 5′ flanking region of the *MEF2C* gene. This gene codes for a protein that may play a role in osteoblasts and in maintaining the differentiated state of mature muscle cells is an essential transcriptional activator of the bone formation inhibitor, SOST; and this activation is controlled by parathyroid hormone [25].

With so many novel findings as well as confirmation of previous findings, the study also used a formal text mining algorithm called "GRAIL" [26] to determine the degree of relatedness of implicated genes using PubMed abstracts. This analysis found that the implicated genes clustered within the RANK-RANKL-OPG, mesenchymal-stem-cell differentiation, endochondral ossification, and the Wnt signaling pathways. In addition, the meta-analysis discovered loci containing genes not known to play a role in bone biology. When the loci associated with BMD were then tested for association with fracture risk, it was found that 14 BMD loci were also associated with fracture risk ($P < 5 \times 10^{-4}$), of which six reached $P < 5 \times 10^{-8}$, including: 18p11.21 (*C18orf19*), 7q21.3 (*SLC25A13*), 11q13.2 (*LRP5*), 4q22.1 (*MEPE*), 2p16.2 (*SPTBN1*) and 10q21.1 (*DKK1*).

The results from GWA study meta-analyses of DXA-derived BMD traits in individuals of European descent have been followed by a moderately large GWA study with close to 9,000 participants in the Korean Genome Epidemiology Study. However, in that study, bone density was measured at the radius, tibia, and calcaneus using quantitative ultrasound (speed of sound or "SOS") [27]. Perhaps not surprisingly, the results did not confirm many of the loci identified in the large GEFOS efforts, as the phenotype measure in the Asian samples was made at different skeletal sites and using a different technology that is not highly correlated with BMD by DXA. A small GWA study in premenopausal women from Indiana (n = 1,524) failed to identify any genome-wide significant associations; however, the top 50 findings were taken forward for replication in an African-American sample (n = 669) of premenopausal women, and one locus on chromosome 14 near the *CATSPERB* gene showed some evidence of replication. Only two other loci identified in larger GWA study efforts were suggestively associated

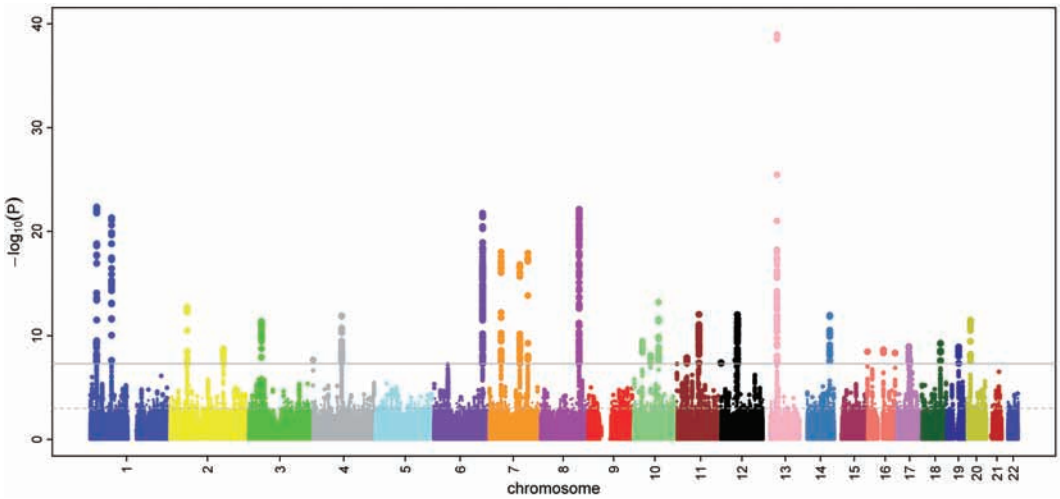

Fig. 13.1. Manhattan plots from the most recent GWA study meta-analysis of the GEFOS Consortium (Ref. 23). The plot displays the genome-wide significant associations between all of the 2,543,686 SNPs that were imputed using the HapMap data from the Centre d'Etude du Polymorphisme Humain (CEPH) samples consisting of 30 U.S. trios who provided samples, which were collected in 1980 from U.S. residents with northern and western European ancestry. Each point on the plot represents a p-value for association with lumbar spine BMD from the meta-analysis using a fixed-effects model. (Reproduced with permission from Estrada K, Styrkarsdottir U, Evangelou E, et al. 2012. Genome-wide meta-analysis identifies 56 bone mineral density loci and reveals 14 loci associated with risk of fracture. *Nat Genet* 44: 491–501.)

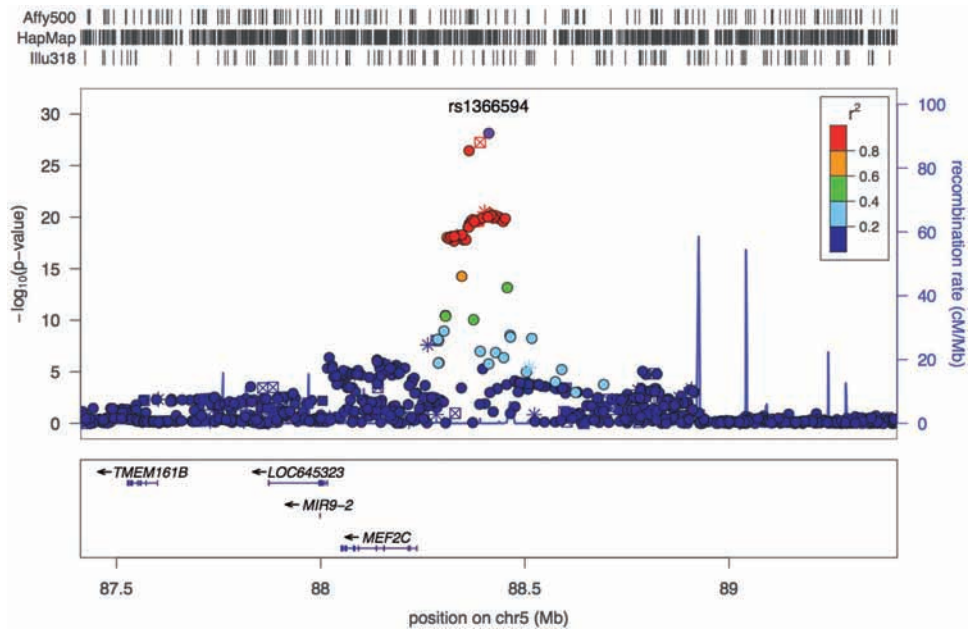

Fig. 13.2. This is a regional plot of p-values for association between SNPs in the 5′ flanking region of the *MEF2C* gene and BMD from the GEFOS meta-analysis results (Ref. 23). (Reproduced with permission from Estrada K, Styrkarsdottir U, Evangelou E, et al. 2012. Genome-wide meta-analysis identifies 56 bone mineral density loci and reveals 14 loci associated with risk of fracture. *Nat Genet* 44: 491–501.)

with BMD of the spine or hip in the premenopausal sample [28]. These two additional GWA study efforts in sample sizes that were considerably smaller than the larger GEFOS meta-analyses highlight the consistent findings from GWA studies in general; namely, that the combined effects of many relatively common genetic variants on a complex trait like BMD require large sample sizes. There remains a considerable unexplained proportion of the high heritability observed for BMD, as is true of other complex phenotypes [29].

Most recently, a group of investigators from Europe used pQCT phenotypes in a GWA study meta-analysis in just over 1,500 teenagers and found an SNP in the receptor activator of nuclear factor-κB ligand (RANKL) gene *(TNFSF11)* to be associated with cortical BMD, with some evidence of a stronger effect and more significant association in the young male participants than in the young women [30]. The significance of this study lies in the use of a phenotype that provides skeletal compartment specific information. If cortical versus trabecular bone modeling and remodeling are influenced by different genes, it will be important to refine the skeletal phenotypes to better understand the underlying genetic architecture.

The unexplained heritability of bone phenotypes using GWA studies suggests that there may be larger numbers of variants with small effects that have not yet been identified, or rare variants with larger effects. Also, the possibility exists that there are structural variants, such as copy number variants, that have not yet been captured on some of the genotyping arrays or have not been adequately investigated. Very few GWA study efforts have investigated the X-chromosome due to early challenges in imputation and analytic approaches [31–33]. There may also be gene by gene interactions that the current studies have not been powered to detect.

The future of GWA studies for the field of skeletal genetics remains promising. As large consortia are able to identify novel loci, the promise of new biologic discoveries lies ahead. The next steps will involve a more thorough testing of the identified loci for discovery of the functional variants, finer mapping and sequencing of promising loci, and studies of gene and environment interactions. There are a number of obvious interactions that might be explored, including differences in the loading on the skeleton according to genetic makeup, or pharmacogenetic studies to identify the variants predicting responses to common medications used to treat osteoporosis, or even nutrigenomic studies to identify variations in response to nutritional interventions used to treat osteoporosis such as vitamin D and calcium.

INTRODUCTION

Bone remodeling presupposes a continuous recruitment of osteoclastic and osteoblastic cells to newly established bone remodeling sites where bone resorption and bone formation are taking place, coupled in space and time. While osteoclastic cells originate from hematopoietic precursors that reach bone surfaces through the circulation, the nature and route by which the osteoblastic cells are recruited to bone formation surfaces are not completely understood. The classical description of osteoblastic cells is that they are fibroblast-like, derived from stem cells present primarily in bone marrow stroma and thus termed "marrow stromal stem cells" (MSCs) (also known as skeletal, or mesenchymal stem cells) and recent evidence suggests their presence in the perivascular niche on abluminal surfaces of blood vessels [1].

Traditionally, MSC are isolated from low-density mononuclear cells through plastic adherence and described as CD105+, CD73+, CD90+, CD14–, CD34–, CD45–, CD79–, CD19– cells [2]. In addition, they have been characterized as CD44+, CD63+, CD146+, Stro-1+ cells [3]. Some recent histomorphometric studies suggest that osteoblastic cells are recruited to bone formation surfaces through blood vessels since bone resorption and bone formation are visualized to take place in specialized "bone remodeling compartments" that are lined by a layer of flat cells connected to a capillary, which provides a conduit for both the osteoclastic and osteoblastic cells to reach bone surfaces [4]. However, in systemic infusion studies, plastic adherent MSCs exhibit poor homing to noninjured skeletal tissues [5], suggesting that MSCs are not circulating (i.e., they are solid-phase cells in contrast to hematopoietic stem cells, which are fluid-phase cells).

On the other hand, a number of experimental studies have tested for the existence of a circulating osteoblastic population, termed "circulating osteogenic precursor (COP) cells," which have the ability to access bone formation sites from the circulation. The biological characteristics and possible roles of COP cells have been studied using a variety of experimental approaches that are summarized here.

PARABIOSIS EXPERIMENTS

Parabiosis experiments are based on creating a conjoint pair of mice that share a common circulatory system. Using this model, Kumagai et al. created a conjoint pair

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

of a mouse constitutively overexpressing green fluorescence protein (GFP) and a wild-type (WT) syngeneic mouse [6]. Following fibular fracture in the conjoined WT partner, GFP+ alkaline phosphatase (ALP)+ cells were found localized to the fracture callus, suggesting recruitment through the circulation. However, Boban et al. examined for the existence of COP cells in transgenic collagen I 2.3-GFP (Col.I2.3-GFP) or osteocalcin (OCN)-GFP mice that were joined to transgenic parabionts overexpressing thymidine kinase (TK) under the control of the Col.I2.3 promoter (Col2.3ΔTK) [7]. When Col2.3ΔTK transgenic mice are given ganciclovir (GCV), the osteoblastic cells are destroyed, but upon removal of the drug the bone recovers uneventfully. Following GCV-induced osteoblast ablation, the authors found no evidence for the presence of GFP marked cells in the Col2.3ΔTK mice, suggesting that matrix-forming osteoblastic cells and osteocytes expressing Col.I or OCN do not circulate.

BONE MARROW TRANSPLANTATION EXPERIMENTS

Olmstead-Davis et al. provided evidence for the presence of COP cells as belonging to the "side population" (SP) of bone marrow cells. SP cells are identified by their ability to expel a DNA binding dye. When transplanted in marrow-ablated mice, SP cells regenerated not only osteoblastic cells but also hematopoietic cells, suggesting that SP cells contain a common precursor for osteoblastic and hematopoietic lineages [8]. Similar results were obtained by Dominici et al., where GFP-marked, plastic nonadherent bone marrow cells generated osteoblasts, osteocytes, and hematopoietic cells following transplantation into lethally irradiated mice [9]. In addition, Hayakawa et al. reported that hematopoietic cells and MSCs can be reconstituted in lethally irradiated WT mice with GFP+ mononuclear bone marrow cells obtained from GFP-transgenic mice [10].

ECTOPIC BONE FORMATION EXPERIMENTS

Otsuru et al. demonstrated the presence of COP cells that contribute to bone morphogenetic protein (BMP)2-induced ectopic bone formation in mice [11]. Following lethal irradiation and subsequent GFP+-transgenic bone marrow transplantation, GFP+ osteoblastic cells expressing osteocalcin were found in the newly formed ectopic bone. Also, transplantation of GFP+ peripheral blood mononuclear cells isolated from BMP2-implanted GFP mice to BMP2-implanted wild-type nude mice led to accumulation of GFP+ osteocalcin+ cells in the ectopic bone [11]. The authors characterized COP cells as CD45– CD44+ CXCR4+, and capable of *in vitro* and *in vivo* differentiation into osteoblasts [12].

COP CELLS IN HUMAN DISEASES

Few studies have examined the presence of donor MSC and osteoblastic cells in bones of patients that have received successful bone marrow transplantation. Koc et al. examined if donor-derived MSCs were transferred to allogenic hematopoietic stem cell transplant recipients for treatment of lysosomal or peroxisomal storage diseases [13]. Bone marrow MSCs were cultured from 13 patients 1 to 14 years after transplantation. Despite successful donor-type hematopoietic engraftment, there was no evidence for the presence of donor MSCs based on fluorescent *in situ* hybridization (FISH) analysis using probes for X- and Y-chromosomes in gender-mismatched transplantations or radiolabeled PCR amplification of polymorphic simple sequence repeats [13]. In contrast, bone marrow transplantation was shown to improve lethal osteogenesis imperfecta (OI), and transplantation of plastic-adherent, bone marrow MSCs resulted in engraftment and clinical improvement in five out of six patients with severe OI [14]. In addition, Suda et al. reported the presence of donor-derived COP cells in patients that received gender-mismatched hematopoietic stem cell transplantation [15].

MSC MOBILIZATION STUDIES USING PHARMACOLOGICAL AGENTS

Hong et al. were able to isolate COP cells following their mobilization with substance P in mice and rats from the peripheral blood mononuclear cell fraction as CD45–, CD29+, and capable of mesoderm-type cell differentiation (osteoblast, adipocyte, and chondrocyte) [16]. Pitchford et al. [17] reported peripheral blood enrichment of MSC-like cells (plastic adherent, CD29+, CD105+, CD34–, CD45–, VE-Cadherin-, vWF-) following treatment with VEGF and the CXCR4 antagonist AMD3100, suggesting mobilization from bone marrow to peripheral blood. Also, Tondreau et al. have demonstrated that G-CSF-mobilized CD133+ cells in peripheral blood contain plastic-adherent MSC-like cells capable of osteoblast differentiation [18].

APPROACHES FOR ISOLATION AND CHARACTERIZATION OF COP CELLS

Different approaches have been utilized to obtain COP from peripheral blood with variable success.

Plastic adherence

Kuznetsov et al. identified circulating MSCs (termed "circulating connective tissue precursors" [19] or "circu-

lating skeletal stem cells" [20]) from human and experimental animal peripheral blood through plastic-adherence, and the cells were described as osteonectin+ osteopontin+ collagen type I (Col. I)+, alpha smooth muscle (ASM)+ CD45– and endothelial marker negative cells. The frequency of these cells was extremely low in humans but more abundant in experimental animals, e.g., in the guinea pig [19, 20]. Interestingly, Zvaifler et al. modified this method and reported a more successful isolation of MSCs from peripheral blood of healthy volunteers with a similar phenotype [21]. Rochefort et al. reported that the frequency of plastic-adherent MSCs present in peripheral blood increased in a rat model for chronic hypoxia, suggesting that pathophysiological conditions including hypoxia can mobilize MSCs from bone marrow to peripheral blood [22]. Also, Otsuru et al. isolated plastic-adherent CD45– CD44+ CXCR4+ cells from murine peripheral blood and demonstrated their homing to sites of BMP2-induced ectopic bone formation [11,12]. Circulating MSC-like cells have also been isolated from umbilical cord blood [23, 24].

Plastic-nonadherent cells

Based on the notion that fluid-phase cells are poor at plastic adherence, Long et al. have reported the presence of osteocalcin (OCN)+ or osteopontin+ bone marrow plastic-nonadherent cells [25, 26]. Eghbali-Fatourechi et al. extended these studies to isolate a plastic-nonadherent cell population from peripheral blood [27], demonstrating that OCN+ cells exhibit mononuclear cell morphology and that up to apprxoimately 50% of these cells express CD34 [28]. However, these cells seem to exhibit under standard *in vitro* culture conditions low growth rates and less robust osteoblast differentiation capacity compared with bone marrow MSCs [27].

COP cells isolated from vascular lineage cells

A number of investigators have described the osteoblastic differentiation potential of vascular cells. For example, a common progenitor (termed "mesangioblasts") that can differentiate into endothelial and mesodermal cells (osteoblasts, adipocytes, myocytes) has been isolated in cultures of embryonic dorsal aorta [29, 30] as Flk1+ CD34+ VE-cadherin+ alpha smooth muscle+ cells [29, 30]. Some studies suggest the presence of a counterpart for this cell population in the bone marrow of postnatal organisms [31, 32].

Also, circulating endothelial cells have been described that acquire an osteoblast-like phenotype *in vitro* and enhance fracture healing when applied locally [33]. In a lineage tracing study to identify cells recruited to sites of ectopic bone formation in mice, Lounev et al. demonstrated that Tie2+ cells (as a putative marker for endothelial cells), but not MyoD+ (muscle cells) or smooth muscle myosin heavy chain+ cells, made significant contributions to the newly formed bone [34]. Furthermore, vascular endothelial cells may transform into mesodermal multipotent stem-like cells by an activin-like kinase-2 (ALK2) receptor–dependent mechanism [35]. Interestingly, endothelial markers are expressed in chondrocytes and osteoblasts in lesions from individuals with fibrodysplasia ossificans progressiva (FOP) [35]. Thus, expression of constitutively active ALK2 in endothelial cells may cause an endothelial-to-mesenchymal transition and acquisition of a stem cell–like phenotype. However, multipotent mesenchymal cells that reside in the skeletal muscle interstitium may also be a source of progenitors for heterotopic ossification and, at least in BMP2-induced skeletogenesis in the mouse, the endothelium may not exclusively supply these precursor cells [36].

Isolation of COP cells from fibrocytes, monocytes, and other cells from the hematopoietic lineage

Several hematopoietic-derived cell populations present in peripheral blood have been characterized as having osteogenic potential. Matsumoto et al. demonstrated that the human peripheral blood CD34+ cell fraction contains a minor population of OCN+ cells that upon intravenous infusion were identified at bone formation sites in a rat femoral fracture model [37]. Several studies have examined the biological characteristics of circulating connective tissue cells called "fibrocytes." The cells were first identified in *in vivo* assays of wound repair models [38]. Fibrocytes are cultured from the mononuclear cell fraction of peripheral blood through adherence to fibronectin-coated plastic, and characterized by fibroblast-like morphology and a combined hematopoietic (CD34+, CD45+, CD13+) and stromal mesodermal phenotype typified by collagen type I. Fibrocytes exhibit variable levels of CXCR4 expression and differentiate into mesoderm-type cells (e.g., osteoblast, adipocyte, and chondrocyte), but the efficiency of differentiation is low and no evidence for *in vivo* bone formation has been demonstrated [39].

Kuwana et al. identified a related population called "monocyte-derived mesenchymal progenitors" (MOMPs) in the peripheral blood mononuclear cell fraction based on adherence to fibronectin-coated plastic plates [40]. The cells initially exhibited monocyte-like morphology and then acquired fibroblast-like morphology in culture. The cells are CD14+ CD45+ CD34+ Col I+ and can differentiate into osteoblastic, adipocytic, and myocytic cells using standard differentiation protocols [39]. Suda et al. corroborated these results and described the cells as a CD14+ CD34+ CD45+ CXCR4+ col I+ ALP+ Tie2+ population that formed heterotopic bone *in vivo* upon implantation in immune-deficient mice [15]. Similar approaches have been reported to isolate stem cells with wide differentiation potential from peripheral blood

monocytic cells [41, 42]. Thus, MOMPs and fibrocytes seem to be identical cell populations.

WHAT ARE THE POSSIBLE PHYSIOLOGIC AND PATHOLOGIC FUNCTIONS OF COP CELLS?

Several studies have suggested that COP cells participate in a number of physiological processes including long bone development and fracture healing. The number of OCN+ COP (plastic nonadherent) cells in the circulation of adolescent boys is more than five times as many as found in adults, and their number correlated with serum levels of insulin-like growth factor (IGF) I and IGF-binding protein 3 [28]. Also, Eghbali-Fatourechi et al. reported an increase in the number of circulating OCN+ COP cells in three men following recent fractures [28]. Similarly, circulating plastic-adherent COP cells (MSC-like, CD105+, CD73+, CD90+, CD45–, CD14–) were detected in peripheral blood from 22% of patients with hip fractures, 46% of younger patients with fractures, but not in an age- and sex-matched group of women with hip osteoarthritis [43].

Animal studies have provided supportive data for these findings in humans. In the above-mentioned studies of Kumagai et al., where parabiotic animals were formed by surgically conjoining transgenic mice constitutively expressing GFP and syngeneic WT mice, a transverse fibular fracture was created in the contralateral hind limb of the conjoined WT partner and assessed for the contribution of circulating cells to the fracture callus [6]. Based on analysis of GFP+ cells and colocalization of ALP staining, histomorphometric analysis of the fracture callus revealed a significant increase of GFP+ ALP+ cells after 2 and 3 weeks post fracture compared to nonfractured controls. Interestingly, bone healing assessed by biomechanical, radiological, and histological criteria was significantly enhanced by human CD34 cell transplantation in a nonhealing femoral fracture model in nude rats [37] and by plastic-adherent murine MSC-like and CXCR4+ cells injected in a tibia fracture mouse model [44].

It has also been suggested that COP cells participate in the pathogenesis of heterotopic ossification (HO), which can take place in pulmonary, vascular, cardiac, and periarticular soft tissue sites. Strong evidence exists that suggests that circulating fibrocytes are mediators of pulmonary fibrosis [45], so it is also plausible that fibrocytes can mediate both fibrosis and ossification in the lung. There is also increasing evidence that COP cells participate in HO following hip arthroplasty, in end-stage aortic valvular disease, and in a genetic syndrome of extraskeletal bone formation [15, 46, 47]. Animal models of ectopic bone formation also support the notion of COP cell involvement in lesion formation [11, 12, 15]. In FOP, patients with active episodes of extraskeletal bone formation have higher numbers of clonally derived COP cells than patients with stable disease or unaffected individuals, and these COP cells are present in early fibroproliferative lesions [15].

The process of vascular calcification was formerly considered the result of passive calcium deposition but is now recognized to be an active pathophysiologic process resulting in *de novo* bone formation in the late stages. Ossification is present in about 13–15% of carotid endarterectomy and stenotic aortic valve specimens [48,49]. The detection of COP cells in patients with end-stage aortic valve disease suggests that these cells are involved in the process of vascular ossification where there is preexisting calcification [46]. This observation is also supported by reports showing that levels of OCN-positive cells are elevated in patients with peripheral arterial disease and that expression of osteocalcin in endothelial progenitor cells is increased in patients with coronary artery disease [50, 51]. Ossified lesions in vascular disease develop in the setting of injury and inflammation, suggesting that ectopic ossification, regardless of location, shares similar initiating events.

Recent data also suggest that COP cells may reflect changes in bone remodeling due to metabolic bone disease. OCN+ COP cells were lower in patients with hypoparathyroidism compared to controls, and PTH (1-84) administration increased the number of COP cells threefold [52]. COP cells in patients with osteoporosis have been reported to increase, but their osteogenic differentiation is defective [53].

COP CELLS: A SYNTHESIS

The above experimental evidence suggests that COP cells are heterogenous populations of cells that span a continuum of phenotypes from hematopoietic cells to plastic-adherent stromal cells with several intermediate forms (Fig. 14.1) and reflecting functional heterogeneity. In both physiological and pathophysiological processes where COP cells may play etiological or ancillary roles, a common mechanistic link may be homing to sites of injury, inflammation, or relative hypoxia. In individuals undergoing normal physiologic growth or repair of bone tissue, COP cells may be recruited to target tissues by inflammatory signals, such as during fracture repair, or by signals released from a hypoxic microenvironment, such as the growth plate during long bone development. For example, a possible explanation for elevated levels of COP cells during pubertal growth may be formation of an oxygen gradient associated with intense remodeling, and as suggested by Canalis [54], the possibility that circulating osteogenic cells then return to the skeleton where they may function as mature osteoblasts.

The basis for the homing of COP cells to areas of injury and inflammation is best described for heterotopic ossification. Extraskeletal bone formation can be precipitated by soft tissue injury in skeletal muscle, causing the presumptive release of inflammatory cytokines and

migratory factors (Fig. 14.2). Inflammatory signals appear to be necessary for BMP-induced HO, and cells of the monocyte lineage appear to be necessary for triggering ectopic bone formation following injury [55].

In an inflammatory milieu, stromal cell-derived factor-1 (SDF-1) and BMP may serve as important chemoattractant molecules [45, 56, 57]. It is well documented that SDF-1 (CXCL12) is induced by hypoxic tissue injury and forms a gradient that attracts cells expressing its cognate receptor CXCR4. Release of COP cells from bone marrow and their homing to sites of injury may thus occur through CXCR4 (Fig. 14.2). This homing mechanism is established in fibrocyte localization to lesions of pulmonary fibrosis [45]. It is also established in a mouse model of BMP2-induced HO, where osteoprogenitor cells expressing CXCR4 migrate from the bone marrow to regions of ectopic bone formation by SDF-1 chemoattraction [11, 12]. BMP may play roles in both bone formation as well as in attraction of inflammatory cells [58].

The SDF-1/CXCR4 axis may be the final common pathway for mobilization of bone marrow-derived progenitor cells by hypoxia, angiogenic peptides, inflammatory cytokines, and injury [59–61]. This axis has been implicated in processes as diverse as development, regeneration, and tumorgenesis/metastasis. It is not so surprising then that the same homing mechanism may be involved in COP cell mobilization and targeting.

CONCLUDING REMARKS

Several key concepts appear to be generally true regarding the physiological functions of COP cells. The first is that the bone-forming function of COP cells may not be their primary role but is an adaptive response in conditions of injury, repair, or abnormal cytokine signaling. The ultimate fate of COP cells may be to participate in tissue regeneration that under certain circumstances dictates *de novo* bone formation. A corollary of this hypothesis is that local MSCs serve as the primary osteochondro progenitors, whereas COP cells likely play a role in bone formation at nonskeletal sites and during tissue injury, e.g., fracture healing.

Second, COP cell homing may be mediated by the CXCR4/SDF-1 axis that is shared by multiple processes requiring the migration of stem cells. COP cells may share a common mechanism for progenitor cell migration, especially given that their putative roles are likely precipitated by injury and inflammation.

Finally, the burgeoning area of COP cell biology holds promise for development of gene and cell therapy protocols to enhance bone formation as well as diagnostic tests based on COP cell levels as a biomarker for disease states.

INTRODUCTION

Our understanding of human bone development, especially that occurring *in utero*, has been greatly accelerated through the analysis of animal models. However, direct studies of human bone development are still invaluable because pathological and genetic findings from human bone disorders have been extremely important for generating novel hypotheses, validating model organism studies, and uncovering new mechanisms for bone development. Moreover, not all human conditions can be recapitulated by animal models. In this chapter, we will focus on human data related to the physiology of fetal and neonatal bone development and the intrinsic and extrinsic factors that lead to fetal and neonatal bone disorders.

PHYSIOLOGY OF FETAL AND NEONATAL BONE DEVELOPMENT

At the beginning of human fetal development (8 weeks post fertilization), the patterning of skeleton has been largely determined. Compared to the earliest fetus, newborns are approximately 12 times longer in body length (30 mm vs 360 mm in crown-rump length). Hence, the major theme of bone development during the fetal stage is very rapid growth. For example, the rate of femur elongation during gestation between 16 and 41 weeks is 0.35 mm per day on average [1]. Ossification is an important component of bone development and growth, and it involves the coordination of osteoblast differentiation, matrix production, mineralization, and vasculogenesis. Studies have shown that the majority of bones commence ossification during the first several weeks of the fetal stage and that there is a sequential appearance of ossification centers in each individual bone. For example, the ossification of clavicle, humerus, and mandible occur during the embryonic stage (6 or 7 weeks). In contrast, the ossification of the talus or cuboid starts late at 28 weeks or after birth [2]. In order to maintain bone shape while accommodating rapid growth, the progression of ossification must be tightly coupled with bone resorption, and this is mediated by osteoclasts acting both inside and outside the bone. This bone remodeling begins during the fetal period and becomes prominent by the fourth and fifth months of gestation[2].

To adapt to the rapid growth and ossification of the fetal skeleton, a fetus requires a large quantity of building blocks, including proteins and minerals. These substances are transported against a concentration gradient across the placenta from the mother. More than 150 g of calcium and 70 g of phosphorus per kilogram of fetal body weight are transferred via active transport during the third trimester [3]. The actual steps of mineral transport are not completely understood. It has been proposed that calcium is transported across the placenta via a three-step model. TRPV6, a voltage-dependent calcium channel, is present on the maternal side of the placenta.

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

Some studies have suggested that this channel transfers calcium to calbindin D9K, which is an intracellular binding protein in trophoblastic cells. Finally, calcium is transferred via PMCA3, a plasma membrane calcium–ATPase protein on the basolateral membrane to the fetal bloodstream [4–6]. Transport of phosphorus across the placenta is less well understood, but NaPi-IIb, a sodium-dependent inorganic phosphorus transporter, is believed to play an important role in transplacental phosphorus transport [7].

The primary hormone responsible for the active transport of minerals across the placenta to the fetus is parathyroid hormone related peptide (PTHrP) [8]. The fetus, placenta, umbilical cord, and breast tissue produce this hormone. Mice lacking PTHrP exhibit lethal skeletal dysplasia characterized by premature mineralization of all bones that are formed through an endochondral process. In the placenta, it is known to act through a receptor distinct from PTH1R [9]. On the other hand, parathyroid hormone (PTH) and vitamin D, the two critical hormones for maintaining calcium and phosphorus homeostasis in adults, are present at low levels in fetal serum, which may be a response to high serum calcium levels [10]. PTH is important in the mineralization of fetal bones but not in active transport of calcium across the placenta. Similarly, vitamin D does not have a major role in mineral transport, although maternal vitamin D deficiency has been associated with congenital rickets [11]. Calcitonin, on the other hand, may not play a major role in fetal bone development as seen in calcitonin or calcitonin gene related peptide ablated mice [12]. Other hormones that play a role in skeletal health during adulthood, such as growth hormone and cortisol, have been shown to influence birth weight and weight gain during infancy. Furthermore, levels of growth hormone and cortisol were found to be determinants of prospective bone loss rate. This is compatible with the hypothesis that environmental influences during intrauterine life may alter sensitivity of the skeleton to growth hormone and cortisol [13].

After birth, the skeleton maintains a fast rate of growth and requires substantial mineral input to support bone development. Different from the fetus whose calcium level is higher than that in its mother's serum, the newborn exhibits a reduced calcium level, rapidly reaching a base level because the placental source is removed; concomitantly, the PTH level rapidly rises. The neonate becomes dependent on intestinal calcium absorption and the primary hormones responsible for maintaining serum calcium levels are PTH and vitamin D. Skeletal calcium is stored, and renal calcium is reabsorbed to maintain these serum levels. Prematurity, small size for gestational age status, maternal vitamin D deficiency, and maternal diabetes make the calcium nadir more dramatic. During infancy, a phase of rapid bone mineralization, vitamin D deficiency can lead to rickets and hypocalcemia. Hence the American Academy of Pediatrics recommends supplementing all infants with 600 IU of vitamin D daily.

EXTRINSIC FACTORS THAT AFFECT FETAL/NEONATAL BONE DEVELOPMENT

Nutritional influences

Maternal nutrition during pregnancy influences fetal nutrition. Animal models show that a low protein diet during pregnancy leads to low bone area and bone mineral content with altered growth plate morphology in adult rats [14]. In addition, neonatal bone mass was found to be strongly and positively associated with birth weight, birth length, and placental weight, after adjusting for sex and gestational age, indicating the importance of maternal nutrition during pregnancy [15]. There are also studies suggesting that genetic influences on bone mineral density (BMD) and adult bone size may be modified by undernutrition *in utero* [16].

Mechanical influences

Fetal movement *in utero* is a form of mechanical stimulation against resistance, which leads to mineral accretion. The importance of muscle–bone interaction (probably regulated by a network of osteocytes) *in utero* is evident in newborns with muscular disease or hypotonia as they have a lower BMD [17]. Physiological osteoporosis of infancy, a condition of decreased cortical density, presents within 6 months following birth. Although it is mainly attributed to expansion of the bone marrow cavity size [18], lack of resistance in movement after delivery may also be a contributing factor [17]. Whether this is of clinical significance is controversial.

Environmental influences

Approximately 1 in 1000 live births is affected with axial skeletal defects. Many toxins and drugs have been implicated in its etiology, including retinoic acid, valproic acid, arsenic, and carbon monoxide. These can lead to vertebral body defects such as block vertebra and nonsegmented hemivertebra. Uncontrolled maternal diabetes mellitus can cause fetal skeletal defects, specifically caudal dysgenesis along with neonatal hypocalcemia by mechanisms not completely understood [19]. Rats with uncontrolled diabetes have decreased calbindin mRNA in the placenta; this could explain decreased calcium transport across the placenta [20]. In addition, maternal smoking has been associated with decreased numbers of ossification centers, and maternal alcohol consumption affects calciotropic hormones and thus can cause fetal bone defects [19].

Other influences

Seasonal variation has been shown to influence newborn bone mineral content (BMC), possibly due to the effect

on maternal vitamin D levels. Prematurity and small gestational age status are also associated with increased risk of rickets and osteoporosis due to multiple factors including hypoxia, immobility, and decreased mineral supply/intake. In addition, gender and race appear to play a role. In some studies, BMC for male newborns was higher than females and higher for African-American newborns than for Caucasian newborns [21].

INHERITED FETAL/NEONATAL BONE DISORDERS

Multiple signaling and metabolic pathways are involved in fetal bone development, and the identification of human mutations has served as a major guide for uncovering these signaling pathways and mechanisms. Although genetically related dysregulation of these pathways can eventually lead to human skeletal diseases, many of them are difficult to diagnose in newborns. This is because the milder spectrum of diseases may not cause pronounced deformity of the skeleton, and the clinical consequences of abnormal bone mass, such as fracture, may not be evident given the relatively mild mechanical loading in the fetal or neonatal stages. Here we have selected several examples of severe bone diseases that underscore key developmental processes affecting fetal and neonatal bone development to review.

Defects in bone matrix production

Osteogenesis imperfecta (OI) is a group of inborn bone diseases in humans characterized by brittle bones. The most severe forms of OI can lead to bone fractures and lethality in fetuses and neonates. Etiologies of these severe OIs are related to abnormal production, post-translational modification, or metabolism of fibrillar collagens, especially type I collagen, which are the major substrate of bone matrix. For example, dominantly inherited point mutations in *COL1A1* and *COL1A2*, encoding the proa1(I) and proa2(I) chains of type I collagen, lead to post-translational overmodification of collagen chains and severe forms of osteogenesis imperfecta (types II and III) [22]. More recently described recessive mutations in genes that are important for modification or trafficking of type I collagen also cause OI. These genes (and the corresponding gene products) include *CRTAP* (cartilage associated protein) [23], *LEPRE1* (prolyl 3 hydroxylase 1) [24], *PPIB* (cyclophilin B) [25], *FKBP10* (FK506 binding protein 10) [26], *SERPINH1* (heat shock protein 47) [27], and *SERPINF1* (pigment epithelial derived factor) [28].

Defects in mineral homeostasis

Recessive inactivating mutations of the calcium sensing receptor gene (*CASR*) are the cause of neonatal severe primary hyperparathyroidism (NSHPT) [29, 30]. This disease is characterized by extreme hypercalcemia and severe neonatal hyperparathyroidism, including demineralization of the skeleton, respiratory distress and parathyroid hyperplasia. Without prompt parathyroidectomy of the affected infants, NSHPT is usually lethal. In contrast, familial hypocalciuric hypercalcemia (FHH), caused by haploinsufficiency of *CASR*, affords a much milder hypocalcaemia and does not exhibit the complexity of hyperparathyroidism.

Defects in mineral deposition

Perinatal and infantile hypophosphatasia is a pernicious inborn metabolic disease manifesting *in utero* with profound hypomineralization that results in caput membraneceum, deformed or shortened limbs, and rapid death due to respiratory failure. Infantile hypophosphatasia is caused by recessive mutations in the gene encoding tissue-nonspecific iso-enzyme of alkaline phosphatase (*TNSALP*), a glycoprotein localized to the plasma membranes of osteoblasts and chondrocytes that hydrolyzes monophosphate esters at an alkaline pH optimum [31]. The deficiency of *TSNALP* activity leads to extracellular accumulation of inorganic pyrophosphate (PPi), which potently inhibits growth of hydroxyapatite crystal and causes severe hypomineralization in the infant's bone [32]. Haploinsufficiency of *TNSALP* also causes hypophosphatasia, but in a milder manner, usually diagnosed later in life.

Defects in osteoclastic function

Infantile malignant osteopetrosis (IMO) is a group of severe autosomal recessive osteopetrosis. The affected bones become very brittle, although bone mass is markedly higher than normal. IMO arises in the fetal stage; thus fractures of the clavicle can be found during delivery and frequent bone fractures occur during infancy. The affected infants suffer from hypocalcemia. Moreover, due to defective osteoclastic function, the bone marrow space that accommodates hematopoiesis is gradually diminished. Hence, if not properly treated in the first year, most of affected infants develop anemia and thrombocytopenia because of encroachment of bone on marrow [33]. Genetically, IMO is caused by mutations in the genes important for osteoclast activity. The bone resorption of osteoclasts primarily relies on the acidification of bone resorption lacuna. Hence, defects in the machinery for acid secretion, such as that caused by mutations in either *CLCN7* or *OSTM1* (*CLCN7* encodes the chloride channel 7, which complexes with and is stabilized by the *OSTM1* gene product, the osteopetrosis-associated transmembrane protein 1) or in *TRCIRG1* (encoding T cell immune regulator 1, a subunit of a vacuolar proton pump) have been identified in the osteoclast-rich IMO patients [34–37].

Defects in cranial suture closure and osteogenesis

The skull of neonates is composed of separate cranial bones connected by fibrous cranial sutures (fontanels). These sutures provide flexibility for the skull to facilitate its passage through the birth canal without damaging the infant's brain. Moreover, cranial sutures contain osteogenic mesenchymal cells, serving as important sites for cranial bone growth to adapt to the rapid brain growth of infancy [38, 39]. The fusion of cranial bones normally starts after infancy and completes by adulthood. Disorders characterized by delayed or premature closure of cranial sutures are not rare in newborns. Cleidocranial dysplasia (CCD) patients have persistently open and unossified skull sutures. This is caused by a haploinsufficiency of Runx2, a master gene that regulates multiple steps of osteoblast differentiation [40–42]. In contrast, premature suture closure leads to craniosynostosis, which can severely restrain growth of the skull, thus leading to increased intracranial pressure that can severely impair neural development [38]. The etiologies of craniosynostosis include dominant activating mutations in the FGF receptors (*FGFR1*, *2*, and *3*) [43–46] or haploinsufficiency of *TWIST1* [47, 48]. Mutations in *MSX2* [49], EFNB1 [50], Gli3 [51], *RAB23* [52], *POR* [53], and *RECQL4* [54] have also been identified in some rare types of craniosystosis.

INTRODUCTION

The magnitude of the variance of bone traits such as bone mass and size around their age-specific mean is large; 1 standard deviation (SD) is about 10–15% of the mean. Thus, individuals at the 95th and 5th percentiles for bone size differ by approximately 50%. The variance in the rate of bone loss is about an order of magnitude less (1 SD = 1% of the mean), so differences in the percentile location of bone traits established at the completion of growth are likely to be more important determinants of fracture risk in adulthood than differences in the rates of bone loss over many years [1].

Whether trait differences appear during intrauterine life or postnatally is uncertain, but whatever the timing, trait variances are established well before puberty and probably within the first 2 years of life [2, 3]. For example, Wang et al. reported that the magnitude of variance in tibial cross-sectional area (CSA) and cortical volumetric bone mineral density (vBMD) in prepubertal children was no different from their premenopausal mothers [3]. However, variance in cortical vBMD, a function of the degree of bone matrix mineralization and intracortical porosity, decreased in the adolescent years, suggesting that bone's material composition becomes more similar among individuals as maturity is reached [2, 4]. If so, then variance in bone strength is more likely to be due to differences in bone structure than material composition.

Even though trait variance are largely genetically determined, we found no evidence that ranking in femur length occurred *in utero*; only 7% of the variance in the percentile location of femur length at birth was predicted by the percentile location in earlier gestation [5]. Studies by Wang et al. suggest that morphology at puberty and adulthood is predicted by morphology after 6 months of age, not at birth [6]. Tracking appeared to become established during the first year of life [7].

For example, Wang et al. report crown-heel length (CHL) in infants at 6 months and thereafter, but not at birth, predicted body height, bone size, mass, and strength almost 2 decades later and predicted these traits in their parents [6]; CHL or height then tracked in a trajectory of growth from 6 months of age through adolescence to adulthood. This also applied to bone traits such as total and regional bone mass and size, tibial and radial cross-sectional area, and indices of bending and compressive strength first measured at 11.5 years of age and then during 7 years to maturity at 18 years of age. These observations suggest that the location of an individual's skeletal trait relative to others, and the familial resemblance of bone traits at maturity, appear during the first year of postnatal life.

Loro et al. report that the percentile ranking of traits at Tanner stage 2 was unchanged during 3 years and 60–90% of the variance at maturity was accounted for by the variance before puberty [2]. Thus, an individual with a larger vertebral or femoral shaft cross section, or higher

vertebral vBMD, or femoral cortical area than their peers of the same age before puberty retained this relative position to maturity.

Cheng et al. reported that ranking of total body bone mineral content (BMC) was maintained during 7 years follow-up in adolescence [8]. Emaus et al. reported distal and ultra distal radial bone mineral density measured by single-energy X-ray absorptiometry tracked during 7 years follow-up in 5,366 women and men aged 45–84 years [9]. Healthy premenopausal daughters of women with spine or hip fracture have structural abnormalities at the corresponding site [10]. Girls with forearm fractures during puberty have reduced distal radius vBMD before puberty, and this deficit in vBMD persisted into young adulthood [11].

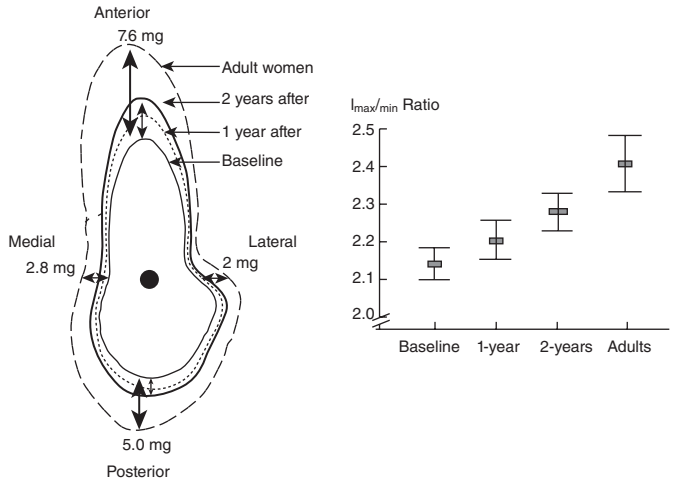

Fig. 16.1. Bone mass distribution around the bone center (the black dot in the center of the bone). Focal periosteal apposition varied from site to site around the bone perimeter. More bone was deposited at the anterio–posterior (AP) regions than at the medio–lateral (ML) regions, increasing the ellipticity and bending strength more along the AP axis (Imax) than the ML axis (Imin) (Ref. 3; reproduced with permission from The Endocrine Society).

MODELING AND REMODELING AND BONE'S EXTERNAL SIZE, SHAPE, AND INTERNAL ARCHITECTURE

Bone modeling assembles bone size and shape according to a genetic program; fetal limb buds grown *in vitro* develop the shape of the proximal femur so the variance in bone shape is largely determined by genetic factors. Bone modeling also adapts a bone's size, shape, and the spatial distribution of its mineralized mass to the prevailing loads [12–14]. Differences in bone size in the playing arm and nonplaying arm of tennis players attest to the ability of periosteal apposition to adapt a structure to its loading circumstances during growth) [15, 16]. Comparable effects of exercise begun in adulthood have never been reported.

In prepubertal girls, tibial cross-sectional shape is already elliptical at 10 years of age [3]. Within 2 years, periosteal apposition increased ellipticity by adding twice the amount of bone anteriorly and posteriorly rather than adding it medially and laterally (Fig. 16.1). Consequently, estimates of bending strength increased more in the antero–posterior (Imax) than medio–lateral direction (Imin). Resistance to bending increased by 44% along the principal axis (Imax) with a 22% increase in bone mass.[3]

Greater periosteal apposition on the anterior and posterior surfaces than medial and lateral surfaces creates the elliptical shape of the tibia and demonstrates how strength is optimized and mass minimized by modifying the spatial distribution of the material rather than using more material. If cortical thickness increased by the same amount of periosteal apposition at each point around the perimeter of a cross section, the amount of bone producing the same increase in bending resistance would be fourfold more than what is observed [3].

This is further illustrated by the heterogeneity in femoral neck shape (Fig. 16.2) [17]. At the junction with the shaft, the size and ellipticity of the femoral neck (FN) cross section is greatest and lessens moving proximally toward the midpoint. Then, the size increases but the shape becomes increasingly circular. This diversity in total cross-sectional size and shape, from cross section to cross section, is achieved using the *same* amount of material distributed differently in space at each cross section. The same amount of bone is assembled as a larger cross section, with mainly cortical bone adjacent to the femoral shaft and most of this cortical mass is distributed inferiorly. More proximally, the proportion of bone that is cortical decreases while the proportion that is trabecular increases. Cortices become thinner, and at the femoral head junction most of the bone is trabecular and the cortex is thin and evenly distributed around the perimeter. These structural features are likely to be partly adaptations to the differing loading patterns throughout the femoral neck.

Differing periosteal apposition at each point around the bone perimeter is accompanied by concurrent resorption on the endosteal or inner surface of the bone. In tubular bones lightness is achieved by endocortical resorption, which excavates the marrow cavity, shifting the thickening cortex outward; distance from the neutral axis increases the bone's resistance to bending [12]. Wang et al. reported that the amount of bone deposited in 2 years on the periosteal surface in prepubertal children with larger tibial cross sections was no different to the amount deposited on the periosteal surface of smaller cross sections [3]. Thus, larger bones deposited less bone *relative* to their starting cross-sectional size than did smaller bones. Larger bones also excavated a larger medullary canal by higher rates of endocortical resorption as reflected in those with the higher bone resorption marker tartrate-resistant acid phosphatase isoform 5b (TRACP).

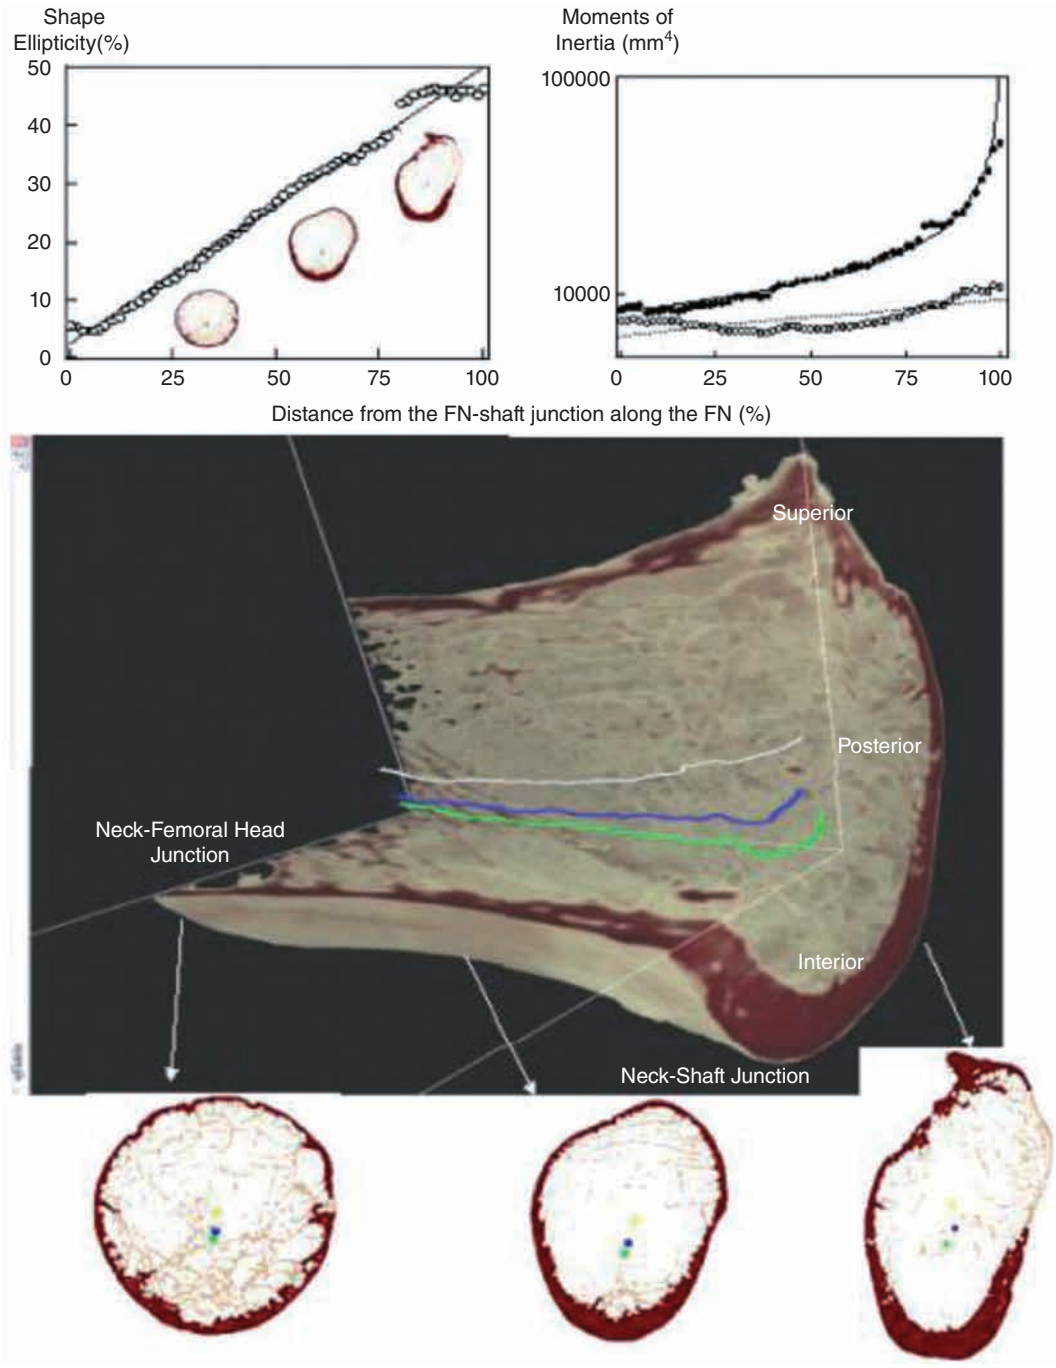

Fig. 16.2. Cross-sectional shape, size, and spatial distribution of the mineralized bone tissue mass, and geometric indices of strength of the femoral neck. From the femoral neck–head junction, there is a gradual shift of the external shape toward increasing ellipticity (upper left panel). Alongside this increasing ellipticity, there is an exponential increase in Imax (closed circles), the geometric index of strength orientated in the supero–inferior direction, while the changes in Imin (open circles), the strength in the antero–posterior direction, is minimal (upper right panel) (Ref. 17; reproduced with permission).

These individuals had a thinner cortex so larger bones were relatively lighter; they had a lower apparent vBMD [3]. Individuals with smaller tubular bone cross sections assemble them with relatively more mass forming a relatively denser bone. In bones with a smaller cross section, the vulnerability to fracture due to slenderness is offset by more periosteal apposition relative to their starting cross-sectional size and less excavation of the marrow cavity so that vBMD is greater [3]. A high peak vBMD is not the result of increased bone formation (which is

costly), it is the result of reduced bone resorption. (The resorption is not followed by formation and is a modeling, not remodeling.) Similarly, a lower vBMD is the result of more bone resorption not less bone formation.

SEX DIFFERENCES IN BONE MORPHOLOGY

Growth in stature is the result of differing contributions of appendicular and axial growth. Appendicular growth continues at a greater rate (approximately 2 times) than axial growth until the onset of puberty at which time appendicular growth decelerates while axial growth accelerates [18–21]. At the first 2 years of puberty (11–13 years of age in girls and 13–15 in boys), the contribution of axial and appendicular growth to the standing height is similar (7.7 vs 7.4 cm in girls and 8.5 vs 8.0 cm in boys), while in the late pubertal stage, the increase in standing height is more derived from axial than appendicular growth (4.5 vs 1.5 cm in both sexes) [18–21]. Males may have a larger skeleton at birth and have a 1–2 year longer prepubertal growth than females because puberty occurs later in males.

Before puberty, bones do not differ in length between the sexes but are wider in males than females in some studies, but not in others [22, 23]. This difference in bone widths are likely to originate *in utero* or the first half-year of life, perhaps because of exposure to sex hormones [24]. Sex differences in bone length, width, mass, and strength emerge largely during puberty.

During puberty, periosteal apposition increases bone width while endosteal resorption enlarges the medullary cavity in boys [25, 26]. Cortical thickness increases because periosteal apposition is greater than endocortical resorption. In girls, periosteal apposition decelerates earlier, and there is no change in medullary size in girls at some sites, but there is medullary contraction at other sites [4, 25–28]. The net effect of cessation of periosteal apposition and medullary contraction in girls is the construction of a bone with a smaller total and medullary size than in boys, but with a similar cortical thickness [26–30]. Estrogen at high levels in postpubertal girls likely promotes the endosteal apposition [31, 32].

At the metaphyses of long bones, vBMD of the trabecular compartment remains constant from 5 years of age to young adulthood in both sexes [33, 34]. At this region, sex differences in BMC, vBMD, and cross-sectional size emerge after puberty; males are reported to have thicker trabeculae and higher bone volume per unit total volume (BV/TV) [35, 36]. Further investigations are needed to confirm these observations.

As the size of the vertebral body increases during growth and the amount of bone within it increases, there is no increase in vBMD before puberty [37]. At puberty, trabecular vBMD increases in both sexes due to an increase in trabecular thickness, not number, but the increase is no different by sex [38]. The vertebral body cross section is approximately 15% larger in boys than in girls before puberty and approximately 25% greater at maturity, but there is no sex difference in trabecular number or thickness [39–42]. That is, the sex differences in morphology is in size, not density; vertebral total CSA, but neither vertebral height nor trabecular density, differs before puberty.

GROWTH OF METAPHYSES AND FRACTURES IN CHILDHOOD

Incidence of fracture, especially at the distal metaphysis of radius, peaks at 10–12 years of age in girls and 12–14 years in boy, coinciding with the pubertal growth spurt [43]. The rate of linear growth peaks earlier than that of bone mass. In particular, growth of the distal radius is more rapid at the distal metaphysis, and at this site, the longitudinal growth outpaces bone formation upon the surfaces of trabeculae emerging from the growth plate that thereby coalesce, forming the cortical bone of the metaphyseal region [44]. This is "corticalization" of the trabeculae, and the relative delay results in a transitory phase of porosity [28, 45]. The vBMD of the metaphysis decrease during puberty due to this transitory phase of porosity, which predisposes to fracture [4, 33, 46]. With increase in weight and bone length and decrease in vBMD, the safety factor or ratio of bone strength index (SSI) to the product of weight and bone length, decreases until later puberty and increases thereafter [47]. In contrast, vBMD of the diaphysis of long bone continues to increase during puberty, although slower in early than in later puberty [4].

The porosity and reduced cortical density in children is transitory. In late puberty, cortical porosity decreased and cortical vBMD increased at the end of growth [48]. This is the result of the slowing of longitudinal bone growth while the trabeculae coalescence continues as bone formation proceeds on trabecular surfaces (Fig. 16.3). Earlier exposure to sex steroids in peri- and postpubertal girls may enhance the consolidation of the metaphyseal cortex at the endocortical surface, decreasing the residual cortical porosity. This partly explains the higher cortical density in girls than boys [49, 50].

The wider metaphysis must be modeled to fit the relative slender diaphysis during longitudinal growth. Unlike the diaphysis where bone diameter increases by periosteal apposition, the metaphyseal cortex is resorbed on periosteal surface while bone formation occurs at the endosteal surface by trabecular coalescence [51]. This modeling by resorption on the periosteum and formation on the endocortical surface with transitory porosity as well as decreased cortical thickness during pubertal growth spurt, makes this region more susceptible to fracture due to stress concentration and buckling during a compressive stress in a fall onto the outstretched hand.

Trabecular structure dominates the volume of metaphyses. It is derived from the cartilage of growth plate (primary trabeculae). Following vascular invasion, osteo-

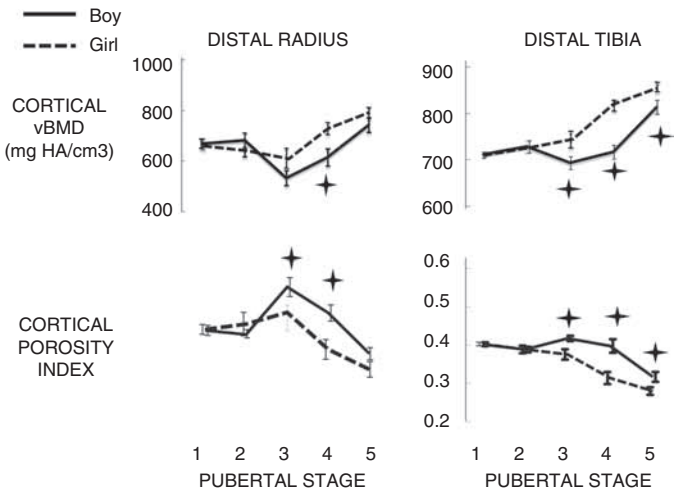

Fig. 16.3. Cortical vBMD and cortical porosity at the distal metaphyses of radius and tibia in girls (dashed line) and boys (solid line). Cortical vBMD is the lowest at Tanner stage III than earlier and later stages at the distal radius due to the rapid growth at this region (Ref. 44; reproduced with permission).

blasts deposit woven bone on the surface of calcified cartilage septa forming primary trabeculae. It is remodeled into thicker but more separated secondary trabeculae. There is little variance in the primary trabecular structural traits between children [52]. However, the subsequent remodeling of the primary trabeculae results in diverse trabecular architecture from individual to individual. Thicker and densely connected trabeculae are more easily coalesced. High trabecular BV/TV in girls predicted thicker cortices in their premenopausal mothers.[53]

The trabecular density at metaphyseal region in females is independent of age in childhood and adolescence. Using high-resolution peripheral quantitative computed tomography, we observed no increase in trabecular number, thickness, or separation at the distal metaphyses of radius or tibia in girls aged 5 to 18 years [44]. In contrast, trabecular vBMD in males increased during puberty, due to increased trabecular thickness without change in trabecular number. Thus, in young adulthood, males have thicker trabeculae but similar trabecular numbers relative to females. This sex difference may have important implication in later life when bone resorption occurs. In females, thin trabeculae are more readily perforated.

EFFECT OF ILLNESSES ON BONE MORPHOLOGY IS MATURATIONAL STAGE–SPECIFIC

Appendicular and axial growth differ, with the former preceding the later; the tempo of growth in bone size and mass also differs. Therefore, the effects of illness during growth depend on the maturational stage at the time of disease exposure, not just the severity of the illness. As longitudinal growth is more rapid in the appendicular than the axial skeleton before and during early puberty, illness may produce greater deficits in appendicular morphology. For example, disease affecting radial growth before puberty and especially during early puberty, compromises the gain in bending strength [54, 55]. Illness during late puberty may produce greater deficits in the axial than in the appendicular morphology, while in postpuberty is unlikely to produce deficits in external morphology [28]. This regional specificity in growth and the effects of illness are obscured by the study of standing height or BMD alone.

Diseases leading to sex hormone deficiency in females during puberty produce loss of sexual dimorphism in leg length as estrogen deficiency allows continued growth in females so the epiphyses do not fuse, and periosteal apposition continues. Periosteal apposition continues increasing bone width while endocortical apposition fails to occur. Cortical thickness is reduced, but only modestly, and the bone is wider. In contrast, the pubertal growth spurt in trunk length may be affected, creating a shorter but wider vertebral body and a shorter sitting height [56–58]. Delayed puberty in males reduces periosteal apposition, producing a narrower bone with a thinner cortex, while appendicular growth in length continues and produces a longer, more slender bone with a thinner cortex predisposed to greater fragility in males than in females. The greater bone diameter in females with delayed puberty produces a biomechanical advantage and less cortical thinning because the lack of endocortical apposition is offset by continued periosteal apposition [59–62].

SUMMARY

Skeletal fragility has its antecedence during growth because the variance in bone traits achieved during growth is an order of magnitude greater than the rates of loss during aging. Thus, factors that modify skeletal morphology, such as exercise and nutrition, are likely to be best instituted during growth. Metaphyseal trabecular morphology predicts both trabecular and cortical morphology and remains largely unchanged from early in life to young adulthood. Advances in imaging allow us to quantify the material composition and microstructure of bone, opening the door to quantifying the determinants of bone strength so that persons at risk for fracture can be identified and offered treatment.

South Africa: A Case Study 138
Summary 138
References 139

Bone acquisition during childhood and adolescence is a critical time to maximize peak bone mass, which has been shown to occur by the end of the second or early in the third decade of life [1]. Although it is widely accepted that peak bone mass is an important determinant of future bone health and fracture risk, there is also evidence that bone mass achieved during childhood influences fracture rates during adolescence [2, 3]. A number of genetic and environmental factors play important roles in determining the rate and magnitude of bone acquisition during the early years. These factors include nutritional status, such as dietary calcium and protein intakes [4], growth rates [5], and the rate and timing of pubertal development [6]. Ethnicity is also an important factor determining not only peak bone mass, but also fracture rates during childhood and adolescence [7] and in later life [8].

A significant variation in the incidence of hip fractures exists among different communities across the world and among different ethnic groups. The highest incidence of hip fractures has been reported in Scandinavia, with a reported age standardized hip fracture rate of 920 per 100,000 per annum in Norwegian women, and the lowest in Africa, at 4.1 per 100,000 persons over 35 years of age in women living in Cameroon [9, 10], and 4.5 and 4.2 fractures per 100,000 per annum for black South African men and women, respectively [8]. Similarly in the United States of America, osteoporotic fractures are less common in African-Americans and occur later in African-American, Asian, and Hispanic populations than in non-Hispanic white populations [11]. Recently, studies conducted in South Africa have shown that fracture rates in blacks during childhood and adolescence are less than half those found in whites of the same age [7].

Understanding the role that genetic and environmental factors play in determining bone mass within ethnic groups in different geographical locations is key in identifying risk factors for fracture and osteoporosis in different populations. Some evidence suggests that the region of residence early in life is more closely associated with the variation in hip fracture incidence than the current region of residency [9, 12]. Within some countries, such as South Africa, it has been reported that the contribution of lifestyle and socioeconomic factors to bone mineral density differs between ethnic groups [13], but despite these differences the overriding contribution of genetics cannot be underestimated. In order to identify the predictors of skeletal health in adults, in particular peak bone mass, understanding ethnic differences in mineral metabolism and bone mass acquisition is an important research area.

ETHNIC DIFFERENCES IN BONE AND MINERAL METABOLISM

Bone turnover rates and urinary calcium excretion have been measured in various ethnic groups in an attempt

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

to understand differences in bone mineral density and fracture incidence. The majority of studies have been conducted comparing black and white ethnic groups. Adult studies in the U.S. show equivocal results, with some studies showing lower bone turnover in African-Americans compared to Caucasians [14, 15], while others have shown no difference [16]. In South Africa, using iliac crest bone histomorphometry, it has been suggested that black adults have a higher bone turnover than white adults [17]. Differences in calcium absorption, serum 25-hydoxyvitamin D and 1,25-dihydroxyvitamin D levels, and urinary calcium excretion between ethnic groups have been explored in children and adolescents [18–23]. Some studies have shown greater fractional absorption of calcium, lower urinary calcium excretion, and therefore higher calcium retention, in African-American compared to Caucasian girls. A similar study in Caucasian and Mexican-American children, none of whom were vitamin D deficient, found higher parathyroid hormone (PTH) and lower 25(OH)D concentrations in the Mexican-American girls, although these differences did not significantly affect calcium absorption, excretion, or bone calcium kinetics [19]. Many of these comparative studies are difficult to interpret because of differences in habitual calcium intakes and vitamin D status between the groups, which themselves influence intestinal calcium absorption, bone turnover, and urinary calcium excretion.

ETHNIC DIFFERENCES IN BONE ACQUISITION, MASS, AND GEOMETRY

Ethnic differences in bone mass have been well described in the literature and clearly show that axial and appendicular bone mass is greater in African-Americans compared to Caucasians [24–27] (see Table 17.1). These findings have led to the generalization that African population groups have greater bone mass and strength compared to Caucasian population groups, and these data have been used as an explanation for the very low fracture rates observed in Africa. Although there are few studies comparing bone mass among children and adolescents of different ethnic groups in other countries, it is clear that black children and adolescents in South Africa and the Gambia do not show the consistently greater bone mass at all sites that is seen in countries such as the U.S. In South Africa, black children have higher bone mass at the hip but not at other sites, while in the Gambia, black children had lower radial bone mineral content than U.K. white children [28–32]. These data illustrate the difficulty in generalizing about an ethnic group, when obvious ethnic gradations in bone mass exist. Similarly, when comparing 9-year-old black South African children to U.S. children of a similar age, after adjusting for age, sex, and body size, whole body bone mineral content (BMC) was significantly higher in the South African group compared to U.S. children [29]. These differences between the same "ethnic" group living in different geographical areas possibly provides evidence that environmental factors have a significant influence on bone mass.

Pediatric studies using computed tomography indicate that, regardless of sex, ethnicity has significant and differential effects on the density and the size of the bones in the axial and appendicular skeletons [33]. In the axial skeleton, the density of cancellous bone in the vertebral bodies is greater in African-American than in U.S. Caucasian adolescents, with the magnitude of the increase from prepubertal to postpubertal values being substantially greater in African-American than in Caucasian subjects (34% vs 11%, respectively). This difference, which first becomes apparent during late stages of puberty then persists throughout life [34]. The cross-sectional areas of the vertebral bodies, however, do not differ between African-American and Caucasian children [33]. Thus, theoretically, the structural basis for the lower vertebral bone strength and the greater incidence of fractures in the axial skeleton of Caucasian subjects resides in their lower cancellous bone density, which probably reflects a smaller number or thickness of cancellous trabeculae. In contrast, in the appendicular skeleton, ethnicity influences the cross-sectional areas of the femora, but not the cortical bone area nor the material density of cortical bone [33]. Although values for femoral cross-sectional area increase with height, weight, and other anthropometric parameters in all children, this measurement is substantially greater in African-American children [33]. As the same amount of cortical bone placed further from the center of the bone results in greater bone strength, the skeletal advantage for African-Americans in the appendicular skeleton is likely the consequence of the greater cross-sectional size of the bones [35]. Data from Asian and Hispanic youth suggest that their bone mass is similar to that of Caucasians, but lower than that of African-American children [36]. Differences in bone and body size account for much of the observed ethnic differences in bone mineral density (BMD) among non-Hispanic, Hispanic, and Asian children [36], and similarly in South African children, site-specific bone length predicts bone mass better than height, with black children having greater regional segment lengths than white children [5].

More recently peripheral quantitative computed tomography (pQCT) has been used to compare measures of volumetric density and bone geometry at appendicular bone sites between ethnic groups in children [37–40] and adults [41–43]. A comparison between 10-year-old African-American, Hispanic, and Caucasian children revealed greater bone strength in the African-American and Hispanic children compared to Caucasian children, as a result of greater volumetric density and cortical area at the 50% tibia and radius sites, after adjusting for differences in age, sex, tibial length, and tibia muscle cross-sectional area [38]. Leonard et al., in a recent cross-sectional study [40], suggest that ethnic differences may

be maturation-dependent as they showed that after adjusting for a number of covariates, polar section modulus was 13.4% higher in the African-American group compared to the Caucasian group in Tanner stage 1, but decreased to only 2.5% higher in Tanner stage 5. Recent South African data have shown ethnic differences in bone size and strength in 13-year-old black children compared to white children at the 38% tibia, a predominantly cortical site, but not at the metaphyseal sites that are predominantly composed of trabecular bone [37]. These findings are consistent with the ethnic differences that have been found using dual-energy X-ray absorptiometry (DXA) when comparing South African black and white adults and children in that differences have been shown at the hip, a predominantly cortical site, but not at the lumbar spine, a predominantly trabecular site.

Data comparing pre- and postmenopausal Chinese-American and white women using high-resolution pQCT has provided additional information on skeletal microarchitecture to help understand why the fracture rate in Chinese women is lower than white women despite lower BMD as measured by DXA [41, 42]. Trabecular and cortical bone density as well as trabecular and cortical thickness were greater in the premenopausal Chinese women compared to their white peers before and after adjusting for covariates [41], and these and other microarchitectural advantages appear to be maintained with aging in Chinese women [42].

ETHNIC DIFFERENCES IN DIETARY CALCIUM AND BONE MASS

Data from Croatia suggest that dietary calcium intake does influence peak bone mass, and that these differences are present at 30 years of age, indicating that the effects of dietary calcium probably occurred during growth rather than in adulthood [44]. Moreover, some epidemiological studies have shown an increased prevalence of osteoporosis in regions where dietary calcium intake is extremely low [45]. Yet the converse is also true with the prevalence of osteoporosis and hip fracture being reported to be highest in those countries (Scandinavia) whose national average dietary calcium intakes are among the highest in the world [46].

There is evidence that a plateau threshold for calcium intake exists above which additional calcium does not increase bone mass. This threshold for adolescents is approximately 1,600 mg/day, but calcium retention is influenced by body size [47], which has been shown to differ between ethnic groups in South Africa and internationally (see Table 17.1).

The most convincing evidence that calcium consumption influences rates of bone mineral accrual comes from controlled supplementation trials in young healthy subjects. A 7-year randomized controlled trial of calcium supplementation, extending through adolescence, showed that calcium supplementation of approximately 670 mg/day on top of habitual dietary calcium intake was associated with greater increases in distal and proximal radius BMD, whole body BMD, and metacarpal cortical indexes, compared to the placebo group [4]. The differences between the treated and control groups subsequently diminished for reasons that are unclear. Whether these benefits are maintained once calcium supplementation is withdrawn was investigated by Winzenberg and colleagues through a meta-analysis of randomized controlled trials. They showed that after the cessation of calcium supplementation, the modest effect on bone mineral density disappeared, except at the upper limb where it was considered unlikely to reduce the risk of fracture in later life [48].

Few studies have addressed the effect of calcium supplementation in children of different ethnic groups. A study conducted on 10-year-old Chinese girls found that a 2-year fortified school milk supplementation trial improved bone mineral acquisition; however, 3 years after supplement withdrawal there were no long-lasting effects on bone mass [49]. Dibba and colleagues have studied the effect of calcium supplements in a group of prepubertal black children living in the Gambia, whose calcium intakes averaged approximately 300 mg/d prior to supplementation [50]. During supplementation, BMC and BMD at the midshaft and distal radius increased, and osteocalcin levels fell in the treatment group, but no effect on radial size or height was detected. At follow-up 12–24 months later, the calcium supplemented group still showed a 5% and 5.1% greater size-adjusted BMC and BMD, respectively, compared to the placebo group at the midshaft of the radius [51].

SOUTH AFRICA: A CASE STUDY

The role of environmental factors, including lifestyle and socioeconomic status (SES), in determining bone mass and strength is very clearly illustrated in the South African population. SES measured using an indicator of social support and disposable income has been positively associated with whole body bone area and bone mineral content in pre- and early pubertal South African children [52]. The very low calcium intake of black South African children has been well characterized and is estimated to be below half the recommended dietary allowance (RDA) for Caucasian children in the United States [53, 54]. This low intake may explain the absence of a higher lumbar spine bone mass in South African black children, which has been observed in the U.S. black population, compared to the respective white populations. The lumbar spine consists of more than 66% trabecular bone, the turnover of which is influenced by the hormonal and metabolic milieu; therefore the suboptimal nutritional status associated with a low calcium intake in black South African children [55] may explain these findings. Similarly, although white South African women participate in more vigorous leisure-time activity, black South African women use walking as a means of transport, and therefore accumulate more moderate-intensity activity [56]. It appears, however, that the response of the bone, particularly at the hip, to physical activity is ethnic-dependent. Recent research has shown that leisure time activity contributes significantly to hip and lumbar spine BMD in white women; however, physical activity does not make a significant contribution at any of the bone sites in black women [13]. Similarly, in children, greater mechanical loading was associated with BMD in white children, but not in black children [28].

SUMMARY

The literature on ethnic variation in hip fracture incidence confirms that many factors contribute to skeletal health. Skeletal mass is accrued throughout childhood and adolescence, and many ethnic differences appear to be present throughout growth. Interethnic studies in bone mass acquisition are important to help elucidate possible etiologies in the early pathogenesis of osteoporosis and the development of interventions that may ameliorate the manifestations of the disease in later life. In particular, exploring the environmental and cultural milieu during bone mass acquisition and its impact on dietary exposures, calcium metabolism, bone mass, and geome-

try is needed to understand the broad range of diversity in different ethnic groups and differing risk profiles.

INTRODUCTION

Bone mineral density (BMD) in later life is a function of peak bone mass and the rate of subsequent bone loss [1]. Childhood is potentially an important time to intervene, as modeling suggests that a 10% increase in peak bone mass will delay the onset of osteoporosis by 13 years [2]. In addition, low BMD in childhood is a risk factor for childhood fractures [3], suggesting that optimizing age-appropriate bone mass could also have a more immediate benefit on childhood fracture rates. This chapter reviews key nutritional influences on childhood bone development.

CALCIUM

It is widely accepted that an adequate calcium intake in childhood is important for bone development, though the results of observational and intervention studies are mixed [4]. In case-control studies, low calcium/dairy intake has been found to be associated with increased fracture risk in 11- to 13-year-old boys, but this has not been confirmed in other groups [5–7]. Low calcium/dairy intake has been found to be associated with recurrent fracture in both sexes [8, 9].

High levels of calcium intake for children are recommended in many developed countries. Current World Health Organization recommendations based on North American and Western European data are from 300 to 400 mg/day for infants, 400 to 700 mg/day for children, and 1,300 mg/day for adolescents) [10]. Modeling of data from calcium balance studies in 348 children [11] suggest that there is a calcium threshold below which skeletal calcium accumulation was related to intake, but above which skeletal accumulation remained constant. This varied with age to up to 1,730 mg in 9- to 17-year-olds. A similar threshold at about 1300 mg was described in girls aged 12–15 years [12]. However, the relationship between short-term calcium balance studies and achieving bone outcome improvements from longer-term calcium supplementation is open to question. In a meta-analysis of randomized controlled trials (RCTs) [13, 14], bone outcomes were no different above or below calcium intakes of 1,400 mg/day, casting doubt on the clinical relevance of the balance studies' results.

This meta-analysis [13, 14] also found that calcium supplementation had no effect on BMD at the femoral neck (FN) or lumbar spine (LS). Supplementation had a small effect on total body (TB) bone mineral content (BMC) but this did not persist once supplementation ceased. There was a small persistent effect on upper limb BMD, equivalent to a 1.7 percentage point greater increase in BMD in the supplemented group compared to the

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

control group, which might reduce the absolute risk of fracture at the peak childhood fracture incidence by at most 0.2% per annum (p.a.). Thus, the small increase in bone density at the upper limb from increasing intake from an average 700 mg/day to 1,200 mg/day is unlikely to result in a clinically significant decrease in fracture risk. Furthermore the evidence did not suggest that increasing the duration of supplementation led to increasing effects. In the meta-analysis, the effect size did not vary with baseline calcium intakes, down to a level of less than 600 mg/day. A subsequent RCT targeting children (mean age 12 years) with an habitual calcium intake less than 650 mg/day resulted in greater increases in TB BMC (2.3%) and total hip (TH) and LS BMD (2.5 and 2.2%, respectively) in children supplemented with an average of 555 mg calcium/day after 18 months, but as in the meta-analysis, the effects did not persist once supplements ceased [15]. As the meta-analysis only included placebo-controlled trials, some RCTs of dairy products were not included [16–22]. Qualitatively, the results of these studies were similar, mainly demonstrating no effect [16] or only small to moderate short-term effects [18–21], which did not persist after supplementation ceased [19, 22]. In the only study with a larger effect, the intervention group had substantially higher levels of vitamin D intake [17], making it unclear how much of the effect was due to calcium and how much was due to vitamin D.

VITAMIN D

Vitamin D deficiency is common in children, especially in late adolescence [23–26]. There is observational evidence that mild vitamin D deficiency (less than 50 nmol/l) may affect bone turnover. The effectiveness of vitamin D supplementation for improving bone density in children was examined in a recent meta-analysis of six RCTs [27, 28]. In all children, vitamin D supplementation had no statistically significant effects on TB BMC, hip BMD, or forearm BMD, and effect sizes were small [standardized mean difference (SMD) 0.10 or less at all 3 sites]. There was a trend to a small effect on LS BMD [SMD +0.15, (95% CI –0.01 to +0.31), p = 0.07]. However, in studies in which the mean baseline serum vitamin D level of the children was low (less than 35 nmol/L), there were significant effects on TB BMC and LS BMD. These were approximately equivalent to a 2.6% and 1.7% percentage point greater increase from the baseline in the supplemented group. No studies were powered for fracture, and it is not known if effects accumulate with ongoing supplementation. Nonetheless, the data suggest that vitamin D supplementation of deficient children could result in clinically useful improvements particularly if in future trials it is demonstrated that effects accumulate with ongoing supplementation.

FRUIT AND VEGETABLES

Fruit and vegetable intake is postulated to have effects on bone through a number of mechanisms. These include the induction of a mild metabolic alkalosis, vitamin K, vitamin C, antioxidants, and phytoestrogens, though phytoestrogens alone have little effect on bone turnover in children [29]. Observational data support a positive relationship between fruit and vegetable intake and bone outcomes in children. Cross sectionally, in 8-year-old children [30], urinary potassium was positively associated with both fruit and vegetable intake and BMD. In addition, girls at Tanner stage 2 [31] who consumed three or more servings of fruit and vegetables daily had higher bone area, lower urinary calcium excretion, and lower parathyroid hormone levels than those consuming fewer than three servings daily, though there were no differences in BMD or bone turnover markers. In other cross-sectional studies, 12-year-old girls who consumed high amounts of fruit had higher heel BMD than moderate fruit consumers [32], and in adolescent boys and girls [33], fruit intake was positively associated with spine size-adjusted BMC (SA-BMC) and, in boys, with FN SA-BMC. Longitudinal data also suggest benefits. Over 7 years, fruit and vegetable intake was an independent predictor of TB BMC in boys, but not girls [34]. In children aged 10–15 years [35], over 1 year, girls who increased their fruit intake had a 4.7% greater increase in stiffness index (SI) (measured by quantitative ultrasound) than those who did not, girls who increased vegetable intake had a 3.6% greater increase, and boys who increased vegetable intake had a 2.4% greater increase. In children who were followed from age 3.8 to 7.8 years of age, a dietary pattern characterized by a high intake of dark-green and deep-yellow vegetables was associated with high bone mass [36]. Fruit and vegetable intake in children can be increased by 0.3 to 0.99 servings per day by dietary intervention [37]. Further research is needed to confirm if bone health is changed by clinically significant amounts by such increases.

DIET IN PREGNANCY

Nutritional influences on childhood bone development may begin *in utero*, and because of *in utero* programming, such influences may affect both early skeletal development and the acquisition of bone mass throughout childhood. RCTs of calcium supplementation during pregnancy have given inconsistent results so it remains unclear whether improving maternal calcium intake in pregnancy is beneficial for *in utero* bone development. One trial demonstrated that either 600 mg or 300 mg of calcium daily resulted in higher neonatal bone density of the ulna, radius, fibula, and tibia (measured by X-ray) [38]. Two grams of calcium in 256 women did not demonstrate any effect on neonatal TB or LS BMC overall, though in mothers with a baseline intake of less than

600 mg/day, TB BMC was higher with supplementation [39]. Conversely, calcium carbonate (1,500 mg/day) given to pregnant Gambian women with a calcium intake of less than 400 mg/day was not beneficial for TB or radial BMC or BMD [40]. Lastly, an RCT in pregnant adolescents compared 1,200 mg/day of calcium from either calcium-supplemented orange juice/calcium carbonate supplements or dairy foods with no-intervention controls. The dairy—but not the calcium supplementation—group had higher total body calcium than the controls, which may have been due to the higher vitamin D content of the dairy foods [41].

RCTs of other supplements in pregnancy with childhood bone outcomes are lacking, and evidence comes from observational data. Maternal serum 25-hydroxy vitamin D (25-OH D) in late pregnancy was positively associated with whole body and LS BMC in the children at age 9 [42]. In another cohort, maternal serum 25-OH D was associated with alterations in femoral development (determined by high resolution 3-dimensional ultrasound) in the fetus as early as 19 weeks gestation [43]. Viljakainen et al. reported that tibial BMC and cross-sectional area (CSA) were both higher in neonates whose mother's first trimester vitamin D was above 42.6 nmol/l compared to those whose mother's vitamin D was below this level [44]. By 14 months, serum vitamin D levels in the children were similar at 64 nmol/l in both groups [45]; the difference in tibial BMC was no longer apparent, but that in CSA persisted, suggesting only partial correction of the original bone deficits. Zinc supplementation in pregnancy in a disadvantaged area in a developing country resulted in increased fetal femur diaphysis length [46]. Maternal folate intake at 32 weeks was positively associated with spinal SA BMC after adjusting for children's weight and height [47] in 9-year-olds, and maternal red blood cell folate at 28 weeks gestation with spine BMD in 6-year-olds [48].

Other nutritional factors have been investigated with observational studies. Maternal dietary intake of magnesium, phosphorus, potassium, and protein during the third trimester of pregnancy has been shown to be positively associated, and maternal fat intake negatively associated, with bone density in their children at age 8 [49]. In the same children at age 16, FN and LS BMD associations with magnesium density and fat density in the maternal diet in pregnancy persisted. LS BMD was also positively associated with maternal milk intake, calcium, and phosphorus density. With all significant nutrients in the same model, fat density remained negatively associated for the FN and LS, whereas magnesium density remained positively associated for the FN [50]. In another cohort [47], maternal magnesium intake at 32 weeks gestation was positively associated with TB BMC and BMD at age 9 years until adjusted for the child's height. Maternal intake of potassium was positively associated with spinal BMC and BMD, until adjusted for the child's weight. A principal component analysis of the maternal diet in the same study identified a pattern of a high intake of fruits, vegetables, and wholemeal bread, pasta, and rice, and low intake of processed foods, which was quantified by a "prudent diet score." A high score was associated with higher TB and lumbar BMC and BMD [51]. Similarly, in a cohort of rural Indian mother–child pairs, intake of milk products, pulses, and fruits were all positively associated with spine BMD in children at age 6 years [48].

Though limited, these data support the need for further research into nutritional interventions in pregnancy.

BREASTFEEDING

Generally, studies show that infants fed human milk have lower bone accretion compared to formula-fed infants, possibly due to low vitamin D content and the decreasing phosphorus content of human milk with continued lactation [52]. However, data on the long-term effects of breastfeeding on bone health in children born at term suggest that this initial lower bone accretion is temporary, and catch-up growth occurs later in childhood. This includes data from an RCT of infant feeding that compared two different formulas and breastfeeding, in which initial differences in BMC accretion did not persist past 12 months of age [53], as well as longitudinal observational data. In 8-year-old children [54], breastfed children had higher FN, LS, and TB BMD compared with bottle-fed children, and the effect was most marked in children breastfed for more than 3 months. In 7- to 9-year-old children, being breastfed was not associated with broadband ultrasound (BUA) or speed of sound (SOS), but in breastfed children, duration of breastfeeding was positively associated with metacarpal diameter [55]. The effects of prolonged breastfeeding may differ from shorter exposures and between sexes, though this is not certain. In one observational study, breastfeeding for more than 7 months resulted in lower TB BMD, LS bone area, and LS BMC at age 32 years in males, but not females [56]. However, breastfeeding duration was not associated with bone density outcomes at age 4 in a different cohort [57].

Other observational studies with bone measures at younger ages [58, 59] did not demonstrate associations between breastfeeding and bone density. However, in a retrospective study, premenopausal women who had been breastfed for more than 3 months had greater cortical thickness at the radius and a trend toward greater cortical area and cortical BMC at the radius, but not at other sites [60]. Importantly, breastfeeding was protective for childhood fractures in a longitudinal study of prepubertal children [61] and in a case-control study of children aged 4–15 years [9], though this was not observed in a longitudinal study of fracture risk from birth to 18 years [62].

SALT

Urinary sodium excretion has been shown to be associated with urinary calcium excretion in girls [63–65],

though not with an acute sodium chloride load [65]. Despite this, in the few studies assessing bone outcomes in children, urinary sodium excretion has not in turn been shown to be associated with bone density [30, 64], though dietary sodium intake was associated with size-adjusted bone area (but not BMC) in a cross-sectional study of 10-year-old girls [66]. Urinary sodium has also been shown to be associated with a high bone turnover state in adolescent boys [67]. Whether high dietary sodium intake adversely affects other bone outcomes in children is uncertain. Initially, more longitudinal studies are needed to determine if sodium intake does in fact have a clinically important effect on bone in children.

SOFT DRINKS AND MILK AVOIDANCE

Carbonated beverage consumption has been linked with decreased BMD in girls but not boys [68, 69] and with increased fracture risk in both sexes. Low milk intake and a higher consumption of carbonated beverages were independent fracture risk factors in children with recurrent fractures [9]. Other studies have reported increased fracture risk with higher cola intake but not non-cola carbonated beverage intake [70, 71]. It is unclear if this effect is due to milk replacement. Two studies have demonstrated that associations between fracture risk [7], peripheral quantitative computed tomography (pQCT) measures [72], and cola drinks persist after adjustment for milk intake, which suggests independent effects. Milk avoidance also appears to have deleterious effects on children's bones. Prepubertal children who avoid milk have lower TB BMC and areal BMD [73], as well as an increased risk of childhood fracture [74]. The effects of low milk consumption in childhood may extend into adult life, with associations seen with lower BMD [75] and higher risk of fracture in adult women [76].

In conclusion, there is increasing evidence linking a number of nutritional factors with children's bone development. Calcium supplementation has been investigated to the greatest extent, but its effects are of limited public health significance. This makes the exploration of other nutritional approaches of key importance.

INTRODUCTION

The basic morphology of the skeleton is determined genetically, but its final mass and architecture are modulated by adaptive mechanisms sensitive to mechanical factors. When subjected to loading, the ability of bones to resist fracture depends on their mass, material properties, geometry, and tissue quality [1]. Knowing whether an intervention during childhood optimizes skeletal mechanics as an adult requires understanding of the effects on each mechanical determinant. Unfortunately, it is only recently that studies have moved beyond areal bone mineral density (aBMD) as an outcome measure to include volumetric density and geometry [2]. None are yet able to determine if childhood adaptations translate into anti-fracture efficacy in adults, but at least the latter variables provide surrogates of bone strength. There is convincing evidence that growing bone has greater capacity to respond to increased mechanical loading than the adult skeleton [2–9]. The question is what to prescribe, what is the window of opportunity, and does adherence to the prescription optimize bone strength so that the risk of fracture is reduced in adulthood and old age.

WHAT IS THE WINDOW OF OPPORTUNITY?

Osteoporotic fractures occur because reduced bone mass decreases the safety factor for skeletal loading. This can result from age-related bone loss and/or failure to achieve optimal peak bone mass [10, 11]. During childhood and adolescence the skeleton undergoes rapid change due to growth, modeling and remodeling, the processes that maximize bone accrual. It is generally believed that bone mass increases substantially during adolescence, reaching a plateau [peak bone mass (PBM)] in the late teen or young adult years [12]. Until recently, the timing of this event was still disputed. Some studies suggested that it was reached by 20 years of age [13, 14], but others concluded that PBM was attained in the third decade of life [15]. Longitudinal bone mineral accrual data measured from childhood (age 8) to young adulthood (up to age 30), demonstrate that PBM occurs by the end of the second, or very early in the third, decade of life [16] (Fig. 19.1). On a regional basis, the lower limb achieves a plateau earliest, within 1 year of peak height velocity (PHV), and the lumbar spine the latest, some 4 years after PHV. Importantly, depending on the skeletal site, 33–46% of the adult BMC was accrued over a 4-year period of adolescent growth surrounding PHV. In females, this total accrual represents double the amount of bone mineral that will subsequently be lost during the postmenopausal years from age 50 to 80 years [17].

Although the variance in peak bone mass is genetically determined [10], it is influenced by mechanical factors such as exercise. The evidence, while not universal [18, 19], is mounting that the prepubertal and early pubertal periods are more advantageous than postpuberty to elicit an adaptive response in growing bones [8, 9, 20–30]. This

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

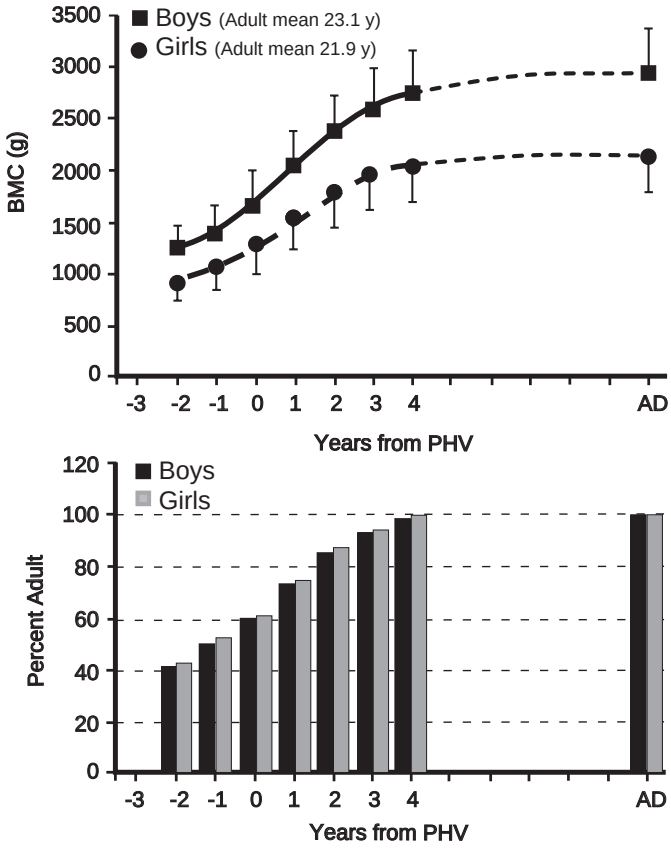

Fig. 19.1. Bone mineral accrual (total body BMC) from preadolescence [2 years before peak height velocity (PHV)] to adulthood (AD). When controlled for maturity, total body BMC reached a plateau by 7 years post-PHV, representing about 18.8 and 20.5 years of age in girls and boys, respectively. Data adapted from Baxter-Jones et al. (Ref. 16).

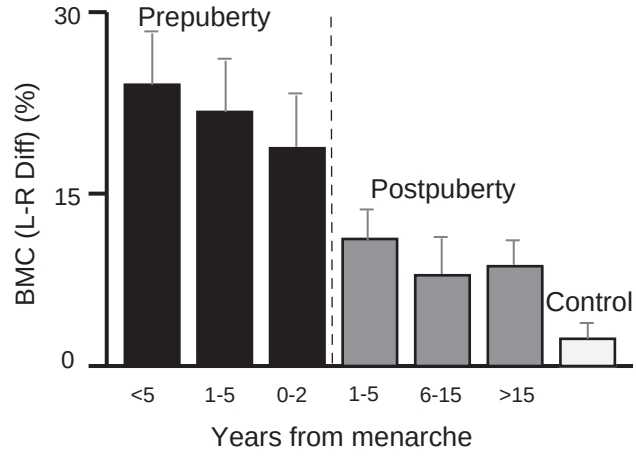

Fig. 19.2. The differences in BMC between the playing and nonplaying arms of women in racquet sports were greatest in those whose training started before puberty, compared to those who started during adulthood (postpuberty). Adapted from Kannus et al. (Ref. 8).

observation is exemplified in unilateral racquet sports in which the differences between the bones of dominant and nondominant arms are greatest in players who started training before puberty, compared to those who started playing during adulthood [8, 9] (Fig. 19.2).

The consequence of physical activity on the skeleton of adults is conservation, not acquisition [5], so factors that optimize PBM must be implemented during growth, when the stimulus of mechanical loading can augment modeling processes that are already active, and the surfaces have a greater proportion of active bone cells. There is also evidence that the increase in estrogen levels in males and females during adolescence augments the amount of functional ERα available to facilitate strain-related responses in bone [31, 32], explaining enhanced sensitivity to physical activity during early puberty [19, 21, 24–26, 28, 33].

CHARACTERISTICS OF AN EFFECTIVE LOADING PRESCRIPTION

If fracture prevention is a consequence of an activity program, then we need to know the characteristics of mechanical stimuli that achieve adaptive morphological changes. We know that static, or isometric, loading provides minimal adaptive stimulus to bone [34–37], and can even inhibit normal appositional growth [38]. Activation of new bone formation also requires that a threshold magnitude of loading is exceeded [39], but that there is an interaction between strain rate and amplitude of loading that modulates this threshold [37, 39–42]. The moderating effect of strain rate occurs because bone tissue is viscoelastic, and interstitial fluid mechanics underlie transduction of applied dynamic loads into bone cell responses [43]. For external loads, such as those experienced during exercise, these responses are optimal in a range of loading frequencies up to about 2.0 Hz [42]. In terms of physical activity, exercises that create relatively high strain rates will be more adaptive than loads applied gently, or in which the load is held constant for a period of time. That is, jumping exercises will create a greater osteogenic effect than simply walking or doing isometric strength exercises.

A key characteristic of loading is that very few loading cycles are required to elicit adaptive responses [36, 43, 44]. The loading effect saturates relatively quickly so that increasing the duration of loading beyond about 40 cycles per day has little additional effect [36]. Cardiovascular health notwithstanding, long exercise sessions will therefore have diminishing returns in terms of growing strong bones. Children do not need to participate in long

periods of exercise, nor disrupt their normal schedule of activities (or inactivity), to provide an adequate adaptive stimulus to their skeleton. Moreover, a given physical activity will be more osteogenic if it is divided into shorter bouts with rest periods in between [45–48]. This is because the sensitivity of the bone cells to the loading stimulus returns after a period of rest. For example, new bone formation was 80% greater in tibiae subjected to four bouts of 90 cycles per day for 2 weeks, compared to one bout of 360 cycles [45]. When a similar program was extended to 16 weeks, groups that received four bouts of 90 cycles per day had significantly greater bending strength in the loaded ulnae compared to those who received a single bout of 360 cycles [47]. In ulnae loaded four times per day, the increased strength was attributed to greater geometric adaptations that resist axial bending (Fig. 19.3) [47].

These mechanical loading principles have been adopted increasingly in physical activity interventions [18, 24–26, 28, 49–53]. But stronger bones can also be achieved in children who undertake greater levels of normal physical activity than sedentary children [22], or compete in high-impact sports such as gymnastics [54, 55]. Although numerous controlled trials have applied some of these principles to maximize modeling in growing bone [2, 21, 27, 49, 52, 56], the Healthy Bones II [25, 26] and "Action Schools! BC" programs [18, 24, 50] in Vancouver, British Columbia, were specifically designed around principles to optimize the osteogenic index [57] of a practical and sustainable activity intervention. In Action Schools! BC, the bone-loading component of the program included an extra 15 minutes of simple activities for 5 days per week, and "bounce at the bell" [50], in which just 3 minutes of variegated jumping activities were implemented 3 times per day (at each school bell) for 4 days per week. During initial trials, the program induced an increase in bone mass [bone mineral content (BMC)] at the lumbar spine and femoral neck of about 2% in both boys and girls. Simple additions to other physical education programs in schools have also improved the indices of bone strength in children quite effectively [51]

Controlled trials, using programs like Action Schools! BC, have increased bone strength, estimated using pQCT, in the distal tibia [18], and 2–4% increases in spine and total body BMC [24] of prepubertal boys, and BMC and section modulus of the femoral neck (an index of bending strength) in peripubertal girls [24]. By optimizing the osteogenic index, this program is able to achieve modest, but significant, increases in parameters of bone strength that are similar to other studies that involve more intensive bone-loading programs [2, 21, 49, 52, 58].

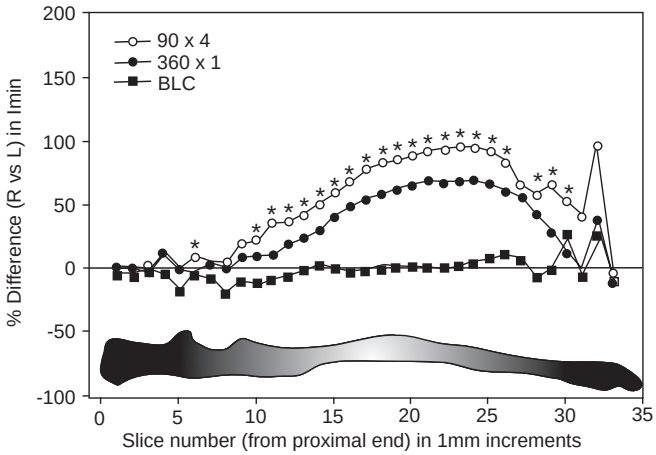

Fig. 19.3. When daily loading was divided into 4 bouts of 90 cycles per day, instead of a single bout of 360 cycles, ulnae showed significantly greater increases in the geometric property responsible for resistance to bending (cross-section moment of inertia—CSMI). Graph illustrates the difference between loaded and unloaded limbs (%) for the CSMI (Imin) of loaded animals, and baseline controls (BLC). Adapted from Robling et al. (47).

PEAK BONE MASS OR PEAK BONE STRENGTH?

Skeletal adaptation to mechanical loading must increase bone strength without unduly increasing the metabolic cost of locomotion. This design gives rise to a trade-off between the goals of strength and lightness. Efficient adaptation, therefore, cannot simply increase bone mass but must effect efficient increases in the geometry, and hence the structural properties, of bone (Fig. 19.4). These

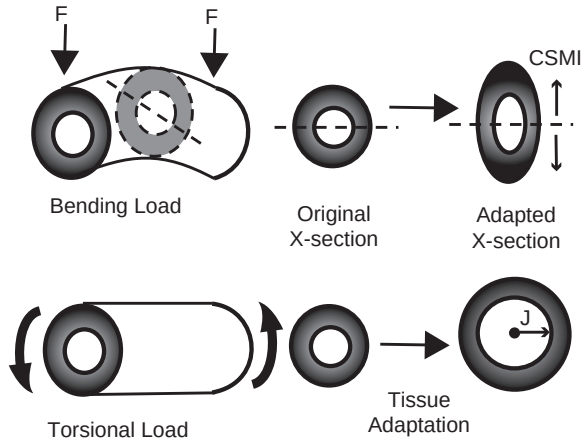

Fig. 19.4. The aim of skeletal adaptation is not to increase bone mass per se, but to improve resistance to increased loads efficiently. Thus, increased strength is achieved, without jeopardizing lightness. Modeling on appropriate bone surfaces improves the biomechanical determinants for enhanced bending or torsional strength [cross-sectional moment of inertia (CSMI) or polar moment of inertia (J), respectively]. These changes improve bending and torsional strength, disproportionately to the change in BMC or BMD, and hence can be misinterpreted by DXA. Adapted from Forwood (Ref. 1).

adaptations are often independent of the material properties. The contribution of altered bone geometry to fracture risk is unappreciated by clinical assessment using dual-energy X-ray absorptiometry (DXA), because it cannot distinguish geometry and density, nor cortical and cancellous bone [1, 59]. The resolution of DXA is also too low to detect small changes in bone dimensions that can provide substantial increases in bone strength. An excellent example of this characteristic is the modest 5% increase in the aBMD of rat ulnae after 16 weeks of axial loading three times per day [47]. This is starkly contrasted by an incredible 64% increase in ultimate breaking strength. Such a marked discrepancy occurs because the new bone formation occurs at the periosteal surface where a relatively small increase in bone apposition provides a disproportionate mechanical advantage at the locations of greatest strain. That is, the small amount of bone is strategically placed away from the axis of bending where it has an exponential effect to resist bending loads (Figs. 19.3 and 19.4). Nonetheless, the vast majority of physical activity studies have relied upon measures of BMD or BMC, derived from DXA, to assess the adaptive response. The use of hip structural analysis, derived from DXA, has provided some mechanical indices to assess maturation of bone strength [22, 29]. But the increasing use of microcomputed tomography (micro-CT) in animal studies, and peripheral quantitative CT (pQCT) in children [2, 9, 18, 60, 61, 62], specifically allows adaptations in density and geometry to be distinguished and proves that increased bone strength, not mass, is the goal of adaptation [9, 62]. The important question to address is whether these changes are maintained into adulthood and old age.

PERSISTENCE OF CHILDHOOD BONE ADAPTATION

During childhood and adolescence it is clear that the mechanical component of physical activity effects adaptations in the growing skeleton. The increases in bone mass [bone mineral density (BMD)] are relatively modest, between 1% and 5%, but may be manifested by geometric adaptations that augment bone strength by a significantly greater degree. It is practically impossible to prove that the adaptations of childhood prevent osteoporotic fracture in old age. Confounding variables associated with retrospective studies, such as self-selection for physique, reduce the certainty that a given activity created long-lasting skeletal protection. But a small number of studies have now traversed childhood and followed adolescents into adulthood. Early studies of this phenomenon suggested that the gains in bone mass from childhood training were lost in adulthood [63–65]. Some of these studies were cross sectional, or started relatively late in adolescence, when it is harder to control for confounding variables such as maturity. Longitudinal studies from childhood through adolescence report a sustained effect

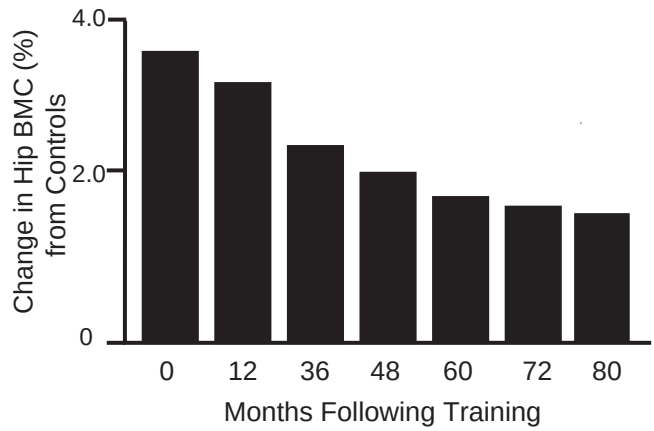

Fig. 19.5. Results of a school-based jumping intervention for 7 months in children aged approximately 8 years [49]. At the end of the 7-month program (0 months), hip BMC was significantly greater than controls (3.6%). When followed for up to 8 years of detraining, the exercise group retained greater hip BMC (1.4%) after controlling for baseline age, change in height, weight and sports participation (Refs. 66, 67). Adapted from Gunter et al. (Ref. 67).

on BMC accrual up to 8 years after training, or cessation of a physical activity intervention [49, 66–68] (Fig. 19.5). In addition, physically active children achieve greater bone mass (BMC) during adolescence than their sedentary peers [20, 22], and their higher BMC is maintained into adulthood [69].

Retention of childhood bone mass into adulthood may be modest, but preservation of skeletal architecture and geometry, underlying bone strength, could be more significant. The distinction between preservation of bone mass or architecture is elegantly illustrated by lifelong preservation of adapted bone structure after short-term exercise in rapidly growing rodents [70]. Forearm training started at 5 weeks of age, with a short 7-week exercise program, following which animals were limited to cage activity for up to 92 weeks (2 years of age, equivalent to senescence for rodents). Increases in bone mass induced by exercise (aBMD and BMC) were not retained into adulthood. There was, however, long-term preservation of bone structural changes, which was manifested in superior strength and fatigue life in the trained animals [70]. Similar retention of exercise-induced structural adaptation from childhood has been observed following cessation of racquet sports in male and female tennis players who had started training during childhood (about 10 years of age) [71, 72]. Up to 3 years after retirement a greater bone mass was retained at the age of 30, modeled into an architecture that provided greater indices of bone strength, such as cortical area and cross-sectional moment of inertia. Taken together, these data support the argument that physical activity during childhood can effect structural adaptations in the skeleton that persist well in to adulthood. The greater strength afforded by

these structural changes could reduce the risk of fracture in adults, more than that predicted by bone mass alone.

CONCLUSIONS

Compared to adults, the skeleton of children and adolescents is capable of greater structural adaptations in response to the mechanical stimulus of physical activity. The evidence is persuasive that the prepubertal and early pubertal periods are more advantageous to effect adaptive responses. To grow healthy bones, physical activity should not consist of static or isometric exercises but should incorporate repetitive cyclical loads that include a range of strain magnitudes and directions, such as running and jumping. Since only a few cycles of loading are required to elicit an adaptive response, distributed bouts of loading that incorporate rest periods are more osteogenic than single sessions of long duration. These parameters of loading have been translated into feasible public health interventions that have achieved improved bone mass and strength in children and adolescents. Those architectural adaptations can persist into adulthood and be translated into a lower risk of fracture.

Pregnancy 156
Lactation 159
Adolescent Pregnancy and Lactation 162
Implications 162
References 162

Normal pregnancy places a demand on the calcium homeostatic mechanisms of women, as the fetus and placenta draw calcium from the maternal circulation in order to mineralize the fetal skeleton. Similar demands are placed on lactating women, in order to supply sufficient calcium to breast milk and enable continued skeletal growth in a nursing infant. Despite a similar magnitude of calcium demand presented to pregnant and lactating women, the adjustments made in each of these reproductive periods differ significantly. These hormone-mediated adjustments normally satisfy the daily calcium needs of the fetus and infant without long-term consequences to the maternal skeleton. Detailed references on this subject are available in several comprehensive reviews [1–3] (see Fig. 20.1).

PREGNANCY

The developing fetal skeleton accretes about 30 g of calcium by term, and about 80% of it during the third trimester when the fetal skeleton is rapidly mineralizing [4]. This calcium demand appears to be largely met by a doubling of maternal intestinal calcium absorption, mediated by 1,25-dihydroxyvitamin D (calcitriol or 1,25-D) and other factors.

Mineral ions and calcitropic hormones

Normal pregnancy results in characteristic alterations in serum chemistries and calciotropic hormones [1]. The total serum calcium falls early in pregnancy due to a fall in the serum albumin, but the ionized calcium (the physiologically important fraction) remains constant. Serum phosphate and magnesium levels are normal.

In studies of women from North America and Europe, the serum parathyroid hormone (PTH) level, when measured with two-site "intact" assays, falls to the low–normal range (i.e., 10–30% of the mean nonpregnant value) during the first trimester, but increases steadily to the mid–normal range by term [5–9]. In contrast, the PTH value did not suppress in studies of women from Asia and Gambia and may reflect the lower calcium and vitamin D intakes in those populations [10]. Total 1,25-D levels double early in pregnancy and maintain this increase until term; free 1,25-D levels are increased from the third trimester [1, 11]. The rise in 1,25-D does not appear to be driven by PTH, since PTH levels are falling while 1,25-D is increasing. Maternal kidneys, and not the placenta, likely account for most, if not all, of the rise in 1,25-D during pregnancy, as shown by an anephric woman who had very low 1,25-D levels before and during pregnancy [12]. The renal 1α-hydroxylase is upregulated in response to factors such as PTH-related protein (PTHrP), estradiol, prolactin and placental lactogen. Serum calcitonin levels are also increased during pregnancy.

PTHrP levels increase during pregnancy and may derive from multiple tissues in the mother and fetus. PTHrP may contribute to the elevation in 1,25-D and suppression of PTH during pregnancy. PTHrP may have other roles such as regulating placental calcium transport in the fetus [1, 13]. Also, PTHrP may have a role in protecting the maternal skeleton during pregnancy, since the

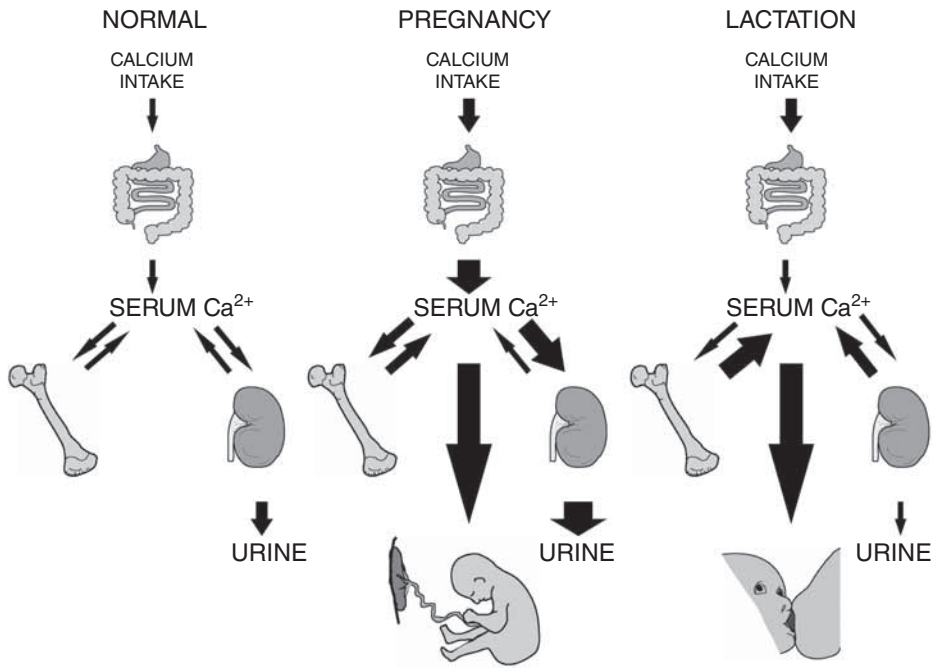

Fig. 20.1. Schematic illustration contrasting calcium homeostasis in human pregnancy and lactation, as compared to normal. The thickness of arrows indicates a relative increase or decrease with respect to the normal and nonpregnant state. Although not illustrated, the serum (total) calcium is decreased during pregnancy while the ionized calcium remains normal during both pregnancy and lactation. Adapted from Ref. 1, © 1997, The Endocrine Society.

carboxyl-terminal portion of PTHrP ("osteostatin") has been shown to inhibit osteoclastic bone resorption [14].

Pregnancy induces significant changes in other hormones, including sex steroids, prolactin, placental lactogen, and insulin-like growth factor-1 (IGF-1). Each of these may have direct or indirect effects on calcium and bone metabolism during pregnancy, but these issues have been largely unexplored.

Intestinal absorption of calcium

Intestinal absorption of calcium is doubled during pregnancy from as early as 12 weeks of gestation; this appears to be a major maternal adaptation to meet the fetal need for calcium. The increased intestinal calcium absorption may be largely the result of a 1,25-D-mediated action on intestinal cells, although it is notable that intestinal calcium absorption doubles months before an increase in free 1,25-D levels occur. Also, studies in rodents indicate that a pregnancy-induced increase in intestinal calcium absorption occurs despite severe vitamin D deficiency or absence of the vitamin D receptor [15–17]. Prolactin, placental lactogen, and other factors also stimulate intestinal calcium absorption, as demonstrated in rodents [18, 19]. Enhancing calcium absorption early in pregnancy causes a positive calcium balance in women [20], and this may enable the maternal skeleton to store calcium prior to the peak fetal demand during the third trimester.

Renal handling of calcium

The 24-hour urine calcium excretion increases as early as the 12th week of gestation and often exceeds the normal range [1]. Since fasting urine calcium values are normal or low, the increased 24-hour urine calcium reflects the increased intestinal absorption of calcium (absorptive hypercalciuria). The elevated calcitonin levels of pregnancy might also promote renal calcium excretion.

Skeletal calcium metabolism

Animal models indicate that histomorphometric parameters of bone turnover are increased during pregnancy and that bone mineral content of normal mice may increase or decrease depending upon the genetic background [1, 21, 22]. Comparable histomorphometric data are not available for human pregnancy, but one small study indicated that bone resorption parameters were increased at 8–10 weeks in 15 women who electively terminated pregnancy as compared to nonpregnant controls and pregnant women at term [23].

Most human studies of skeletal calcium metabolism in pregnancy have examined changes in serum markers of bone formation, and urine markers of bone resorption. These studies are fraught with a number of confounding variables, including lack of prepregnancy baseline values;

effects of hemodilution in pregnancy on serum markers; increased glomerular filtration rate (GFR); altered creatinine excretion; placental, uterine, and fetal contribution to the levels of markers in blood; degradation and clearance by the placenta; and lack of diurnally timed or fasted specimens. Given these limitations, many studies have reported that urinary markers of bone resorption (24-hr collection) are increased from early to mid-pregnancy (including deoxypyridinoline, pyridinoline, and hydroxyproline). Conversely, serum markers of bone formation (generally not corrected for hemodilution or increased GFR) are often decreased from prepregnancy or nonpregnant values in early or mid-pregnancy, rising to normal or above before term (including osteocalcin, procollagen I carboxypeptides, and bone specific alkaline phosphatase). Total alkaline phosphatase rises early in pregnancy due largely to contributions from the placental fraction; it is not a useful marker of bone formation in pregnancy.

Based on the scant bone biopsy data, and the measurements of bone markers (with aforementioned confounding factors), one may cautiously conclude that bone resorption is increased in pregnancy, from as early as the 10th week of gestation. There is comparatively little maternal–fetal calcium transfer occurring at this stage of pregnancy, as compared to the peak rate of calcium transfer in the third trimester. One might have anticipated that markers of bone resorption would increase particularly in the third trimester, but no marked increase is seen at that time.

Changes in skeletal calcium content have been assessed through the use of sequential areal bone mineral density (aBMD) studies during pregnancy. Due to concerns about fetal radiation exposure, few such studies have been done. Such studies are confounded by the changes in body composition, weight and skeletal volumes during normal pregnancy that can lead to artifactual changes in the aBMD reading obtained. Using single and/or dual-photon absorptiometry, several prospective studies did not find a significant change in cortical or trabecular aBMD during pregnancy [1]. Several recent studies have utilized dual energy X-ray absorptiometry (DXA) before conception (range 1–8 months prior, but not always stated) and after delivery (range 1–6 weeks postpartum) [studies reviewed in detail in Ref. 24]. Most studies involved 16 or fewer subjects. One study found no change in lumbar spine aBMD measurements obtained preconception and within 1–2 weeks postdelivery, whereas the other studies reported decreases of 4–5% in lumbar aBMD with the postpartum measurement taken between 1 and 6 weeks postdelivery. Since the puerperium is associated with bone density losses of 1–3% per month (see lactation section, below), it is possible that obtaining the second measurement 2 to 6 weeks after delivery contributed to the bone loss documented in many of the studies. Other longitudinal studies have found a progressive decrease during pregnancy in indices thought to correlate with volumetric BMD, as determined by ultrasonographic measurements at another peripheral site, the os calcis. None of all the aforementioned studies can address the question as to whether skeletal calcium content is increased early in pregnancy in advance of the third trimester. Further studies, with larger numbers of patients, will be needed to clarify the extent of bone loss during pregnancy.

It seems certain that any acute changes in bone metabolism during pregnancy do not cause long-term changes in skeletal calcium content or strength. Numerous studies of osteoporotic or osteopenic women have failed to find a significant association of parity with bone density or fracture risk [1, 25].

Osteoporosis in pregnancy

Women occasionally present with fragility fractures and low bone mineral density (BMD) during or shortly after pregnancy; in most cases, the possibility that low bone density was present prior to pregnancy cannot be excluded. Some women may experience excessive resorption of calcium from the skeleton due to changes in mineral metabolism induced by pregnancy and other factors, such as low dietary calcium intake and vitamin D insufficiency. The apparently increased rate of bone resorption in pregnancy may contribute to fracture risk, because a high rate of bone turnover is an independent risk factor for fragility fractures outside of pregnancy. Therefore, fragility fractures in pregnancy or the puerperium may be a consequence of preexisting low bone density and increased bone resorption, among other possible factors. During lactation, additional changes in mineral metabolism occur that may further increase fracture risk in some women (see below).

Focal, transient osteoporosis of the hip is a rare, self-limited form of pregnancy-associated osteoporosis. It is probably not a manifestation of altered calciotropic hormone levels or mineral balance during pregnancy, but rather might be a consequence of local factors. These patients present with unilateral or bilateral hip pain, limp, and/or hip fracture in the third trimester. There is objective evidence of reduced bone density of the symptomatic femoral head and neck that has been shown by magnetic resonance imaging (MRI) to be the consequence of increased water content of the femoral head and the marrow cavity; a joint effusion may also be present. The symptoms and the radiological appearance usually resolve within 2 to 6 months postpartum.

Primary hyperparathyroidism

Although probably a rare condition (there are no data available on its prevalence), primary hyperparathyroidism in pregnancy has been associated in the literature with an alarming rate of adverse outcomes in the fetus and neonate, including a 30% rate of spontaneous abortion or stillbirth. The adverse postnatal outcomes are thought to result from suppression of the fetal and neo-

natal parathyroid glands; this suppression may occasionally be prolonged after birth for months. To prevent these adverse outcomes, surgical correction of primary hyperparathyroidism during the second trimester has been almost universally recommended. Several case series have found elective surgery to be well tolerated and to dramatically reduce the rate of adverse events when compared to the earlier cases reported in the literature. Many of the women in those early cases had a relatively severe form of primary hyperparathyroidism that is not often seen today (symptomatic, with nephrocalcinosis and renal insufficiency). While mild, asymptomatic primary hyperparathyroidism during pregnancy has been followed conservatively with successful outcomes, complications continue to occur so that in the absence of definitive data, surgery during the second trimester remains the most common recommendation [26].

Familial hypocalciuric hypercalcemia

Although familial hypocalciuric hypercalcemia (FHH) has not been reported to adversely affect the mother during pregnancy, the maternal hypercalcemia has caused fetal and neonatal parathyroid suppression with subsequent tetany.

Hypoparathyroidism and pseudohypoparathyroidism

Early in pregnancy, some hypoparathyroid women have fewer hypocalcemic symptoms and require less supplemental calcium. This is consistent with a limited role for PTH in the pregnant woman and suggests that an increase in 1,25-D and/or increased intestinal calcium absorption will occur in the absence of PTH. However, it is clear from other case reports that some pregnant hypoparathyroid women require increased calcitriol replacement in order to avoid worsening hypocalcemia. It is important to maintain a normal ionized calcium level in pregnant women since maternal hypocalcemia due to hypoparathyroidism has been associated with the development of intrauterine fetal hyperparathyroidism and fetal death. The ionized calcium, rather than the total calcium, should be followed, because of the fall of serum albumin during pregnancy. Late in pregnancy, hypercalcemia may occur in hypoparathyroid women unless the calcitriol dosage is substantially reduced or discontinued. This effect may be mediated by the increasing levels of PTHrP in the maternal circulation in late pregnancy.

In limited case reports of pseudohypoparathyroidism, pregnancy has been noted to normalize the serum calcium level, reduce the PTH level by half, and increase the 1,25-D level two- to threefold [27]. The mechanism by which these changes occur despite pseudohypoparathyroidism remains unclear.

Vitamin D deficiency and insufficiency

Maternal 25-hydroxyvitamin D levels do not change significantly during pregnancy [28–31], even in women starting with the extremely low level of 20 nmol/l (8ng/ml) [31], and so it does not appear that pregnant women require higher intakes of vitamin D to maintain a set 25-hydroxyvitamin D level. There are as yet no large randomized trials that have examined the effects of vitamin D deficiency or insufficiency on human pregnancy. However, available data from small clinical trials of vitamin D supplementation, observational studies, and case reports suggest that, consistent with animal studies, vitamin D deficiency is not associated with any worsening of maternal calcium homeostasis and that the fetus will have a normal serum calcium and fully mineralized skeleton at term (this topic is reviewed in detail in Refs. 32 and 33). The only consistent benefit seen in randomized trials is that vitamin D supplementation during pregnancy increases maternal and cord blood 25(OH)D levels without altering cord blood calcium or anthropometric parameters in the baby.

Low calcium intake

Since absorptive hypercalciuria typically occurs during pregnancy, this may be viewed as evidence that calcium intake normally exceeds maternal requirements. Calcium supplementation did not improve maternal or neonatal bone density in one study [34], By constrast, in a randomized trial of 2 g of calcium supplementation versus placebo found there was an increase in neonatal BMD in the women with the lowest quintile of calcium intake (less than 600 mg per day) [35]. This suggests that calcium supplementation may benefit only those women (and their babies) with very low dietary intakes of calcium.

Low calcium intake has been associated with increased risk of preeclampsia. Calcium supplementation appears to reduce the risk of preeclampsia when the dietary calcium intake is low, whereas there is no effect when dietary calcium intake is adequate [36–39].

LACTATION

The average daily loss of calcium in breast milk is 210 mg, with losses as high as 1,000 mg calcium reported for women nursing twins. A temporary demineralization of the skeleton appears to be the main mechanism by which lactating humans meet these calcium requirements. This demineralization does not appear to be mediated by PTH or 1,25-D but may be mediated by PTHrP in the setting of a fall in estrogen levels.

Mineral ions and calciotropic hormones

The mean ionized calcium level of exclusively lactating women is increased, although it remains within the

normal range. Serum phosphate levels are also higher during lactation, and the level may exceed the normal range. Since reabsorption of phosphate by the kidneys appears to be increased, the increased serum phosphate levels may, therefore, reflect the combined effects of increased flux of phosphate into the blood from diet and from skeletal resorption in the setting of decreased renal phosphate excretion.

Intact PTH, as determined by a two-site immunoradioactive monoclondal antibody (IRMA) assay, has been found to be reduced 50% or more during the first several months of lactation. It rises to normal at weaning but may rise above normal postweaning. In contrast to the high 1,25-D levels of pregnancy, maternal free and bound 1,25-D levels fall to normal within days of parturition and remain there throughout lactation. Calcitonin levels fall to normal after the first 6 weeks postpartum. Mice lacking the calcitonin gene lose twice the normal amount of bone mineral content during lactation, which indicates that physiological levels of calcitonin may protect the maternal skeleton from excessive resorption during this time period [21]. Whether calcitonin plays a similar role in human physiology is unknown. Thyroidectomized women have not been studied during pregnancy and lactation, though studies in such women might not be definitive because of extrathyroidal production of calcitonin in placenta, pituitary, and lactating breast.

PTHrP levels, as measured by two-site IRMA assays, are significantly higher in lactating women than in nonpregnant controls. The source of PTHrP may be the breast, since PTHrP has been detected in breast milk at concentrations exceeding 10,000 times the level found in the blood of patients with hypercalcemia of malignancy or normal human controls. Further, lactating mice with the PTHrP gene ablated only from mammary tissue have lower blood levels of PTHrP than control lactating mice [40]. Studies in animals suggest that PTHrP may regulate mammary development and blood flow, and the calcium content of milk. In addition, PTHrP reaching the maternal circulation from the lactating breast may cause resorption of calcium from the maternal skeleton, renal tubular reabsorption of calcium, and (indirectly) suppression of PTH. In support of this hypothesis, deletion of the PTHrP gene from mammary tissue at the onset of lactation resulted in more modest losses of bone mineral content during lactation in mice [40]. In humans, PTHrP levels correlate with the amount of BMD lost: negatively with PTH levels and positively with the ionized calcium levels of lactating women [41–43]. Furthermore, observations in aparathyroid women provide evidence of the impact of PTHrP in calcium homeostasis during lactation (see below).

Intestinal absorption of calcium

Intestinal calcium absorption decreases to the nonpregnant rate from the increased rate of pregnancy. This corresponds to the fall in 1,25-D levels to normal.

Renal handling of calcium

In humans, the GFR falls during lactation, and the renal excretion of calcium is typically reduced to levels as low as 50 mg per 24 hours. This suggests that the tubular reabsorption of calcium must be increased, perhaps by the actions of PTHrP.

Skeletal calcium metabolism

Histomorphometric data from animals consistently show increased bone turnover during lactation, and losses of 35% or more of bone mineral are achieved during 2–3 weeks of normal lactation in the rat [reviewed in Ref. 1]. Comparative histomorphometric data are lacking for humans, and in place of that, serum markers of bone formation, and urinary markers of bone resorption have been assessed in numerous cross-sectional and prospective studies of lactation. Some of the confounding factors discussed with respect to pregnancy apply to the use of these markers in lactating women. In this instance, the GFR is reduced and the intravascular volume is contracted. Urinary markers of bone resorption (24-hr collection) have been reported to be elevated two- to threefold during lactation and are higher than the levels attained in the third trimester. Serum markers of bone formation (not adjusted for hemoconcentration or reduced GFR) are generally high during lactation and increased over the levels attained during the third trimester. Total alkaline phosphatase falls immediately postpartum due to loss of the placental fraction, but may still remain above normal due to the elevation in the bone-specific fraction. Despite the confounding variables, these findings suggest that bone turnover is significantly increased during lactation.

Serial measurements of aBMD during lactation [by single photon absorptionmetry (SPA), dual photon absorptionmetry (DPA) or DXA) have shown a fall of 3.0 to 10.0% in bone mineral content after 2 to 6 months of lactation at trabecular sites (lumbar spine, hip, femur, and distal radius), with smaller losses at cortical sites and whole body [1, 25]. These aBMD changes are in accord with studies in rats, mice, and primates in which the skeletal resorption has been shown to occur largely at trabecular and to a lesser degree at endocortical surfaces. The loss occurs at a peak rate of 1–3% *per month*, far exceeding the rate of 1–3% per year that can occur in women after menopause who are considered to be losing bone rapidly. Loss of mineral from the maternal skeleton appears to be a normal consequence of lactation and may not be preventable by raising the calcium intake above the recommended dietary allowance. Several studies have demonstrated that calcium supplementation does not significantly reduce the amount of bone lost during lactation [44–47]. Not surprisingly, the lactational decrease in BMD correlates with the amount of calcium lost in the breast milk [48].

The mechanisms controlling the rapid loss of skeletal calcium content are not well understood. The reduced

estrogen levels of lactation are clearly important, but are unlikely to be the sole explanation. To estimate the effects of estrogen deficiency during lactation, it is worth noting the alterations in calcium and bone metabolism that occur in reproductive-age women who have estrogen deficiency induced by GnRH agonist therapy for endometriosis and other conditions. Six months of acute estrogen deficiency induced by GnRH agonist therapy leads to 1–4% losses in trabecular (but not cortical) aBMD, increased urinary calcium excretion, and suppression of 1,25-D and PTH [reviewed in Ref. 1]. In lactation, women are not as estrogen deficient but lose more aBMD (at both trabecular and cortical sites), have normal (as opposed to low) 1,25-D levels, and have reduced (as opposed to increased) urinary calcium excretion. The difference between isolated estrogen deficiency and lactation is due to the effects of PTHrP, which complements the effects of estrogen withdrawal in lactation. Stimulated in part by suckling and high prolactin levels, the effects of PTHrP and estrogen deficiency combine to coordinate the marked skeletal resorption that occurs during lactation (see Fig. 20.2).

The bone density losses of lactation appear to be substantially reversed during weaning [1, 25, 45], although the speed and completeness of recovery may differ by skeletal site and technique used. This corresponds to a gain in bone density of 0.5 to 2% per month in the woman who has weaned her infant. The mechanism for this restoration of bone density is uncertain. In the long-term, the consequences of lactation-induced depletion of bone mineral appear clinically unimportant. The vast majority of epidemiologic studies of pre- and postmenopausal women have found no adverse effect of a history of lactation on peak bone mass, bone density, or hip fracture risk.

Osteoporosis of lactation

Rarely, women suffer fragility fractures during lactation, and osteoporotic readings are confirmed by DXA. Like osteoporosis in pregnancy, this may represent a coincidental, unrelated disease; the woman may have had low bone density prior to conception. Alternatively, some cases might represent an exacerbation of the normal degree of skeletal demineralization that occurs during lactation, and a continuum from changes in bone density and bone turnover that may have occurred during pregnancy. For example, excessive PTHrP release from the lactating breast into the maternal circulation, combined with estrogen deficiency, could conceivably cause excessive bone resorption, osteoporosis, and fractures. Consistent with this, PTHrP levels were high in one case of lactational osteoporosis and were found to remain elevated for months after weaning [49]. Also, in most cases where vertebral compression fractures occurred during lactation, bone density spontaneously increases after weaning, consistent with lactation-induced loss of bone causing fragility [50].

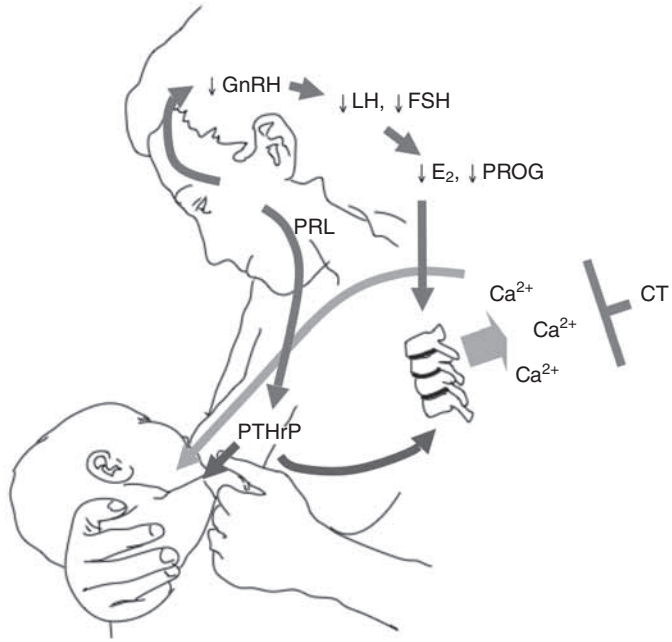

Fig. 20.2. The breast is a central regulator of skeletal demineralization during lactation. Suckling and prolactin both inhibit the hypothalamic gonadotropin-releasing hormone (GnRH) pulse center, which in turn suppresses the gonadotropins [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], leading to low levels of the ovarian sex steroids (estradiol and progesterone). PTHrP production and release from the breast is controlled by several factors including suckling, prolactin, and the calcium receptor. PTHrP enters the bloodstream and combines with systemically low estradiol levels to markedly upregulate bone resorption. Increased bone resorption releases calcium and phosphate into the blood stream, which then reaches the breast ducts and is actively pumped into the breast milk. PTHrP also passes into milk at high concentrations, but whether swallowed PTHrP plays a role in regulating calcium physiology of the neonate is unknown. Calcitonin (CT) may inhibit skeletal responsiveness to PTHrP and low estradiol. Reprinted from Ref. 64, ©2005, with kind permission of Springer Science and Business Media B.V.

Hypoparathyroidism and pseudohypoparathyroidism

Levels of calcitriol and calcium supplementation required for treatment of hypoparathyroid women fall early in the postpartum period, especially if the woman breastfeeds, and hypercalcemia may occur if the calcitriol dosage is not substantially reduced [51]. As observed in one case, this is consistent with PTHrP reaching the maternal circulation in amounts sufficient to allow stimulation of 1,25-D synthesis and maintenance of normal (or slightly increased) maternal serum calcium [52].

The management of pseudohypoparathyroidism has been less well documented. Since these patients are likely resistant to the renal actions of PTHrP, and the

placental sources of 1,25-D are lost at parturition, the calcitriol requirements might well increase and may require further adjustments during lactation.

Vitamin D deficiency and insufficiency

During lactation, maternal 25-hydroxyvitamin D levels are unchanged [53, 54] because very little vitamin D or 25-hydroxyvitamin D passes into breast milk. The available data from small clinical trials, observational studies, and case reports indicate that lactation proceeds normally regardless of vitamin D status, and breast milk calcium content is unaffected by vitamin D deficiency or by supplementation with doses as high as 6,400 IU per day (topic reviewed in detail in Refs. 32 and 33). This is likely because maternal calcium homeostasis is dominated by skeletal resorption induced by estrogen deficiency and PTHrP. It is the neonate who will suffer the consequences of being born of a vitamin D deficient mother and especially if exclusively breastfed without supplements or sunlight exposure. A small pilot study indicated that 6,400 IU daily of vitamin D raised the vitamin D and 25(OH)D content of breast milk enough for the suckling neonate to attain a 25(OH)D level over 75 nmol/l (30 ng/ml); the same level was achieved by giving 300 IU directly to the baby [55].

Low calcium intake

The calcium content of milk appears to be largely derived from skeletal resorption; consequently, low calcium intake does not alter breast milk calcium content nor does it accentuate maternal bone loss during lactation [56–59]. Instead, the calcium receptor, expressed by lactating mammary epithelial cells, regulates the calcium content of milk by upregulating expression of the plasma membrane calcium ATPase isoform 2 (PMCA2) [60, 61]. The calcium receptor also regulates the fluid content of milk and mammary production of PTHrP [60].

ADOLESCENT PREGNANCY AND LACTATION

Adolescent pregnancy and lactation do not reduce peak bone mass, as previously feared [62]. In a NHANES III analysis of 819 women aged 20–25, women who had been pregnant as adolescents had the same BMD as nulliparous women and women who had been pregnant as adults [63]. Women who breastfed as adolescents had higher BMD than women who had not breastfed, as well as nulliparous women [63]. Thus it appears that, as with adults, adolescents lose bone during lactation and recover fully afterwards without any long-term adverse effects on the skeleton.

IMPLICATIONS

In both pregnancy and lactation, novel regulatory systems specific to these settings complement the usual regulators of calcium homeostasis. The fetal calcium demand is met in large part by intestinal calcium absorption that more than doubles from early in pregnancy, an adaptation that may not be fully explained by the increase in 1,25-D levels. In comparison, skeletal calcium resorption is a dominant mechanism by which calcium is supplied to the breast milk, while renal calcium conservation is also apparent. These changes during lactation appear to be driven by PTHrP in association with estrogen deficiency rather than PTH and vitamin D. Consistent with this, treatment of lactating women with calcium supplements has little or no impact on bone loss.

These observations indicate that the maternal adaptations to pregnancy and lactation have evolved differently over time, such that dietary calcium absorption dominates in pregnancy, whereas lactation programs an obligatory but temporary skeletal calcium loss that is completely restored after weaning. The rapidity of calcium regain by the skeleton of the lactating woman occurs through a mechanism that is not understood. A full elucidation of the mechanism of bone restoration after lactation might lead to the development of novel approaches to the treatment of osteoporosis and other metabolic bone diseases. Finally, while it is apparent that some women will experience fragility fractures as a consequence of pregnancy or lactation, the vast majority of women can be assured that the changes in calcium and bone metabolism during pregnancy and lactation are normal, healthy, and without adverse consequences in the long-term.

Introduction 165
Effects on Bone 165
Effects on Calcium Metabolism 166
Summary 167
References 167

INTRODUCTION

Menopause refers to the cessation of menstruation, which occurs at about 48–50 years of age in healthy women. The decline in ovarian hormone production is gradual and starts several years before a woman's last period. Changes in bone mass and calcium metabolism are evident during this perimenopausal transition. Estrogen is the ovarian product that has the greatest impact on mineral metabolism, though both progesterone and ovarian androgens may have some influence. Menopause ushers in a period of bone loss that extends until the end of life, and which is the central contributor to the development of osteoporotic fractures in older women.

EFFECTS ON BONE

Before the menopause, there is virtually no bone loss in most regions of the skeleton [1, 2], and fracture rates are stable. The most obvious effect of menopause on bone is an increase in the incidence of fractures; in the forearms and vertebrae this is clearly apparent within the first postmenopausal decade. It is attributable to the rapid decline in bone mass that occurs in the perimenopausal years. Bone loss is more marked in trabecular than in cortical bone because the former has a greater surface area over which bone resorption can take place (e.g., a loss of 1.4% per year at the hip compared with 1.6% per year at the spine, in a recent study [3]). Thus, the fractures that occur early in the menopause are in trabecular-rich regions of the skeleton such as the distal forearm and vertebrae. The loss of bone and increase in fracture rates are preventable with estrogen replacement.

The perimenopausal increase in bone loss is driven by increased bone resorption [4]. Bone biopsies in normal postmenopausal women show an increase in the proportion of bone surfaces at which resorption is taking place and an increase in the depth of resorption pits. These changes follow from an increase in the activation frequency of remodeling units and a prolongation of their resorptive phase. Indices of bone resorption are twice the levels found in premenopausal women whereas markers of bone formation are only about 50% above premenopausal levels [5], leading to negative bone balance. The resulting loss of bone leads to the perforation and loss of trabeculae [6], and endosteal resorption, cortical thinning, and increased porosity in cortical bone [7]. The changes in histomorphometric indices and biochemical markers can be returned to premenopausal levels with estrogen replacement therapy.

The changes in bone turnover that accompany menopause are in part accounted for by the direct actions of estrogen on bone cells. Estrogen receptors are present in both osteoblasts and osteoclasts. Estrogen promotes the development of osteoblasts in preference to adipocytes from their common precursor cell [8], increases osteoblast proliferation [9], and increases production of a

number of osteoblast proteins [e.g., insulin-like growth factor-1, type I procollagen, transforming growth factor-β (TGFβ), and bone morphogenetic protein-6]. Thus, estrogen tends to have an anabolic effect on the isolated osteoblast, which is complemented by its inhibition of apoptosis in osteocytes [10] and osteoblasts [11]. *In vivo*, however, the initiation of estrogen replacement therapy is usually associated with a reduction in osteoblast numbers and activity [12]. This is accounted for by the tight coupling of osteoblast activity to that of osteoclasts, and the overriding effect of estrogen to reduce osteoclastic bone resorption. However, there is now evidence that high concentrations of estrogen increase some histomorphometric indices of osteoblast activity (e.g., mean wall thickness) in humans, possibly by increasing osteoblast synthesis of growth factors [13].

Estrogen's suppression of osteoclast activity is contributed to by increased osteoclast apoptosis [14], by reduced osteoblast/stromal cell production of receptor activator of nuclear facgtor-κB ligand (RANKL), and by increased production of osteoprotegerin [15]. These direct effects are buttressed by estrogen action on bone marrow stromal and mononuclear cells, which produce cytokines, such as interleukin-1 (IL-1), interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α), potent stimulators of osteoclast recruitment and/or activity [16]. Estrogen also regulates T-cell production of TNF-α, via changes in IL-7 [17] and interferon-γ [18]. Estrogen decreases production of each of these cytokines [19], and modulates levels of IL-1 receptors [20]. Bone loss following ovariectomy is reduced by blockers of these cytokines, and blockade of TNF-α and IL-1 has been shown to reduce bone resorption in postmenopausal women [21]. IL-1 and TNF-α may act in part by regulating stromal cell production of IL-6 and macrophage colony stimulating factor [22]. The CD40 ligand on the surface of T cells binds to CD40 on stromal cells and osteoblasts and is pivotal to estrogen actions on these cells and, through regulating their production of macrophage colony stimulating factor (M-CSF), RANKL, and osteoprotegerin, to estrogen effects on bone resorption [23]. These cytokine interactions have recently been reviewed in detail [24]. Estrogen also has antioxidant effects, decreasing reactive oxygen species in mouse bone [25], thereby reducing osteocyte apoptosis [26] and contributing to reduced bone resorption via increased levels of nitric oxide [27], and by decreasing T-cell proliferation and resultant TNF-α production [24]. Estrogen's effects on osteoclasts and on bone marrow cytokines may also be supported by its regulation of other systemic bone-active factors, such as growth hormone [28] and follicle-stimulating hormone (FSH) [29].

EFFECTS ON CALCIUM METABOLISM

The bone loss that follows menopause is accompanied by negative changes in external calcium balance. Decreases in intestinal calcium absorption and increases in urinary calcium loss contribute approximately equally to these negative changes [30]. Menopause is associated with reduced circulating concentrations of total, but not free, 1,25-dihydroxyvitamin D (1,25$(OH)_2$D), implying that its main effect is on vitamin D binding protein. However, intestinal mucosal cells contain estrogen receptors and respond directly to 17β-estradiol with enhanced calcium transport [31], probably through regulation of the epithelial calcium channel CaT1 [32], suggesting estrogen's effects are independent of vitamin D.

In the kidney, it is clear that tubular reabsorption of calcium is higher in the presence of estrogen [33, 34]. One study [34] found higher parathyroid hormone (PTH) concentrations in the presence of estrogen and inferred that this was the mechanism of the renal calcium conservation. However, higher PTH levels have not been the finding in a number of other studies. Thus, it is likely that estrogen directly modulates renal tubular calcium absorption via its own receptor in the kidney, as suggested by *in vitro* studies of renal tubule cells, which show a stimulatory effect of 17β-estradiol on calcium membrane transport [35].

The changes in the handling of calcium by the gut and kidney could each be a *cause* of postmenopausal bone loss, or they could represent homeostatic *responses* to it. If the former were the case, then PTH concentrations would be elevated in postmenopausal women to maintain plasma calcium concentrations in the face of intestinal and renal losses. This, in turn, would cause bone loss. If, on the other hand, bone loss were the primary event, then suppression of PTH would be expected, leading to secondary declines in intestinal and renal calcium absorption. The effect of menopause on PTH concentrations has been addressed many times without any consistent pattern emerging. This suggests that estrogen has direct effects on bone, kidney, and gut, and the opposing effects of these actions on PTH secretion leads to inconsistent changes in PTH concentrations. Further, estrogen itself may directly modulate PTH secretion [36, 37].

There are small but consistently demonstrable effects of menopause on circulating concentrations of calcium. Total calcium is 0.05 mmol/L higher after the menopause [33, 38]. This is partly attributable to a contraction of the plasma volume and resulting increase in albumin concentrations that occur in the absence of estrogen [39, 40], and partly to an increase in plasma bicarbonate, which leads to an increase in the complexed fraction of plasma calcium. The higher bicarbonate levels of postmenopausal women are attributable to a respiratory acidosis that results from the loss of the respiratory stimulatory effects of progesterone on the central nervous system, an action that is potentiated by estrogen [41, 42]. Despite changes in protein-bound and complexed calcium fractions, ionized calcium concentrations are usually found to be the same in pre- and postmenopausal women.

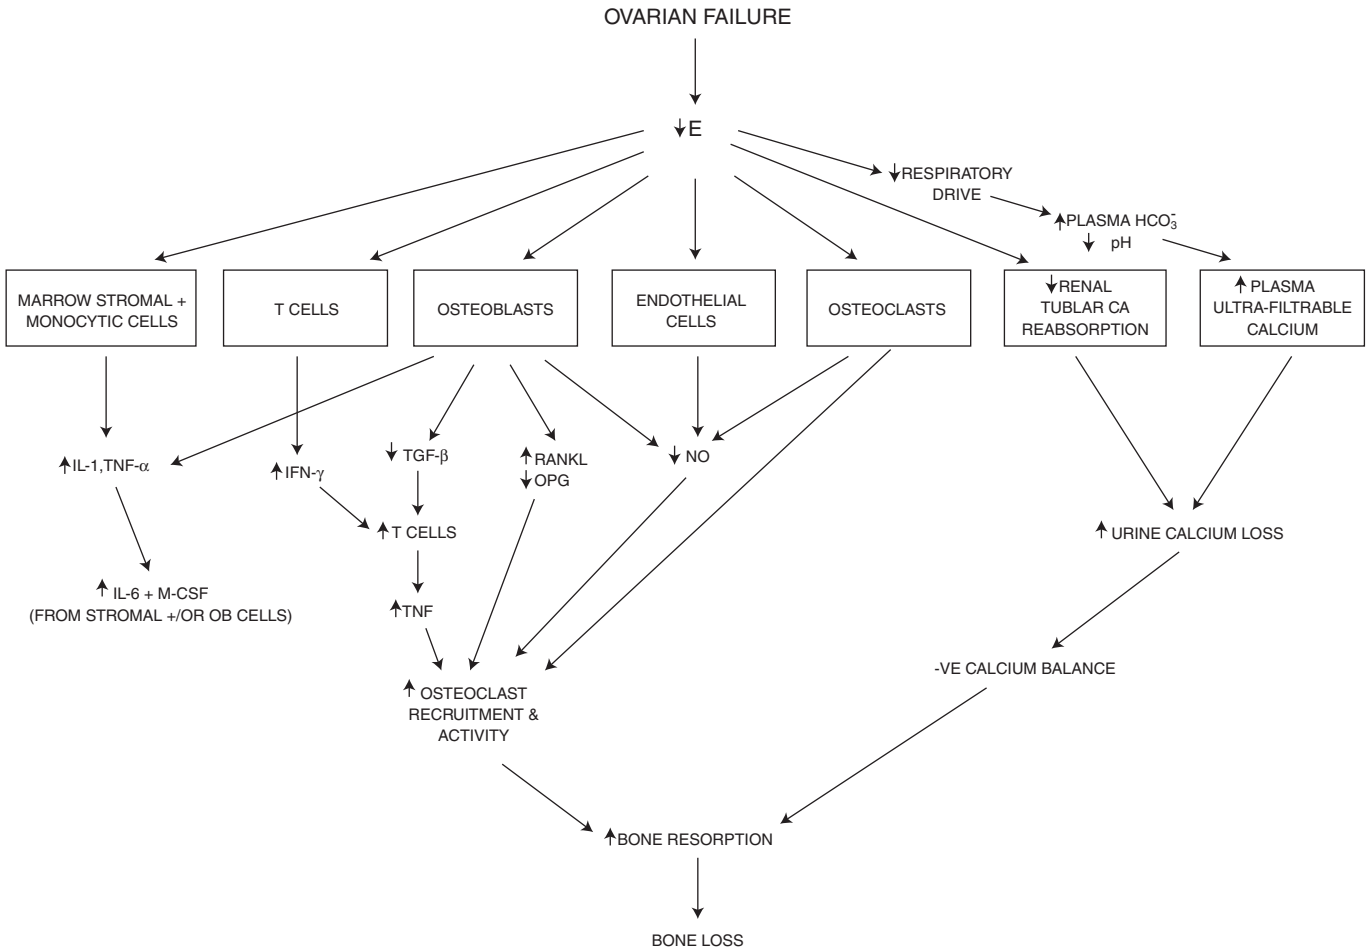

Fig. 21.1. The potential pathways by which menopause leads to bone loss. For simplicity, the figure does not show a contribution from loss of any anabolic effect of estrogen on the osteoblast. The fall in ovarian production of androgens and progesterone also contributes to some of these changes.

SUMMARY

The effects of menopause on skeletal physiology are summarized in Fig. 21.1. The major effect is an increase in bone turnover, which is dominantly an increase in bone resorption. This results in bone loss that may be contributed to by reductions in both intestinal and renal tubular absorption of calcium. Bone loss persists throughout the entire postmenopausal period and results in a high risk of fractures in those women whose peak bone mass was in the lower part of the normal range.

CALCIUM (CA)

Distribution

Total body distribution

In adults, the body contains about 1,000 g of calcium, of which 99% is located in the mineral phase of bone as the hydroxyapatite crystal [$Ca_{10}(PO4)_6(OH)_2$]. The crystal plays a key role in the mechanical weight-bearing properties of bone and serves as a ready source of calcium to support a number of calcium-dependent biological systems and to maintain blood ionized calcium within the normal range. The remaining 1% of total body calcium is located in the blood, extracellular fluid, and soft tissues. In serum, total calcium is 10^{-3} M and is the most frequent measurement of serum calcium levels. Of the total calcium, the ionized fraction (50%) is the biologically functional portion of total calcium and can be measured clinically; 40% of the total is bound to albumin in a pH-dependent manner; and the remaining 10% exists as a complex of either citrate or PO_4 ions.

Cell levels

Cytosol calcium is about 10^{-6} M, which creates a 1,000-fold gradient across the plasma membrane [extracellular fluid (ECF) calcium is 10^{-3} M] that favors calcium entry into the cell. There is also an electrical charge across the plasma membrane of about 50 mV with the cell interior negative. Thus, the chemical and electrical gradients across the plasma membrane favor calcium entry, which the cell must defend against to preserve cell viability. Calcium-induced cell death is largely prevented by several mechanisms including extrusion of calcium from the cell by adenosine triphosphate (ATP)-dependent energy driven calcium pumps and calcium channels; Na–Ca exchangers; and the binding of intracellular calcium by proteins located in the cytosol, endoplasmic reticulum (ER), and mitochondria. Calcium binding to ER and mitochondrial sites buffer intracellular calcium and can be mobilized to maintain cytosol calcium levels and to create pulsatile peaks of calcium to mediate membrane receptor signaling that regulate a variety of biologic systems.

Blood levels

Calcium in the blood is normally transported partly bound to plasma proteins (about 45%), notably albumin; partly bound to small anions such as phosphate and citrate (about 10%); and partly in the free or ionized state (about 45%) [1]. Although only the ionized calcium is available to move into cells and activate cellular processes, most clinical laboratories report total serum calcium concentrations. Concentrations of total calcium in normal serum generally range between 8.5 and 10.5 mg/dL (2.12 to 2.62 mM); levels above this are considered to be hypercalcemic. The normal range of ionized calcium is 4.65–5.25 mg/dL (1.16–1.31 mM). When protein concentrations, and especially albumin concentrations, fluctuate, total calcium levels may vary, whereas the ionized calcium may remain relatively stable. Dehydration or hemoconcentration during venipuncture may elevate serum albumin and falsely elevate total serum calcium. Such elevations in total calcium, when albumin levels

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

are increased, can be "corrected" by subtracting 0.8 mg/dL from the total calcium for every 1.0 g/dL by which the serum albumin concentration is greater than 4 g/dL. Conversely, when albumin levels are low, total calcium can be corrected by adding 0.8 mg/dL for every 1.0 g/dL by which the albumin is less than 4 g/dL. Even in the presence of a normal serum albumin, changes in blood pH can alter the equilibrium constant of the albumin–Ca^{2+} complex, with acidosis reducing the binding and alkalosis enhancing it. Consequently, major shifts in serum protein or pH requires direct measurement of the ionized calcium level to determine the physiologic serum calcium level.

Mineral homeostasis

The ECF concentration of calcium is tightly maintained within a rather narrow range because of the importance of the calcium ion to numerous cellular functions including cell division, cell adhesion and plasma membrane integrity, protein secretion, muscle contraction, neuronal excitability, glycogen metabolism, and coagulation.

The skeleton, the gut, and the kidney each play a major role in assuring calcium homeostasis. Overall, in a typical individual, if 1,000 mg of calcium are ingested in the diet per day, approximately 200 mg will be absorbed. Approximately 10 g of calcium will be filtered daily through the kidney and most will be reabsorbed, with about 200 mg being excreted in the urine. The normal 24-hour excretion of calcium may, however, vary between 100 and 300 mg per day (2.5 to 7.5 mmoles per day). The skeleton, a storage site of about 1 kg of calcium, is the major calcium reservoir in the body. Ordinarily, as a result of normal bone turnover, approximately 500 mg of calcium is released from bone per day and the equivalent amount is accreted per day (Fig. 22.1).

Tight regulation of the ECF calcium concentration is maintained through the action of calcium-sensitive cells that modulate the production of hormones [2–5]. These hormones act on specific cells in bone, gut, and kidney, which can respond by altering fluxes of calcium to maintain ECF calcium. Thus a reduction in ECF calcium stimulates release of parathyroid hormone (PTH) from the parathyroid glands in the neck. This hormone can then act to enhance bone resorption and liberate both calcium and phosphate from the skeleton. PTH can also enhance calcium reabsorption in the kidney while at the same time inhibit phosphate reabsorption producing phosphaturia. Hypocalcemia and PTH itself can both stimulate the conversion of the inert metabolite of vitamin D, 25-hydroxyvitamin D_3 [25(OH)D_3], to the active moiety 1,25-dihydroxyvitamin D_3 [1,25$(OH)_2D_3$] [6], which in turn will enhance intestinal calcium absorption, and to a lesser extent renal phosphate reabsorption. The net effect of the mobilization of calcium from bone, the increased absorption of calcium from the gut, and the increased reabsorption of filtered calcium along the nephron is to restore the ECF calcium to normal and to

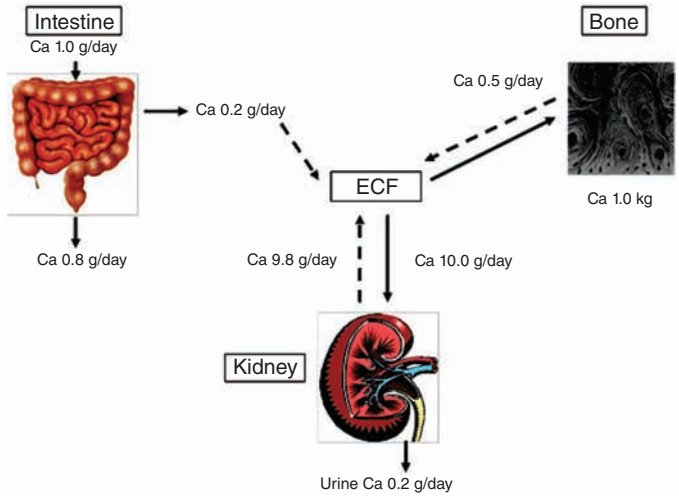

Fig. 22.1. Calcium balance. On average, in a typical adult approximately 1 g of elemental calcium (Ca^{+2}) is ingested per day. Of this, about 200 mg/day will be absorbed and 800 mg/day excreted. Approximately 1 kg of calcium is stored in bone, and about 500 mg/day is released by resorption or deposited during bone formation. Of the 10 g of calcium filtered through the kidney per day, only about 200 mg or less appears in the urine, the remainder being reabsorbed.

inhibit further production of PTH and 1,25$(OH)_2D_3$. The opposite sequence of events, i.e., diminished PTH and 1,25$(OH)_2D_3$ secretion, along with stimulation of renal calcium-sensing receptor (CaSR) occurs when the ECF calcium is raised above the normal range. The effect of suppressing the release of PTH and 1,25$(OH)_2D_3$ and stimulating CaSR diminishes skeletal calcium release, decreases intestinal calcium absorption and renal calcium reabsorption, and restores the elevated ECF calcium to normal.

PTH and 1,25$(OH)_2D_3$ actions on target tissues

Intestinal calcium transport

Net intestinal calcium absorption can be determined by the external balance technique in which a diet of known composition with a known amount of calcium is ingested, and urine calcium excretion and fecal calcium loss are measured. Negative absorption occurs when net absorption declines to about 200 mg calcium per day (5.0 mmol). The portion of dietary calcium absorbed varies with age and amount of calcium ingested and may vary from 20% to 60%. Rates of net calcium absorption are high in growing children, during growth spurts in adolescence, and during pregnancy and lactation. The efficiency of calcium absorption increases during prolonged dietary calcium restriction to absorb the greatest portion of that ingested. Net absorption declines with age in men and women, and so increased calcium intake is required to

compensate for the lower absorption rate. Fecal calcium losses vary between 100 and 200 mg per day (2.5 to 5.0 mmol). Fecal calcium is composed of unabsorbed dietary calcium and calcium contained in intestinal, pancreatic, and biliary secretions. Secreted calcium is not regulated by hormones or serum calcium.

About 90% of absorbed calcium occurs in the large surface area of the duodenum and jejunum. Increased calcium requirements stimulate expression of the epithelial calcium active transport system in the duodenum, ileum, and throughout the colon sufficient to increase fractional calcium absorption from 20% to 45% in older men and women to 55% to 70% in children and young adults.1,25$(OH)_2D_3$ increases the efficiency of the small intestine and colon to absorb dietary calcium. Active calcium absorption accounts for absorption of 10–15% of a dietary load [7]. Active transcellular intestinal absorption involves three sequential cellular steps; a rate-limiting step involving transfer of luminal calcium into the intestinal cell via the epithelial calcium channel; expression of TRPV6, a channel-associated protein; annexin2 calbindin-D9K; and to a lesser extent, the basolateral extrusion system PMCA1b [8, 9]. Reductions in dietary calcium intake can increase PTH secretion and 1,25$(OH)_2D_3$ production. Increased 1,25$(OH)_2D_3$ can then increase expression of TRPV6, resulting in enhanced fractional calcium absorption and compensation for the dietary reduction [10]

Intestinal epithelial calcium transport includes both an energy-dependent, cell-mediated saturable active process that is largely regulated by 1,25$(OH)_2D_3$, and a passive, diffusional paracellular path of absorption that is driven by transepithelial electrochemical gradients. The cell-mediated pathway involving the TRPV6 calcium channel is saturable with a Kt (1/2 maximal transport) of 1.0 mM. Passive diffusion increases linearly with luminal calcium concentration. In adults fed a diet low in calcium, enhanced 1,25$(OH)_2D_3$ production increases the efficiency of absorption through an increase in saturable calcium transport. During high dietary calcium intake absorption 1,25$(OH)_2D_3$ is suppressed, and passive paracellular transport accounts for most all absorption. Causes of increased and decreased intestinal calcium absorption are listed in Table 22.1.

Table 22.1. Conditions That Increase or Decrease Intestinal Calcium Absorption

Increased Calcium Absorption	Decreased Calcium Absorption
Increased renal 1,25$(OH)_2D_3$ production	Decreased renal 1,25$(OH)_2D_3$ production
Growth	Vitamin D deficiency
Pregnancy	Chronic renal insufficiency
Lactation	Hypoparathyroidism
Primary hyperparathyroidism	Aging
Vitamin D-dependent rickets type 1	
Idiopathic hypercalciuria	
Increased extra-renal 1,25$(OH)_2D_3$ production	Normal 1,25$(OH)_2D_3$ production
Sarcoid and other granulomatous diseases	Glucocorticoid excess
B-cell lymphoma	

Renal calcium handling

The kidney plays a central role in ensuring calcium balance, and PTH has a major role in fine-tuning this renal function [11–13] by stimulating both renal calcium reabsorption (proximal tubule) and excretion (distal nephron). Multiple influences on calcium handling are listed in Table 22.2 (Chapters 26, 28, and 73 contain descriptions of the molecular actions of PTH on the kidney.) PTH has little effect on modulating calcium fluxes in the proximal tubule where 65% of the filtered calcium is reabsorbed, coupled to the bulk transport of solutes such as sodium and water [12]. In this nephron region, PTH can also stimulate the 25$(OH)D_3$-1α hydroxylase [1α(OH)ase], leading to increased synthesis of 1,25$(OH)_2D_3$ [14]. A reduction in ECF calcium can itself stimulate 1,25$(OH)_2D_3$ production, but whether this occurs via the CaSR is presently unknown. Finally, PTH can also inhibit Na and $HC0_3^-$ reabsorption in the proximal tubule by inhibiting the apical type 3 Na^+/H^+ exchanger [15], and the basolateral Na^+/K^+-ATPase [16] by inhibiting apical Na+/Pi– cotransport.

About 20% of filtered calcium is reabsorbed in the cortical thick ascending limb of the loop of Henle (CTAL), and 15% is reabsorbed in the distal convoluted tubule (DCT). At both sites PTH binds to the PTH receptor (PTHR) [17, 18] and enhances calcium reabsorption. In the CTAL, at least, this appears to occur by increasing the activity of the Na/K/2Cl cotransporter that drives NaCl reabsorption and stimulates paracellular calcium and magnesium reabsorption [19]. The CaSR is also resident in the CTAL [20], where increased ECF calcium activates phospholipase A2, thereby reducing the activity of the Na/K/2Cl cotransporter and of an apical K channel, and diminishing paracellular calcium reabsorption. Consequently, a raised ECF calcium antagonizes the effect of PTH in this nephron segment, and ECF calcium can, in fact, participate in this way in the regulation of its own homeostasis. Inhibition of NaCl reabsorption and loss of NaCl in the urine may contribute to the volume depletion observed in severe hypercalcemia. ECF calcium may therefore act in a manner analogous to "loop" diuretics such as furosemide.

In the DCT, PTH can influence [8] luminal calcium transfer into the renal tubule cell via the transient receptor potential channel (TRPV5). It can also influence translocation of calcium across the cell from apical to

Table 22.2. Hormones and Conditions That Regulate Urine Ca and Mg Excretion

basolateral surface involving proteins such as calbindin-D28K, and active extrusion of calcium from the cell into the blood via a Na+/Ca exchanger, designated NCX1. PTH markedly stimulates calcium reabsorption in the DCT primarily by augmenting NCX1 activity via a cyclic AMP-mediated mechanism.

Bone resorption and calcium release

In bone, the PTHR is localized on cells of the osteoblast phenotype, which are of mesenchymal origin [21] but not on osteoclasts, which are of hematogenous origin. A major physiologic role of PTH appears to be to maintain normal calcium homeostasis by enhancing osteoclastic bone resorption and liberating calcium into the ECF. Bone formation and resorption are discussed in detail in Section I and Chapters 25–29.

Mediators of bone remodeling

Calciotropic hormones PTH, PTHrP, and $1,25(OH)_2D_3$ initiate osteoclastic bone resorption and increase the activation frequency of bone remodeling. Physiologic control of bone turnover can be disrupted by an excess of each of these calciotropic hormones, resulting in altered ECF calcium homeostasis and hypercalcemia. The molecular basis for physiologic and pathologic states of bone turnover is detailed in Chapters 2–4, 25, 26, 29, and in Section VII.

Regulation of hormone production and actions on calcium homeostasis

PTH production

A major regulator of parathyroid gland secretion of PTH is ECF calcium. The relationship between ECF calcium and PTH secretion is governed by a steep inverse sigmoidal curve that is characterized by a maximal secretory rate at low ECF calcium, a midpoint or "set point," which is the level of ECF calcium that half-maximally suppresses PTH, and a minimal secretory rate at high ECF calcium [22, 23]. The parathyroid glands detect ECF calcium via a CaSR [24]. Sustained hypocalcemia can eventually lead to parathyroid cell proliferation [25] and an increased total secretory capacity of the parathyroid gland. $1,25(OH)_2D_3$ reduces PTH synthesis and parathyroid cell proliferation [26]. Molecular events in PTH secretion and CaSR function are found in Chapters 26 and 28.

Vitamin D production and actions

The renal production of $1,25(OH)_2D_3$ is stimulated by hypocalcemia, hypophosphatemia, and elevated PTH levels. The renal 1α(OH)ase is also potently inhibited by $1,25(OH)_2D_3$ as part of a negative feedback loop. The molecular details of the vitamin D metabolic pathway are described in Chapter 29.

Vitamin D is essential for normal mineralization of bone that may be due to an indirect effect by enhancing intestinal calcium and phosphate absorption and maintaining these ions within a range that facilitates hydroxyapatite deposition in bone matrix. A major indirect function of $1,25(OH)_2D_3$ on bone appears to be to enhance mobilization of calcium stores when dietary calcium is insufficient to maintain a normal ECF calcium [27]. As with PTH [28], $1,25(OH)_2D_3$ enhances osteoclastic bone resorption by binding to receptors in the preosteoblastic stromal cell and stimulating the RANK/RANK system to enhance the proliferation, differentiation, and activation of the osteoclastic system from its monocytic precursors [29]. Endogenous and exogenous $1,25(OH)_2D_3$ have also been reported to have an anabolic role *in vivo* [30,31]. $1,25(OH)_2D_3$ has a direct effect on renal calcium handling through stimulation of CaSR. It remains controversial whether $1,25(OH)_2D_3$ plays a direct role in enhancing tubular calcium reabsorption.

MAGNESIUM

Total body distribution

There is about 1.04 mol (25 g) of magnesium in the adult, of which about 66% is within the skeleton, 33% is intracellular, and 1% is in the ECF, including blood [1, 2]. Magnesium content of the hydroxyapatite crystal in bone varies widely and is mainly on the surface of bone where a portion is in equilibrium with ECF magnesium. Magnesium is the most abundant divalent cation within cells where it is found at a concentration of about 5×10^{-4} M in the cytosol. In the cells it serves as a cofactor and regulates a number of essential biological systems [1]. The concentration of magnesium in the ECF approaches that of the intracellular environment. Both intracellular and ECF are tightly regulated by factors that are poorly understood.

Cellular content

Ionic cytosolic magnesium accounts for 5% to 10% of total cellular magnesium. Cytosol magnesium is regulated by binding to intracellular organelles, of which 60% is within mitochondria where it participates in phosphate transport and ATP utilization. Control of intracellular magnesium is poorly understood.

Homeostasis

Of the total serum magnesium, 70% is either ionic or complexed, and the remaining 30% is protein bound [1, 2]. Blood levels are not as tightly regulated as calcium but fluctuate with influx and efflux across the ECF with changes in intestinal magnesium absorption, net renal magnesium reabsorption, and influx and efflux across bone. Blood ionic magnesium regulates PTH secretion but the potency is less than that of calcium.

Intestinal absorption

Magnesium is a requirement for bone health; however, unlike calcium, magnesium is found in all food groups and is especially rich in foods of cellular origin. Therefore, magnesium deficiency due to inadequate intake does not occur in the absence of severe defects in intestinal or renal function. Net intestinal magnesium absorption is in direct proportion to dietary magnesium ingestion. Under conditions of stable magnesium intake, external magnesium balance studies show that when magnesium intake is greater than 28 mg (2 mmol), magnesium absorption exceeds magnesium secretion, and magnesium balance becomes positive. The efficiency of magnesium absorption is 35% to 40% over the range of usual intakes (168 to 720 mg/day; or 7 to 30 mmol). Net magnesium absorption also varies with dietary constituents such as phosphate, which forms insoluble complexes with magnesium and thereby reduces magnesium absorption. In contrast to its actions on calcium and phosphorus absorption, $1,25(OH)_2D_3$ does not stimulate magnesium absorption. There is no correlation between serum $1,25(OH)_2D_3$ levels and net magnesium absorption [32].

Absorptive and secretory magnesium fluxes across both small intestine and colon are largely voltage dependent, indicating the presence of a large paracellular pathway of magnesium transport that is driven by luminal magnesium concentrations. The magnesium ion channel TRPM6 has been identified in the apical membrane of intestinal brush border epithelial cells that appears to play an important role in magnesium homeostasis [32]. Whether TRPM6 is regulated by PTH or 1,25(OH)2D3 has yet to be determined.

Renal handling

Ultrafilterable magnesium is 70% of the total serum magnesium (ionized plus complexed). Based on the urine magnesium excretion (about 24 mmol per 24 hours), about 95% of the filtered load of magnesium undergoes tubular reabsorption before the final urine is formed. A small fraction of reabsorbed magnesium (15%) occurs along the proximal tubule, whereas about 70% of filtered magnesium is reabsorbed along the cortical TALH [19, 33]. The magnesium ion may also stimulate basolateral membrane CaR, which decreases renal magnesium reabsorption. DCT magnesium reabsorption is via a transcellular transport process and accounts for about 10% of magnesium reabsorption.

Magnesium reabsorption is highly regulated, with a number of factors that may increase or decrease renal tubule magnesium reabsorption (Table 22.2). As there is little distal tubule magnesium reabsorption, ECF volume expansion decreases magnesium reabsorption and increases urine magnesium excretion. Hypermagnesemia increases urine magnesium excretion, at least in part through an activation of CaR [20]. In contrast, hypomagnesemia increases TALH magnesium reabsorption and decreases urine magnesium excretion. Loop diuretics increase urine magnesium excretion, and thiazide diuretic agents have a minimal effect of magnesium transport (Table 22.2). The magnesium ion channel TRPM6 is found in the apical membrane of the renal distal convoluted tubule and may be involved in magnesium homeostasis in both the kidney and intestine.

Much of normal mineral and bone homeostasis in the adult can be explained by the interactions of parathyroid hormone (PTH), 1,25-dihydroxyvitamin D or calcitriol (1,25-D), calcitonin, and the sex steroids. In contrast, less is known about how mineral and bone homeostasis is regulated in the fetus. Due to obvious limitations in studying human fetuses, human regulation of fetal mineral homeostasis must be largely inferred from studies in animals, and some observations in animals may not apply to humans. This chapter briefly reviews existing human and animal data; two comprehensive reviews on the subject contain more detailed references [1, 2].

Fetal mineral metabolism has adapted to maintain a high extracellular level of calcium (and other minerals) that is physiologically appropriate for fetal tissues and to provide sufficient calcium (and other minerals) to fully mineralize the skeleton before birth. Mineralization occurs rapidly in late gestation, such that a human accretes 80% of the required 20–30 g of calcium in the third trimester [3, 4], while a rat accretes 95% of the required 12.5 mg of calcium in the last 5 days of its 3-week gestation [5].

MINERAL IONS AND CALCIOTROPIC HORMONES

Human and other mammalian fetuses consistently maintain the serum calcium (both total and ionized) at significantly higher values than in the mother during late gestation. Similarly, serum phosphate is significantly elevated while serum magnesium is minimally elevated above the maternal concentration.

These increased serum mineral concentrations have physiological importance. Maintaining the fetal calcium concentration above the maternal level is required to achieve normal mineralization of the fetal skeleton, as discussed below. Survival to the end of gestation is unaffected by significant hypocalcemia in *Pthrp* null, *Pthr1* null, *Hoxa3* null, *Trpv6* null, and *Hoxa3/Pthrp* double mutant fetuses [6–9]. But survival after birth may be aided by a high blood calcium level *in utero*. The serum calcium declines 20–30% after birth in humans [10–12] and 40% in rodents [13, 14] before increasing to adult values over the succeeding 24 hours. A lower fetal blood calcium may predispose to an even lower trough level being reached after birth, thereby increasing the risk of tetany and death. The early postnatal mortality of *Pthrp* null, *Pthr1* null, and *Hoxa3* null fetuses is consistent with this possibility [8, 15, 16], whereas hypocalcemic *Tpv6* null fetuses do not show perinatal mortality [9, 17].

The high level of calcium in the fetal circulation is robustly maintained despite maternal hypocalcemia from a variety of causes. For example, the serum calcium is normal in fetal mice lacking the vitamin D receptor (*Vdr* null fetuses) and also in pups born of severely vitamin D deficient rodents [18–22]. Similarly, the cord blood calcium is normal in human babies with severe vitamin D deficiency (25-hydroxyvitamin D levels of 10 nmol/l versus 138 nmol/l in offspring of vitamin

D-treated mothers) [23], while children with naturally occurring deletions in the VDR do not present with hypocalcemia or rickets until their second year of life [2].

Calciotropic hormone levels are maintained at levels that differ from the adult. These differences appear to reflect the relatively different roles that these hormones play in the fetus and are not an artifact of altered metabolism or clearance of hormones. Intact PTH levels are much lower than maternal PTH levels near the end of gestation, but PTH is important for fetal development since fetal mice lacking parathyroids or PTH are hypocalcemic and have undermineralized skeletons [7, 8, 24, 25]. Circulating 1,25-D levels are also low in late gestation, owing to suppression of the fetal 1α-hydroxylase by high serum calcium and phosphate, and low PTH. 1,25-D may also be relatively unimportant for fetal mineral homeostasis, since several vitamin D deficiency models, 1α-hydroxylase null pigs, and *Vdr* null mice, all have normal serum mineral concentrations and fully mineralized skeletons at term (reviewed in detail in Ref. 2). Fetal calcitonin levels are higher than maternal levels and may be responding to the higher serum calcium in the fetus, but calcitonin does not play an essential role in fetal calcium homeostasis [26].

At term, cord blood levels of parathyroid hormone-related protein (PTHrP) are up to 15-fold higher than simultaneous PTH levels. PTHrP is produced in many tissues and plays multiple roles during embryonic and fetal development (see the chapter on parathyroid hormone-related protein). Absence of PTHrP (in *Pthrp* null fetuses) leads to abnormal endochondral bone development, modest hypocalcemia [15], and reduced placental calcium transfer [15, 27]. These *Pthrp* null fetuses have secondary hyperparathyroidism [7], but the blood calcium is reduced to the maternal level, confirming that PTH does not make up for lack of PTHrP in maintaining a normal fetal calcium concentration. Conversely, PTHrP does not make up for absence of PTH, given that fetuses lacking either parathyroids or PTH are hypocalcemic and have no compensatory increase in circulating PTHrP levels [7, 8, 24].

The role (if any) of the sex steroids in fetal skeletal development and mineral accretion is uncertain. Mice lacking estrogen receptor alpha and beta or the aromatase appear normal at birth and develop altered skeletal metabolism postnatally, but the fetal skeleton has not been examined [28–32]. Similarly, while postnatal skeletal roles of receptor activator of nuclear factor-κB (RANK), RANK ligand (RANKL), and osteoprotegerin are well known in humans and various knockout mouse models, the role that this system plays in fetal mineral metabolism is not yet known. Notably, mice lacking RANK or RANKL appear normal at birth and maintain normal serum calcium and phosphorus until weaning [33, 34].

FETAL PARATHYROIDS

Intact parathyroid glands are required for maintenance of normal fetal calcium, magnesium, and phosphate levels. Lack of parathyroids causes the fetal blood calcium to fall below the maternal level in mice [7, 8], whereas lack of either PTH or PTHrP causes the fetal calcium to fall to the maternal level [24]. Fetal parathyroids and PTH are also required for normal accretion of mineral by the skeleton and may be required for regulation of placental mineral transfer, as discussed below. Studies in fetal lambs have indicated that the fetal parathyroids may contribute to mineral homeostasis by producing both PTH and PTHrP, while detailed study of rats indicated that the fetal parathyroids produce only PTH (reviewed in Ref. 35). Whether human fetal parathyroids produce PTH alone, or PTH and PTHrP together, is unclear.

CALCIUM SENSING RECEPTOR (CaSR)

The parathyroid CaSR regulates the serum calcium level in adults by inhibiting PTH, but it does not appear to set the high serum calcium level of fetuses. Instead, the CaSR likely suppresses fetal PTH in response to the elevated fetal blood calcium [36]. On the other hand, inactivating mutations of the CaSR (*Casr* null fetuses) disrupt fetal homeostasis by inducing hyperparathyroidism with increased serum calcium, 1,25-D, and bone turnover, and this results in a lower skeletal calcium content by term [36]. The CaSR is also expressed within human and murine placentas [37], and may play some role in regulating placental mineral transfer. *Casr* null fetuses have a reduced rate of placental calcium transfer but whether this is a direct consequence of the loss of placental CaSR is not known [36].

FETAL KIDNEYS AND AMNIOTIC FLUID

Fetal kidneys partly regulate calcium homeostasis by adjusting the relative reabsorption and excretion of calcium, magnesium and phosphate in response to the filtered load and other regulatory factors, such as PTHrP and PTH. The fetal kidneys also synthesize 1,25-D, but since *Vdr* null fetal mice and severely vitamin D deficient rodent fetuses show no alteration in serum minerals or skeletal mineral content [2], it appears likely that production of 1,25-D by the fetal kidneys is relatively unimportant.

Renal calcium handling during fetal life may have minimal importance because calcium excreted by the kidneys is not permanently lost. Fetal urine is the major source of fluid and solute in amniotic fluid, and with swallowing the excreted calcium is made available again to the fetus.

PLACENTAL MINERAL ION TRANSPORT

As noted above, the bulk of placental calcium and other mineral transfer occurs late in gestation at a rapid rate.

Active transport of calcium, magnesium, and phosphate across the placenta is necessary for the fetal requirement to be met; only placental calcium transfer has been studied in detail. Analogous to calcium transfer across the intestinal mucosa, it has been theorized that calcium enters calcium-transporting cells through channels in maternal-facing basement membranes, is carried across these cells by calcium binding proteins, and is then actively extruded at the fetal-facing basement membranes by Ca^{2+}-ATPase.

Data from animal models indicate that a normal rate of maternal-to-fetal calcium transfer can usually be maintained despite the presence of maternal hypocalcemia or maternal hormone deficiencies such as aparathyroidism, vitamin D deficiency, and absence of the VDR [1, 6]. Whether the same is true for human pregnancies is less certain (see below, fetal response to maternal hypoparathyroidism). A "normal" rate of maternal–fetal calcium transfer does not necessarily imply that the fetus is unaffected by maternal hypocalcemia. Instead, it is an indication of the resilience of the fetal–placental unit to be able to extract the required amount of calcium from a hypocalcemic maternal circulation.

Fetal regulation of placental calcium transfer has been studied in a number of different animal models. Thyroparathyroidectomy in fetal lambs results in a reduced rate of calcium transfer across isolated, perfused placentas, suggesting that the parathyroids regulate placental calcium transfer [38]. In contrast, mice lacking parathyroids as a consequence of ablation of the *Hoxa3* gene have a normal rate of placental calcium transfer [8]. The discrepancy between these findings in lambs and mice may be due to whether or not the parathyroids are an important source of PTHrP in the circulation, as discussed above. Studies in fetal lambs and in *Pthrp* null fetal mice are in agreement that PTHrP, and in particular mid-molecular forms of PTHrP, stimulate placental calcium transfer [27, 39, 40]. There is also evidence that PTH is expressed within murine placenta from where it may stimulate placental transfer of calcium and other cations [24]. Conversely, calcitonin and 1,25-D are not required for placental calcium transport [18, 26].

FETAL SKELETON

A complete cartilaginous skeleton with digits and intact joints is present by the 8th week of gestation in humans. Primary ossification centers form in the vertebrae and long bones between the 8th to 12th weeks, but it is not until the third trimester that the bulk of mineralization occurs. At the 34th week of gestation, secondary ossification centers form in the femurs, but otherwise most epiphyses are cartilaginous at birth, with secondary ossification centers appearing in other bones in the neonate and child [41].

The skeleton must undergo substantial growth and be sufficiently mineralized by the end of gestation to support the organism, but as in the adult, the fetal skeleton participates in the regulation of mineral homeostasis. Calcium accreted by the fetal skeleton can be subsequently resorbed to help maintain the concentration of calcium in the blood, and this resorption can become more pronounced with severe maternal hypocalcemia [6] or in *Casr* null fetal mice [36]. Functioning fetal parathyroid glands are needed for normal skeletal mineral accretion, and both hypoparathyroidism (thyroparathyroidectomized fetal lambs, aparathyroid fetal mice, *Pth* null fetuses) and hyperparathyroidism (including *Casr* null fetal mice) reduce the net amount of skeletal mineral accreted by term.

Further comparative study of fetal mice lacking parathyroids, PTH, or PTHrP has demonstrated the interlocking roles of PTH and PTHrP in regulating the development and mineralization of the fetal skeleton [35]. PTHrP is produced locally in proliferating chondrocytes and perichondrium from where it directs the development of the cartilaginous scaffold that is later broken down and transformed into bone [42]. PTHrP is also expressed in preosteoblasts and osteoblasts from where it acts in an autocrine and paracrine manner to stimulate osteoblast function [43]. PTH acts from the systemic circulation to stimulate osteoblasts and contribute to maintaining the fetal blood calcium and magnesium at levels that facilitate mineralization. In the absence of PTHrP, a severe chondrodysplasia results from rapid differentiation and early apoptosis of chondrocytes [15]; accelerated and abnormal calcification also occurs, resulting in an apparently normal mineral content [7, 15]. Secondary hyperparathyroidism enables the *Pthrp* null growth plates to maintain normal expression of collagen α1(I) and collagenase-3, upregulated expression of osteocalcin and osteopontin, and increased mineralization [15, 44]. But when the PTH/PTHrP receptor (PTH1R) is ablated (*Pthr1* null fetuses), the resultant phenotype combines the *Pthrp* null chondrodysplasia with decreased osteoblast function, as evidenced by reduced expression of collagenase-3, osteocalcin, and osteopontin, and reduced mineralization [16, 44].

In the absence of parathyroids or PTH, the chondrocytic aspects of endochondral bone formation proceed normally but the bone compartment is significantly undermineralized at term [7, 24, 25]. Whether defects in osteoblast function are present when PTH is absent is unclear, since the expression of osteoblast-specific genes is normal in aparathyroid *Hoxa3* null fetuses but inconsistently reduced in *Pth* null fetuses [7, 24, 25]. The blood calcium and magnesium are significantly reduced in fetuses lacking parathyroids or PTH, and so the lack of PTH may impair mineralization simply by reducing the amount of mineral presented to the skeletal surface and to osteoblasts.

FETAL RESPONSE TO MATERNAL HYPERPARATHYROIDISM

In humans, maternal primary hyperparathyroidism has been associated with adverse fetal outcomes, including

spontaneous abortion and stillbirth, which are thought to result from suppression of the fetal parathyroid glands [45]. Since PTH cannot cross the placenta [46, 47], fetal parathyroid suppression may result from increased calcium flux across the placenta to the fetus, facilitated by maternal hypercalcemia. The suppressed parathyroid function may persist for months in the neonate and has been permanent in some cases [48, 49]. Similar suppression of fetal parathyroids occurs when the mother has hypercalcemia due to familial hypocalciuric hypercalcemia [50, 51]. Chronic elevation of the maternal serum calcium in mice results in suppression of the fetal PTH level [36], but fetal survival is not notably affected by this.

FETAL RESPONSE TO MATERNAL HYPOPARATHYROIDISM

Maternal hypoparathyroidism during human pregnancy can cause fetal hyperparathyroidism. This is characterized by fetal parathyroid gland hyperplasia, generalized skeletal demineralization, subperiosteal bone resorption, bowing of the long bones, osteitis fibrosa cystica, rib and limb fractures, low birth weight, spontaneous abortion, stillbirth, and neonatal death [6]. Similar skeletal findings have been reported in the fetuses and neonates of women with pseudohypoparathyroidism, renal tubular acidosis, and chronic renal failure [6]. These changes in human skeletons differ from what has been found in animal models of maternal hypoparathyroidism, in which the fetal skeleton and the blood calcium are generally normal.

FETAL RESPONSE TO MATERNAL VITAMIN D DEFICIENCY

Cord blood levels of 25OHD are usually within 80–100% of the maternal value at term [2] because 25-hydroxyvitamin D (25OHD) readily crosses the placenta. This means that if the mother is vitamin D deficient or insufficient, then the fetus will be as well.

As mentioned earlier, fetal calcium metabolism and skeletal mineral content are normal in animal models of severe vitamin D deficiency, and in *Vdr* null mice [2]. The available but limited human data indicate that calcium homeostasis and skeletal mineral content in human fetuses may also be unaffected by severe vitamin D deficiency and absence of VDR.

These data include the finding of normal ash weight, skeletal mineral content (by atomic absorption spectroscopy), and absence of radiological signs of rickets, in severely vitamin D deficient infants who died of obstetrical accidents [52]. Observational data of infants with severe vitamin D deficiency or genetic absence of 1α-hydroxylase or VDR show that hypocalcemia and rickets do not normally develop or become recognized until at least several months after birth, with the peak incidence occurring in the second year [2]. Studies of bone mineral density in newborns have not shown any association with vitamin D sufficiency [2]. Recently, two large randomized trials examined the use of up to 4,000 IU of vitamin D per day during pregnancy and found no effect of vitamin D use or 25-hydroxyvitamin D levels on cord blood calcium or skeletal parameters in the newborns [53].

The available animal and human data predict that human fetuses will have a normal skeleton and serum calcium despite a severe vitamin D deficiency. It is the vitamin D-deficient neonates and infants who are at risk for postnatal hypocalcemia followed by the later development of rickets [2]. The reason maternal vitamin D deficiency may have little or no effect on fetal calcium homeostasis is that secondary hyperparathyroidism in the mother minimizes the hypocalcemia as compared to what occurs with maternal hypoparathyroidism, and because placental transport of calcium (and relevant genes involved in cation transport) does not require calcitriol or VDR.

However, recent clinical studies have questioned whether the fetal skeleton is truly normal with even maternal insufficiency of vitamin D. These studies examined associations between single measurements of maternal serum 25OHD during pregnancy and various skeletal outcomes in the fetus, neonate, or child. In none of these was an association found with birth weight, cord blood calcium, skeletal lengths, and bone mineral density [54–57]. In one study, a 25OHD level below 28 nmol/L was reportedly associated with a slightly shorter knee–heel length, but the difference was not statistically significant after correcting for gestational age [54]. A second study found that maternal 25OHD levels *below* 50 nmol/L were associated with greater distal metaphyseal cross-sectional area in the femur and concluded that this was evidence of early rickets [55]. But a third study found that maternal 25OHD levels *above* 42.6 nmol/L were associated with greater metaphyseal cross-sectional area in the tibia, and concluded that this meant stronger bone [56]. The latter pair of studies exemplify how subjective the interpretations can be, with greater metaphyseal cross-sectional area considered an adverse effect in one study and a benefit in another.

A fourth well-publicized study by Javaid found no associations between maternal serum 25OHD and birth weight, length, placental weight, abdominal circumference, head circumference, or cord blood calcium [57]. At the 9-*month* follow-up there was still no association of maternal 25OHD with skeletal and anthropometric parameters in the infants. However, a maternal serum 25OHD level below 27.5 nmol/L during pregnancy was associated with a modestly lower bone mineral content in offspring at 9 *years of age* compared to offspring of mothers whose 25OHD levels had been 50 nmol/L or higher. These findings have been used to promote the theory that vitamin D exposure during fetal development programs childhood peak bone mass [58].

There are several caveats to keep in mind about these associational studies. Unstated are which radiological parameters were prespecified and how many were examined before a single statistically significant finding was reported in each study. Why the tibia in one study and the femur in another, and not both or more skeletal sites? The possibility of chance and clinically insignificant findings cannot be excluded. The studies are confounded by factors that predispose to low maternal 25OHD levels, including obesity, lower socioeconomic status, poorer nutrition and lack of exercise, and prenatal care or vitamin supplementation, etc. Therefore, is lower 25OHD simply a marker of a less healthy pregnant woman? In the Javaid study, much time elapsed between birth (when no effect was seen) and 9 years of age (when lower bone mineral content was found). Does low 25OHD *in utero* program lower bone mineral content at 9 years of age? Or does lower maternal 25OHD in late pregnancy signal that lower socioeconomic status, poorer nutrition, and other factors in the mother will remain unchanged and continue to be shared with the child? Ultimately, associational studies are hypothesis generating and do not prove causality, thus clinical trials of vitamin D supplementation are needed to control for confounding and definitively determine if vitamin D supplementation during pregnancy confers any skeletal benefit on the fetus, neonate, infant, or child. The two largest clinical trials described above did not find any skeletal benefit [53]; unfortunately, bone mineral density measurements in the newborns were apparently not done as originally planned.

INTEGRATED FETAL CALCIUM HOMEOSTASIS

The evidence discussed in the preceding sections suggests the following summary models.

Calcium sources

The main flux of calcium and other minerals is across the placenta and into fetal bone, but calcium is also made available to the fetal circulation through several routes (see Fig. 23.1). The kidneys reabsorb calcium; calcium excreted by the kidneys into the urine and amniotic fluid may be swallowed and reabsorbed, and calcium is also resorbed from the developing skeleton. Some calcium returns to the maternal circulation (backflux). The maternal skeleton is a potential source of mineral, and it may be compromised in mineral deficiency states in order to provide to the fetus.

Blood calcium regulation

The fetal blood calcium is set at a level higher than the maternal value through the actions of PTHrP and PTH acting in concert (among other potential factors). The CaSR suppresses PTH in response to the high calcium level, but the low level of PTH is required for maintaining the blood calcium and facilitating mineral accretion by the skeleton. The synthesis and secretion of 1,25-D are, in turn, suppressed by low PTH, and high blood calcium and phosphate. The parathyroids may play a central role by producing PTH and PTHrP, or may produce PTH alone. PTHrP and PTH are produced by the placenta, and PTHrP is also produced by many other fetal tissues.

PTH and PTHrP, both present in the fetal circulation, independently and additively regulate the fetal blood calcium. Neither hormone can make up for absence of the other: if one is missing, the blood calcium is reduced, and if both are missing, the blood calcium is reduced even further. PTH upregulates in the absence of PTHrP, but PTHrP does not upregulate when parathyroids or PTH are absent. PTH may contribute to the blood calcium through actions on the PTH1R in several target tissues (kidney, bone, placenta), while PTHrP may act through the PTH1R and other novel receptors that respond to the mid or carboxy-terminal portions of the molecule.

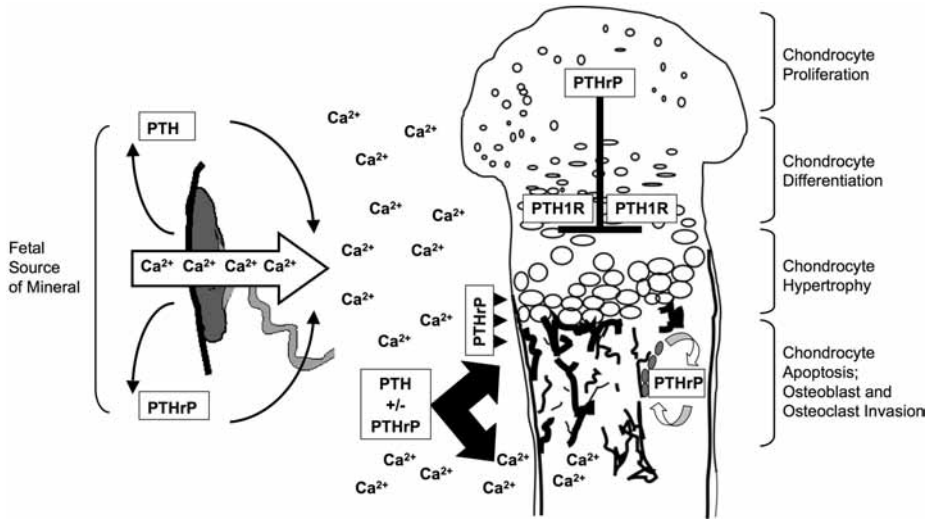

Fig. 23.2. Relative roles of PTH, PTHrP, and 1,25-D during fetal life. The placenta is the main source of minerals. PTH and PTHrP are expressed within the placenta but may also act on it from systemic sources. PTHrP stimulates calcium and possibly magnesium transfer; PTH also regulates calcium transfer and the expression of cation transporters. The regulators of placental phosphorus transfer are unknown. Within the endochondral skeleton, PTHrP is produced by proliferating chondrocytes and perichondrial cells (arrowheads) from which sites it acts on prehypertrophic chondrocytes (where the PTH1R is expressed) in order to delay their differentiation into hypertrophic chondrocytes. Hypertrophic chondrocytes undergo apoptosis, vascular invasion occurs, chondroclasts and osteoclasts resorb the cartilaginous matrix, and osteoblasts lay down primary spongiosa. PTHrP is also produced within preosteoblasts and osteoblasts from where it acts in a paracrine and autocrine fashion to stimulate bone formation (semicircular arrows). During fetal life PTHrP and PTH both regulate the fetal blood calcium, magnesium, and phosphorus, the concentrations of which are maintained above ambient maternal levels in order to facilitate mineralization. The regulation of blood calcium, placental calcium transfer, endochondral bone formation, and skeletal mineralization do not require 1,25-D or VDR during fetal life. Adapted with permission from Ref. 60. 2012 Elsevier.

The increased fetal blood calcium level is not a simple consequence of active placental calcium transfer because placental calcium transfer is normal in aparathyroid and *Pth* null mice and relatively increased in mice lacking the PTH1R, and yet each model is hypocalcemic [8, 24, 27]. Also, *Casr* null fetuses have reduced placental calcium transfer but markedly increased blood calcium levels that appear to result from fetal bone resorption [36].

Placental calcium transfer

Placental calcium transfer is regulated by both PTHrP and PTH, and the placenta (and possibly the parathyroids) is likely an important source of both hormones. The CaSR may also be involved in some aspect of calcium sensing within the calcium-transporting cells of the placenta.

Skeletal mineralization

PTH and PTHrP have separate roles with respect to skeletal development and mineralization (Fig. 23.2). PTH normally acts systemically to direct the mineralization of the bone matrix by maintaining the blood calcium at the adult level, and by direct actions on osteoblasts within the bone matrix. In contrast, PTHrP acts locally to direct endochondral bone development and osteoblast function, and acts from outside of bone to affect skeletal development and mineralization by contributing to the regulation of the blood calcium and placental calcium transfer. PTH may have the more dominant effect to maintain skeletal mineral accretion since the absence of PTH leads to an undermineralized skeleton while absence of PTHrP does not.

INTRODUCTION

Disorders of phosphate (Pi) homeostasis, in concert with powerful *in vitro* and *in vivo* studies have demonstrated that fibroblast growth factor-23 (FGF23) is central to the control of renal Pi and vitamin D homeostasis. Although the molecular mechanisms are unique to each disorder, elevated FGF23 is associated with syndromes manifested by hypophosphatemia with paradoxically low or normal $1,25(OH)_2$ vitamin D ($1,25(OH)_2D$), and include: autosomal dominant hypophosphatemic rickets (ADHR), X-linked hypophosphatemic rickets (XLH), tumor-induced osteomalacia (TIO), and autosomal recessive hypophosphatemic rickets (ARHR1 and ARHR2). Heritable disorders of hyperphosphatemia and often elevated $1,25(OH)_2D$, such as tumoral calcinosis (TC), are associated with reduced FGF23 activity. These collective findings have provided unique insight into the activity of FGF23 on renal Pi and vitamin D metabolism.

THE FGF23 GENE AND PROTEIN

The *FGF23* gene resides on human chromosome 12p13 (mouse chromosome 6). It comprises three coding exons and contains an open reading frame of 251 residues [1]. The tissue with the highest FGF23 expression is bone. FGF23 mRNA is observed in osteoblasts, osteocytes, flattened bone-lining cells, and osteoprogenitor cells [2]. Quantitative PCR demonstrated that FGF23 mRNA was most highly expressed in long bone, followed by thymus, brain, and heart [3].

Western analyses revealed that wild type FGF23 is secreted as a full length 32 kD species, as well as cleavage products of 12 and 20 kD [3–5]. Cleavage of FGF23 occurs within a subtilisin-like proprotein convertase (SPC) proteolytic site ($_{176}RXXR_{179}/S_{180}$), which separates the conserved FGF-like N-terminal domain from the variable C-terminal tail.

FGF23 ACTIVITY

FGF23 has overlapping function with PTH to reduce renal Pi reabsorption, but it has the opposite effects on $1,25(OH)_2D$. The two primary transport proteins responsible for Pi reabsorption in the kidney are the type II sodium–phosphate cotransporters NPT2a and NPT2c, expressed in the apical membrane of the proximal tubule. FGF23 delivery leads to renal Pi wasting through the downregulation of both Npt2a and Npt2c [6].

Normally, hypophosphatemia is a strong positive stimulator for increasing serum $1,25(OH)_2D$. However, patients with TIO, ADHR, XLH, and ARHR manifest hypophosphatemia with paradoxically low or inappropri-

ately normal $1,25(OH)_2D$. In mice, the expression of the 1α(OH)ase enzyme and the catabolic 24(OH)ase are reduced, and elevated, respectively, when the animals are exposed to FGF23 [4]. Thus, the effects of FGF23 on the renal vitamin D metabolic enzymes is most likely responsible for the reductions in $1,25(OH)_2D$ in the setting of persistent hypophosphatemia in ADHR, XLH, TIO, and ARHR patients.

REGULATION OF FGF23 *IN VIVO*

In humans, dietary Pi supplementation increased FGF23 whereas Pi restriction and the addition of Pi binders suppressed serum FGF23 [7], indicating that FGF23 plays a role in maintenance of Pi homeostasis. In animal studies, the FGF23 response to serum Pi has been more dramatic than in the human studies. Mice given high and low Pi diets produce the expected correlations between FGF23 and dietary Pi intake [8].

Vitamin D has important regulatory effects on FGF23. In mice, injections of 20–200 ng $1,25(OH)_2D$ led to dose-dependent increases in serum FGF23 [9]. These changes in FGF23 occurred before changes in serum Pi, indicating that FGF23 is directly regulated by vitamin D. Physiologically, this would be consistent with results examining the role of FGF23 in vitamin D metabolism. FGF23 has been shown to downregulate the 1α(OH)ase mRNA [6, 9]; thus, as $1,25(OH)_2D$ rises in the blood as a product of 1α(OH)ase activity, vitamin D would then stimulate FGF23, which would complete the feedback loop and downregulate 1α(OH)ase expression.

FGF23 RECEPTORS

FGF23 is a member of unique class of FGFs, including FGF19 and FGF21, that are endocrine, as opposed to paracrine/autocrine, factors. FGF23 requires the co-receptor αKlotho (αKL) for bioactivity. α*KL*-null mice have severe calcifications as well as markedly elevated serum Pi [10], which parallels *Fgf23*-null mice [11, 12], and that of TC patients. However, both the α*KL*-null and *Fgf23*-null mice have more extreme phenotypes than that observed in patients. Importantly, these defects in the α*KL*-null and *Fgf23*-null mice can be ameliorated with a low Pi diet to reduce serum Pi [13]. In parallel with *Fgf23*-null mice, α*KL*-null mice have increased Npt2a in the proximal tubule [14], indicating that the hyperphosphatemia is secondary to increased renal reabsorption of Pi.

αKL is produced as several isoforms. Membrane bound KL (mKL) is a 130-kD single-pass transmembrane protein characterized by a large extracellular domain and a very short (10 residue) intracellular domain that does not possess signaling capabilities [15]. The mKL protein can also be cleaved extracellularly near the transmembrane domain, giving rise to a circulating form of αKL. A secreted isoform of KL (sKL) is approximately 80 kD and is spliced within exon 3 to result in an isoform that does not contain the transmembrane domain [15].

The most likely mechanism for FGF23 signaling through αKL is the recruitment of canonical FGF receptors (FGFRs) to form heteromeric complexes. One group has identified a specific complex between FGFR1c and αKL [16] and another found that FGFR3c and FGFR4 were also involved [17]. Signaling appears to be through mitogen activated protein kinase (MAPK) cascades [17]. More recently, animal studies showed that genetic deletion of FGFR3 and FGFR4 partially corrected the phenotype in the Hyp mouse, indicating that these receptors are physiologically relevant receptors for FGF23 [18]. FGFR1 may be more important for phosphate homeostasis, while FGFR3c and FGFR4 may be more relevant to vitamin D status [18]. Importantly, within the kidney, αKL localizes to the distal tubule [14]; however, FGF23 mediates its effects on NPT2a, NPT2c, and vitamin D within the proximal tubule [4, 6]. Acute delivery of FGF23 results in p-ERK1/2 signaling in the renal DCT [19]; therefore, the mechanisms underlying a local DCT-PT axis in the kidney following FGF23 delivery are unclear.

SERUM ASSAYS

FGF23 is measured in the circulation via several assays. One extensively used assay is a "C-terminal" FGF23 ELISA with both the capture and detection antibodies binding the C-terminal to the FGF23 $_{176}$RXXR$_{179}$/S cleavage site [20]. This assay thus recognizes full-length FGF23 as well as C-terminal proteolytic fragments. In a study with a large number of controls and TIO patients, this ELISA was used to test the levels of FGF23 in TIO and XLH [20], and showed that serum FGF23 is detectable in normal individuals. The mean FGF23 was greater than tenfold elevated in TIO patients and rapidly fell after tumor resection. Importantly, many XLH patients (13 out of 21) had elevated FGF23 compared to controls [20], and in those with "normal" FGF23, these levels may be "inappropriately normal" in the setting of hypophosphatemia.

An "intact" FGF23 ELISA assay has been developed that uses conformation-specific monoclonal antibodies that span the $_{176}$RXXR$_{179}$/S$_{180}$ SPC site and thus recognizes N- and C-terminal portions of FGF23 [21]. This assay detects a mean circulating concentration of 29 pg/ml in normal individuals [21]. The results of these two assays generally agree with regard to the relative ranges of FGF23 concentrations in XLH and TIO patients, and that FGF23 is elevated in most XLH patients. Based upon limited data from two TIO patients undergoing resection, the half-life of FGF23 is between 20 and 50 minutes [22, 23].

FGF23-ASSOCIATED SYNDROMES

Disorders associated with increased FGF23 bioactivity

Autosomal dominant hypophosphatemic rickets (ADHR; OMIM 193100)

Importantly, ADHR is distinguished from other hereditary hypophosphatemias by having either early or delayed onset with variable expressivity [24]. The ADHR mutations replace arginine (R) residues at positions 176 or 179 with glutamine (Q) or tryptophan (W) within the FGF23 subtilisin-like proprotein convertase (SPC) cleavage site, $_{176}$RXXR$_{179}$/S$_{180}$ [1, 4, 25] (Table 24.1). Following insertion of the ADHR mutations into wild type FGF23, FGF23 secreted from mammalian cells was primarily full length (32 kD), active polypeptide, as opposed to the 32 kD and cleavage products typically observed for wild type FGF23 expression [5].

Tumor-induced osteomalacia (TIO)

TIO is an acquired disorder of isolated renal Pi wasting that is associated with tumors. TIO patients present with similar biochemistries as patients with ADHR [26], and osteomalacia is seen upon bone biopsy. Clinical symptoms include muscle weakness, fatigue, and bone pain [26]. Insufficiency fractures are common and proximal muscle weakness can become severe [26]. FGF23 is elevated in patients with TIO [20, 21] and tumors that cause TIO have a dramatic over expression of FGF23 mRNA [25]. Surgical resection of the tumor results in rapid decreases in serum FGF23 [20].

X-linked hypophosphatemic rickets (XLH; OMIM 307800)

X-linked hypophosphatemic rickets is caused by inactivating mutations in *PHEX* (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) [27]. PHEX is a member of the M13 family of membrane-bound metalloproteases and shows the highest expression in bone cells such as osteoblasts, osteocytes, and odontoblasts in teeth [28].

Reports have established that FGF23 is elevated in many XLH patients [20, 21]. Although it was initially thought that PHEX might cleave FGF23, this is not the case [3]. Instead, FGF23 mRNA expression is markedly increased in *Hyp* mice (mouse model of XLH) bone [3, 8]. The elevated FGF23 mRNA levels indicate that the increase in serum FGF23 in XLH is due to overproduction by skeletal cells, as opposed to a decreased rate of FGF23 degradation by cell surface proteases after secretion into the circulation. Although the interactions between FGF23 and PHEX are most likely indirect (see ARHR below), the encoded proteins have overlapping expression in bone [2, 3, 28]. At present, the PHEX substrate is unknown.

Table 24.1. Summary of Heritable and Acquired Disorders Involving FGF23

Disorder	Mutated Gene	Mutation Consequence	Relationship to FGF23	Effect on Serum Pi	Effect on Serum 1,25D	Intact FGF23 ELISA conc. *(Kainos, Inc.)*	C-terminal FGF23 ELISA conc. *(Immutopics, Inc.)*
ADHR	FGF23	Gain of function	Stabilize full-length, active FGF23	↓	↔	↔ or ↑	↔ or ↑
XLH	PHEX	Loss of function	Increased FGF23 production in osteocytes	↓	↔	↔ or ↑	↔ or ↑
ARHR1	DMP1	Loss of function	Increased FGF23 production in osteocytes	↓	↔	↔ or ↑	↔ or ↑
ARHR2	ENPP1	Loss of function	Increased FGF23 production	↓	↔	↔ or ↑	↔
TIO	–	–	FGF23 overproduced by tumor	↓	↔	↔ or ↑	↔ or ↑
TC/HHS	FGF23 or GALNT3	Loss of function	Destabilize full-length, active FGF23	↑	↔ or ↑	↓	↑
TC	KL	Loss of function	Decreased FGF23-dependent signaling	↑	↔ or ↑	↑	↑

Autosomal recessive hypophosphatemic rickets types 1 and 2

(ARHR1; OMIM #241520). Dentin matrix protein-1 (*DMP1*), a member of the small integrin-binding ligand, N-linked glycoprotein (SIBLING) family, is highly expressed in osteocytes. Both *Dmp1*-null mice and patients with ARHR manifest rickets and osteomalacia with isolated renal Pi wasting associated with elevated FGF23. Mutational analyses revealed that one ARHR family carried a mutation that ablated the DMP1 start codon, and a second family exhibited a deletion in the DMP1 C-terminus [29]. Mutations have also been identified in DMP1 splicing sites, which likely result in nonfunctional protein [30]. Mechanistic studies using the *Dmp1*-null mouse demonstrate that loss of DMP1 causes defective osteocyte maturation, leading to elevated FGF23 expression and pathological changes in bone mineralization [29]. Importantly, *Dmp1*-null mice are biochemical phenocopies of the *Hyp* mouse, and patients with ARHR and XLH (as well as the *Dmp1*-null and *Hyp* mice) share a unique bone histology characterized by distinctive periosteocytic lesions [29]. Thus, these findings suggest that PHEX may also have a role in osteocyte maturation in a parallel pathway to DMP1 that leads to over expression of FGF23.

ARHR2 (OMIM #613312). ARHR can also be caused by mutations in the ectonucleotide pyrophosphatase/phosphodiesterase-1 (*ENPP1*) gene that controls physiologic mineralization and pathologic chondrocalcinosis by generating inorganic pyrophosphate. Studies support that ENPP1 may regulate osteoblastic differentiation in an extracellular phosphate-independent manner [31]. Therefore, similar to DMP1, loss of function ENPP1 mutations could potentially result in an early-osteocyte differentiation defect and over expression of FGF23.

Other heritable disorders involving elevated FGF23

In addition to the disorders described above, FGF23 is also upregulated in several bone dysplasias that manifest documented isolated renal Pi wasting. These disorders include McCune Albright syndrome (OMIM 174800) [2] due to somatic activating mutations in G_s; opsismodysplasia (OMIM 258480) [32]; osteoglophonic dysplasia (OMIM 166250) [33] which is due to activating mutations in FGFR1; and epidermal nevus syndrome (ENS) [34].

Disorders associated with reduced FGF23 bioactivity

Familial tumoral calcinosis

Familial tumoral calcinosis (TC; OMIM 211900) is an autosomal recessive disorder characterized by dental abnormalities, as well as soft tissue periarticular and vascular calcification [35]. Biochemical abnormalities include hyperphosphatemia, increased percentage of TRP and inappropriately normal or elevated $1,25(OH)_2D$. Calcium and PTH are usually within the normal ranges, although PTH may be suppressed. Hyperostosis–hyperphosphatemia syndrome (HHS) is a rare metabolic disorder characterized by a biochemical profile that is identical to TC, with localized hyperostosis [36, 37].

TC/HHS due to GALNT3 mutations

The first gene identified for heritable TC was UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyl transferase-3 (*GALNT3*) [38]. GALNT3 is expressed in the Golgi and initiates *O*-linked glycosylation of nascent proteins. These TC patients were originally reported to manifest serum FGF23 levels approximately 30-fold above the normal mean when assessed with the C-terminal FGF23 ELISA [38]. Importantly, it was subsequently demonstrated that the TC patients did indeed have elevated C-terminal FGF23, however the same individuals had low FGF23 when measured with the intact FGF23 ELISA (Table 24.1) [39]. These findings were then confirmed by demonstrating that loss of GALNT3 resulted in the production of nonfunctional FGF23 protein due to intracellular degradation [40]. FGF23 is *O*-glycosylated on specific residues within the $_{176}RHTR_{179}/S_{180}$ site (at threonine 178), thus the lack of glycosylation at this residue is thought to destabilize intact active FGF23 [40].

HHS was also found to be due to inactivating mutations in *GALNT3* [36], and these patients also manifest inappropriate C-terminal to intact FGF23 ELISA values (Table 24.1) [36, 37]. Indeed, some of the HHS mutations are the same as those that result in TC [37], indicating that genetic background may influence disease phenotype and/or that TC and HHS may represent a spectrum of severity within the same disease.

TC due to FGF23 Mutations

TC can also be due to recessive, inactivating mutations in the *FGF23* gene [41–43]. These mutations have all been missense mutations (S71G, M96T, S129F) within the FGF23 N-terminal FGF-like domain. The TC alterations destabilize FGF23, as supported by the findings that the TC patients with *FGF23* mutations have the same FGF23 ELISA pattern as GALNT3-TC patients (i.e., markedly elevated C-terminal concentrations, in concert with low intact values [41, 42]) and the fact that these mutants are cleaved prior to cellular secretion [41–43]. Thus, the common denominator in GALNT3-TC and FGF23-TC is the lack of production of intact FGF23. This lack of intact FGF23 then results in elevation of serum Pi through increased renal reabsorption, which in turn results in elevated secretion of nonfunctional FGF23 fragments through a positive feedback cycle.

TC due to klotho mutations

αKlotho (αKL) is a co-receptor for FGF23, and was therefore tested as a candidate gene for TC in a 13-year old

female with hypothesized end-organ defects in renal FGF23 bioactivity. This patient manifested hyperphosphatemia, hypercalcemia, elevated PTH, elevated intact and C-terminal FGF23 [44] (approximately 100- to 550-fold elevation of the normal means), as well as ectopic calcifications in the heel and brain. She had normal pubertal development, and her disease paralleled *αKL*-null mice with regard to ectopic calcifications, and dramatic elevation of circulating FGF23 [16]. This patient had a novel recessive mutation in a highly conserved residue (Histidine193 Arginine, or H193R) in the extracellular domain of αKL (KL1 domain). Mutant KL expression was markedly reduced compared to that of wild type αKL, which resulted in a striking reduction in the ability of αKL to mediate FGF23-dependent signaling [44]. Thus, an inactivating H193R αKL mutation results in a TC phenotype and demonstrates that αKL is required for FGF23 bioactivity.

Chronic kidney disease (CKD)

FGF23 is elevated in patients with CKD and recent studies indicate that this FGF23 is biologically active [45]. One report has shown that higher FGF23 levels are a predictor of increased progression of renal disease in patients with nondiabetic CKD [46]. Other reports demonstrate an association between high FGF23 concentrations and left ventricular hypertrophy in patients with CKD [47]. Furthermore, epidemiological studies demonstrate higher mortality in renal and nonrenal patients with higher FGF23 concentrations [48]. The pathophysiological significance of these findings remains to be elucidated, and it is unclear as to whether high concentrations of FGF23 are somehow toxic or if high FGF23 concentrations are simply a marker of more severe disease.

INTRODUCTION

Estrogens and androgens influence the development of the skeleton during growth and its maintenance during adulthood. Absence or dysfunction of the sex glands is associated with skeletal abnormalities. This relationship was known to Aristotle (384–322 BC), who emphasized the importance of age on the effects of sex steroids on bone as follows: "If castrated at an early age, animals become taller and more delicate than non-castrate; if they are, however, developed (at the time of castration) they do not increase their size." The interest in the role of sex steroids on bone was greatly intensified in the 1940s by the original suggestion of Fuller Albright that there was an association between the menopause and loss of bone mass [1]. Since that time, it has been extensively documented that a deficiency of estrogens in females or both androgens and estrogens in males adversely affects skeletal development during growth and homeostasis during adulthood, and contributes to the development of osteoporosis in either sex. However, the cellular and molecular mechanism(s) responsible for the adverse effects of the deficiency of either class of sex steroid on the male or female skeleton are still not well understood, nor is the molecular mechanism(s) by which estrogens contribute to the maintenance of the male skeleton. Moreover, until very recently, it has remained unknown whether and how sex steroid deficiency and old age may influence each other's negative impact on bone. In this chapter we will briefly review what is currently known about the biosynthesis of gonadal steroids and how androgens can be converted to estrogens, the role of the estrogen and androgen receptors in the effects of these two hormones on bone, the signaling pathways activated by these receptors, the biologic effects of estrogens or androgens on different bone cell types, their effects on skeletal growth, the interaction between sex steroid deficiency and aging on bone, the contribution of sex steroid deficiency to the development of osteoporosis, and finally the role of natural estrogens or related synthetic compounds in the treatment of osteoporosis. Besides estrogens and androgens, the gonads produce progesterone, but the role of this hormone in bone is minor, if any, and therefore it will not be discussed further in this chapter.

HORMONE BIOSYNTHESIS

Both estrogens and androgens are derived from C19 metabolites of cholesterol [2, 3]. Estrogens in vertebrates comprise a large number of molecules, the most abundant of which are 17β-estradiol (E_2), estrone (E_1), and estriol. E_2 is made in the ovaries and is the main circulating estrogen in premenopausal women (Fig. 25.1). The circulating concentration of E_2 in women is 20–200 pg/ml and fluctuates depending on the stage of the ovulatory cycle. The predominant form of estrogens in postmenopausal

women is E_1, which is synthesized in several extra ovarian sites including bone.

The predominant sex steroid in men is testosterone (T), 95% of which is produced by the testes and reaches circulating levels of 3–10 ng/ml. The remaining 5% of T is made in the adrenals by the conversion of dehydroepiandrosterone (DHEA) by 3β-hydroxysteroid dehydrogenase (HSD) and 17β-HSD. Dihydrotestosterone (DHT) is the second most abundant circulating androgen and is made by the conversion of T by 5α-reductase in peripheral target tissues of androgen action. Even though DHT circulates at lower levels than T (0.25–0.75 ng/ml), it has considerably higher affinity for the androgen receptor (AR), and it is therefore more potent than T. E_2 is also present in the circulation of men (approximately 50 pg/ml), and it is formed by aromatization of testosterone. Of the total circulating level of E_2 in men, approximately 20% is derived from the testes via the action of P450 aromatase on T. The other 80% is derived from DHEA in peripheral tissues via aromatization and dehydrogenation to form the weak estrogen E_1, which is then converted to E_2 via 17β-HSD (Fig. 25.1).

In women, ovarian C19 steroid intermediates also give rise to T, most of which is then converted to E_2 by P450 aromatase, which is highly expressed in the ovary. The relatively low amounts of T and DHT present in women (less than 3 ng/ml) are synthesized in extragonadal tissues via the same pathways as in men.

Fifty to 60% of the total T, and 20% to 40% of the total E_2, present in the circulation are bound with high affinity to sex hormone binding globulin (SHBG) [4]. Most of the remainder is bound nonspecifically to albumin with lower affinity. Of the total circulating level of either estrogens or androgens only approximately 2% is free to enter the cells and exert biologic effects.

After menopause, the circulating levels of estrogens are generally lower than in men of the same age. The circulating levels of T decrease only marginally (–1%/year) during aging in men, whereas the total E_2 level remains constant. However, SHBG increases markedly in elderly men, resulting in a greater decrease of bioavailable T than E_2 [5].

RECEPTORS AND MOLECULAR MECHANISMS OF ACTION

Similar to other steroid hormones, estrogens or androgens exert their biologic effects by binding to specific receptor proteins: the estrogen receptor α (ERα) or β (ERβ) and the androgen receptor (AR), respectively [6]. These receptors are ligand-activated transcription factors, that homo- or heterodimerize upon ligand binding and directly attach to specific DNA sequences called hormone response elements (HREs) in regulatory regions of target genes (Fig. 25.2). DNA-bound receptors interact with

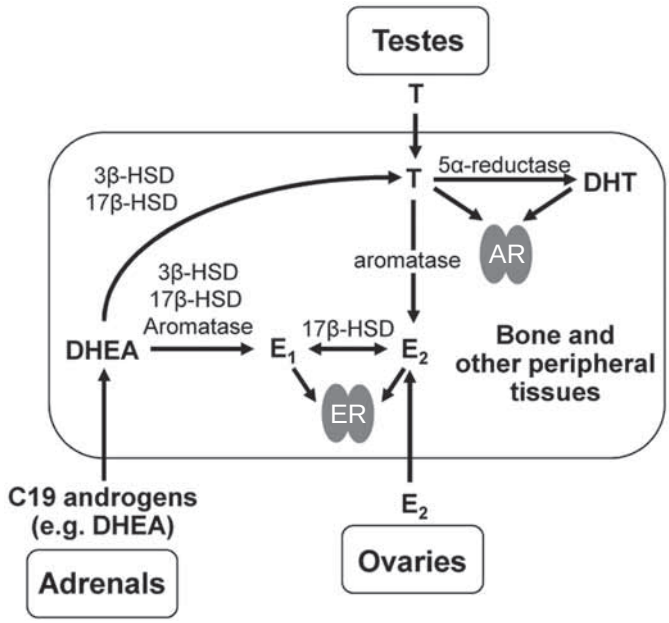

Fig. 25.1. Biosynthesis of estrogens and androgens in the gonads and peripheral tissues. T = testosterone; E_1 = estrone; E_2 = 17β-estradiol; DHT = dihydrotestosterone; DHEA = dehydroepiandrosterone; AR = androgen receptor; ER = estrogen receptor; HSD = hydroxysteroid dehydrogenase.

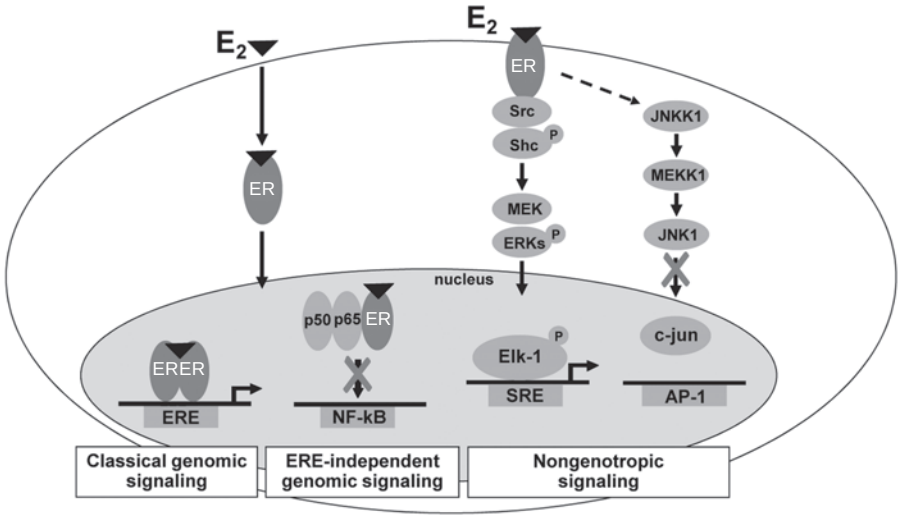

Fig. 25.2. Signaling pathways activated by the estrogen receptor. In the classical genomic signaling pathway 17β-estradiol (depicted by the triangle) binds to its receptor and translocates into the nucleus where it undergoes dimerization, attaches to estrogen response elements (ERE) on DNA, and activates or represses transcription. In the ERE-independent genomic signaling pathway, the ligand-activated receptor binds to other transcription factors (depicted by the p50 and p65 subunits of NF-κB), thereby preventing them from binding to their response elements on DNA. In the nongenotropic mode of action, the ligand-activated receptor (residing in the plasma membrane or the cytoplasm) interacts with cytoplasmic kinases and triggers cascades that positively or negatively regulate the activation of transcription factors such as Elk-1 and c-jun.

several coregulator proteins to form multiprotein complexes that activate or repress the transcriptional machinery [7]. Besides direct protein–DNA interactions, steroid receptors are able to interact indirectly with gene promoters through protein–protein interactions with other transcription factors, as is the case of ER binding to nuclear factor κB (NF–κB). This association inhibits NF–κB activation and the transcription of genes like interleukin 6 (IL-6) [8].

Estrogens and androgens are also able to evoke nongenomic or nongenotropic actions triggered by the activation of cytoplasmic signaling cascades, such as Src, Shc, mitogen activated protein (MAP) kinases including extracellular regulated kinases (ERKs), phosphatidyl inositol-3-kinase (PI3K), and c-jun N-terminal kinases (JNKs). Such actions result from ligand binding to ERs localized in the cytoplasm or the plasma membrane followed by downstream kinase-induced changes in the activation of transcription factors [9]. Via this latter mode of action ERs control an array of genes larger than the one regulated by their direct association with DNA [10].

ERα, ERβ, and the AR have been detected in all skeletal cell types including chondrocytes, bone marrow stromal cells, osteoblasts, osteocytes, and osteoclasts and their progenitors [11]. Nevertheless, compared to reproductive organs, the level of ER expression in bone cells is low in both males and females; and ERβ expression is two to three orders of magnitude lower than ERα [12]. Osteoblast number and bone mass are unaffected in mice lacking ERβ [13]. In addition, studies in mice with a genuine null mutation of ERβ indicate that with the exception of impaired ovarian function, this isotype of the ER is not required (at least in the mouse) for the development and homeostasis of the major body systems [14]. Hence, at this stage it seems that ERβ may not play a major role in bone, with the possible exception that it may exert an inhibitory effect on periosteal apposition [15].

EFFECTS OF SEX STEROIDS ON SKELETAL GROWTH

Sex is an important determinant of the size and shape of the skeleton. The difference in shape between sexes reflects in part the need of the female pelvis to accommodate gestation and delivery of the offspring. Bones grow in length at the growth plate of the epiphyses by the process of endochondral bone formation, whereby calcified cartilage made by chondrocytes is resorbed by osteoclasts and gradually replaced by mineralized bone made by osteoblasts. Simultaneously, bones expand radially, their cortices thicken, and the medullary cavities become larger as a result of bone formation at the periosteum and unbalanced remodeling at the endocortical surface—with resorption exceeding formation [16].

At the initiation of puberty, low levels of estrogens and perhaps androgens are responsible for a spurt in linear bone growth in both sexes, and this effect results from the stimulation of endochondral bone formation [16]. At the end of puberty, high levels of estrogens are essential for the closure of the epiphyses and the cessation of linear growth. In parallel to the acceleration of linear growth, pubertal boys and girls experience an accelerated enlargement of the outer perimeter and further widening of the medullary cavity of long bones. These changes lead to bigger bones in boys than in girls primarily due to a larger increase in periosteal bone formation. In contrast, girls exhibit more endocortical bone formation than boys. Puberty starts earlier in girls, but lasts longer in boys, without major differences in absolute growth rate between sexes. This may account for part of the differences in the size of the skeleton between the two sexes.

Effects on linear growth

Estrogens are essential for the pubertal bone changes in both girls and boys. Thus, aromatase-deficient females and males lacking estrogens do not exhibit a growth spurt and do not undergo closure of their epiphyses [17]. Estrogen replacement of patients with aromatase deficiency enhances bone growth. In addition, administration of E_2 to pre- or early-pubertal girls increases longitudinal growth [18]. Furthermore, overexpression of the aromatase gene in both sexes accelerates growth and leads to premature closure of the epiphyses [19]. The importance of estrogens for the male skeleton is further highlighted by the absence of a pubertal growth spurt in a man with a loss of function mutation of ERα [20]. Linear skeletal growth is dependent on the growth hormone (GH)/insulin-like growth factor (IGF) axis. The stimulatory effect of estrogens in the process is in part attributed to activation of the GH–IGF axis [16].

It is unclear whether androgens have a significant effect on linear growth. In support of the contention that androgens may not play a significant role in linear bone growth, serum testosterone was high normal in the man with the ERα mutation or aromatase-deficient men and women [17, 20]. On the other hand, men with androgen insensitivity syndrome due to AR mutations have intermediate height between normal males and females [21]. Moreover, administration of DHT to boys with delayed growth, or to growing rats and rabbits, stimulates longitudinal bone growth, supporting a role of androgens in this process [16]. To date, there are no consistent data in the murine model of the effects of androgens, estrogens, or their receptors, on pubertal bone growth spurt.

Effects on periosteal expansion

The greater periosteal expansion in boys as compared to girls during puberty has been ascribed to the higher levels of androgens in the male. Nevertheless, administration of E_2 to an aromatase-deficient young man increased bone size; this was presumed to be the result of increased periosteal apposition [22]. Consistent with this finding, studies in rodents have revealed that both estrogens and

androgens, acting via their respective receptors, are involved in expansion of the periosteum in growing males. Thus, male mice with a mutation or deletion of the AR exhibit reduced periosteal expansion [23]. DHT may be the androgen responsible for periosteal expansion in the male. Thus, male mice lacking 5α-reductase type I exhibit reduced cortical thickness [24]. However, deletion of ERα, but not ERβ, also causes decreased periosteal bone formation and decreased femoral width in male mice [13]. Pharmacologic inhibition of E_2 synthesis by an aromatase inhibitor further reduces periosteal expansion in orchidectomized male mice, indicating that the estrogens needed for radial bone growth are derived from peripheral tissues [25]. In line with the need for both AR and ERα for optimal periosteal expansion, periosteal circumference is lower in mice that lack both receptors, as compared to mice lacking only one of the receptors [26].

Unlike the situation in males, estrogens restrain radial bone growth in females, as evidenced by the finding that ovariectomy of growing rats or mice increases periosteal expansion during early, but not late, puberty [25]. Moreover, female mice that lack ERβ exhibit increased periosteal circumference [15]. Whether the opposite effect of estrogens on periosteal apposition in males versus females also occurs in humans is unknown.

Cessation of longitudinal bone growth at the end of puberty is due to a decline in the replication of chondrocytes in the proliferative zone of the growth plate. This results in reduced cartilage synthesis at the distal end of the growth plate, as well as reduced replacement of the cartilage by bone at the proximal end. Consequently, the growth plate closes. The closure of the growth plate at the end of puberty is clearly mediated by E_2 in both men and women as indicated by failure of growth plate closure and continued longitudinal growth in the man who lacks ERα [20], and in aromatase-deficient men and women [17, 27]. Moreover, chondrocyte-specific deletion of ERα results in failure of growth plate closure, indicating a direct suppressive effect of E_2 on chondrocyte proliferation [28]. Consistent with this, ovariectomy increased the number of proliferating chondrocytes in the proliferative zone of growing rats [29].

EFFECTS OF SEX STEROIDS ON SKELETAL MAINTENANCE

Throughout life, older bone is periodically resorbed and replaced with new bone by teams of short-lived osteoclasts and osteoblasts comprising the basic multicellular unit. This process is known as remodeling. It is now abundantly clear that remodeling is orchestrated and targeted to a particular site that is in need for repair by osteocytes: long-lived former osteoblasts that are buried within mineralized bone and can sense and respond to changes in mechanical forces [30].

An oversupply of osteoclasts relative to the need for remodeling or an undersupply of osteoblasts relative to the need for cavity repair are critical pathophysiological changes for most acquired metabolic bone diseases, including osteoporosis [31, 32]. Estrogen or androgen deficiency causes loss of bone associated with an increase in the bone remodeling rate, increased osteoclast and osteoblast numbers, and increased resorption and formation, albeit unbalanced. Conversely, estrogens or androgens decrease bone resorption, restrain the rate of bone remodeling, and help to maintain a focal balance between bone formation and resorption. These effects are evidently the result of hormonal influences on the birth rate of osteoclast and osteoblast progenitors in the bone marrow as well as pro-apoptotic effects on osteoclasts and anti-apoptotic effects on mature osteoblasts and osteocytes.

Over the previous 30 years, a large number of studies with cell models, primary cell cultures, and gonadectomized rodents have suggested several mechanisms to account for the protective effects of sex steroids on skeletal homeostasis. The list includes direct effects of estrogens or androgens on osteoblast and osteoclast progenitor proliferation, differentiation, and lifespan, as well as indirect effects mediated via cytokines (including IL-1β, IL-6, IL-7, TNFα, M-CSF, RANKL, OPG, and prostaglandins) produced by bone marrow stromal cells, T and B lymphocytes, macrophages, and dendritic cells [32, 33]. A study of bone marrow cells from pre- and postmenopausal women suggested that estrogen deficiency may increase RANKL and decrease OPG production by osteoblast progenitors, and T and B cells [34]. Nonetheless, estrogens do not seem to suppress the transcription of the RANKL gene directly (C.A. O'Brien, unpublished observations); RANKL production by osteoblast progenitors or mature osteoblasts does not contribute to osteoclastogenesis during remodeling [30]; and the levels of circulating OPG in pre- and postmenopausal women are not different [35].

During the past decade the relative contribution of some of the aforementioned mechanisms to the overall effects of sex steroids on skeletal homeostasis has been investigated by more vigorous means involving genetic approaches; in particular, the generation of mice in which the ERs or the AR have been deleted or modified either globally (i.e., in all somatic cells) or selectively in different bone cell subtypes. Unfortunately, mice with global deletion of the ERα have not been very informative in regard to the physiologic effects of estrogens on bone either because the deletion was incomplete or because loss of the negative feedback control of sex steroids on gonadotrophins at the hypothalamic/pituitary level led to high serum levels of E_2 and T, thus confounding the interpretation of the bone phenotype. Recent attempts with cell type specific deletion of the ERα, however, have provided more meaningful insights.

Effects on osteoclasts

Selective deletion of the ERα from osteoclasts by two laboratories, one using the cathepsin K promoter

($ER\alpha^{\Delta Oc/\Delta Oc}$ mice) that is expressed in mature osteoclasts [36], and the other using the lysozyme M (LysM) gene promoter ($ER\alpha_{LysM}^{-/-}$ mice), which is expressed in cells of the entire monocyte/macrophage lineage and neutrophils [37], have independently demonstrated that cell autonomous effects of estrogens on osteoclasts mediated via the ERα can account for most, if not all, the antiresorptive properties of estrogens on the female skeleton.

Specifically, $ER\alpha^{\Delta Oc/\Delta Oc}$ female mice exhibited decreased bone volume due to an increase in the number of osteoclasts, resulting from the loss of a cell autonomous pro-apoptotic effect of estrogens on mature osteoclasts [36]. The pro-apoptotic effect of estrogens on osteoclasts, according to the authors of the study, was mediated by an increase in Fas ligand (FasL) production by osteoclasts. The $ER\alpha^{\Delta Oc/\Delta Oc}$ mice did not exhibit changes in osteoclast progenitors under basal conditions and did not undergo any bone loss two weeks following ovariectomy (OVX). Based on these results, Nakamura and colleagues concluded that the pro-apoptotic effect of estrogens on mature osteoclasts accounts for their osteoprotective properties. However, in contrast to the findings of Nakamura et al., others were unable to confirm that estrogens increase the transcription of the *FasL* gene in osteoclasts [37, 38].

In the $ER\alpha_{LysM}^{-/-}$ mice, the number of osteoclast progenitors was twofold higher, as was the number of osteoclasts in cancellous bone. In the estrogen replete state the $ER\alpha_{LysM}^{-/-}$ mice had lower cancellous bone mass, and they did not exhibit the expected decrease of cancellous bone in the estrogen-deficient state [37]. Yet, following loss of estrogens, they experienced a similar decrease in cortical bone as the littermate controls. The evidence that selective abrogation of the effects of estrogens on osteoclasts prevented loss of cancellous bone after estrogen withdrawal indicates that the cell autonomous effects of estrogens via ERα on osteoclast precursors and their progeny are sufficient for the protective effects of estrogens on this bone compartment.

The pro-apoptotic effect of estrogens on osteoclasts was completely abrogated in the $ER\alpha_{LysM}^{-/-}$ mice but was unaffected in mice bearing an ERα knock-in mutation that prevents binding to DNA ($ER\alpha^{NERKI/-}$) [37]. Moreover, a polymeric form of estrogen that is not capable of stimulating the nuclear-initiated actions of ERα was as effective as E_2 in inducing osteoclast apoptosis in cells with the wild-type ERα. These results demonstrate that the attenuation of osteoclast generation and lifespan cannot be exerted by the classical estrogen response element-(ERE) mediated mechanism of estrogen action. Deletion of steroid receptor coactivator-1 leads to skeletal resistance to E_2 in cancellous (but not cortical) bone, raising the possibility that a genotropic mechanism of action may be also required for the antiresorptive effects of estrogens [39] or that at least nongenotropic and genotropic pathways are interdependent.

The extent to which the effects of estrogens or androgens on T and B lymphocytes contribute to the overall antiresorptive effects of sex steroids and the role of the ERα in these cell types remains unclear [33, 40].

Effects on osteoblasts

The ERα deletion in osteoclasts did not affect cortical bone in females and had no effect in either cancellous or cortical bone in males [37]. These findings suggest that whereas elimination of the pro-apoptotic effect of estrogen on osteoclasts is sufficient for loss of bone in the cancellous compartment in which complete perforation of trabeculae by osteoclastic resorption precludes subsequent refilling of the cavities by the bone forming osteoblasts, the effects of estrogens on osteoblasts, and perhaps other cell types, are indispensable for their protective effects on the cortical compartment. ERα deletion from mesenchymal progenitors (Osx1 expressing cells) decreased cortical thickness, and this effect was manifested in both female and male mice, suggesting that ERα promotes proliferation/differentiation and/or survival of osteoblast progenitors in both sexes [41]. Collectively, these lines of evidence favor the view that the effects of estrogens on the birth and death of both osteoclasts and osteoblasts result from cell autonomous actions, mediated by ERα.

The significance of the anti-apoptotic effects of sex steroids on mature osteoblasts remains unclear. Likewise the significance of their pro- and antiproliferative or pro- and antidifferentiation effects on osteoblast progenitors and their mitotic progeny remain unknown. It is also unclear whether the increased bone formation seen in the sex steroid deficient state is the result of the loss of cell autonomous actions restraining the generation of osteoblasts as opposed to indirect effects secondary to increased resorption.

Effects on osteocytes

Osteocytes are by far the most abundant cells present in mammalian bone, and their lifespan corresponds to the age of the bone, as opposed to the short-lived osteoclasts and osteoblasts that are present only during remodeling [42]. Osteocytes are one of the cellular targets of estrogen and androgen action. Estrogens or androgens inhibit osteoblast and osteocyte apoptosis [9, 43], and this effect requires activation of the Src/Shc/ERK signaling pathway and downstream transcription factors such as Elk-1, C/EBPß and CREB [9]. Conversely, estrogen or androgen deficiency increases the prevalence of osteocyte apoptosis in humans [44], rats [45], and mice [43]. Frost had posited that mechanical stain, perceived by a hypothetical skeletal mechanostat, leads to changes in bone remodeling in order to adjust bone mass to a level that is appropriate for the current ambient mechanical forces. He also hypothesized that estrogen decreases the minimum effective strain necessary to initiate bone formation. In support of this hypothesis, estrogens and exercise may exert additive effect on bone mass in humans [46]. Moreover, Lanyon and colleagues have shown in mice that the increased bone formation that normally occurs in response to mechanical loading is diminished in the estrogen deficient state [47].

Reduced physical activity in old age, bed rest, or space flight invariably leads to bone loss [46]. Reduced mechanical forces in the murine model of unloading increase the prevalence of osteocyte apoptosis, followed by bone resorption and loss of bone mineral and strength [48]. On the other hand, mechanical strain is a requirement of osteocyte viability. Physiological levels of mechanical strain prevent apoptosis of cultured osteocytic cells [49]. The evidence for a role of the ER in the pro-survival effect of mechanical strain on osteocytes is consistent with the poor osteogenic response to loading exhibited by mice lacking the estrogen receptors α or β [47].

To conclude this section, the osteocyte ERα may play a role in the mechanosensing function of osteocytes and thereby affect bone strength. Given the fact that osteocytes produce molecules that control osteoclast or osteoblast formation, increased osteocyte apoptosis following sex steroid deficiency could also affect bone mass [30, 50, 51].

LOSS OF SEX STEROIDS AND AGING

For over 60 years, skeletal involution with advancing age has been attributed primarily to the decline of ovarian function at menopause and to a later and smaller decline of estrogens in elderly males [52, 53]. Nonetheless, recent epidemiological evidence in humans has made it clear that the balance between bone formation and resorption becomes progressively negative with advancing age in both women and men prior to, and independently from, any appreciable decline in sex steroids. Consistent with this evidence, most fractures in old age are nonvertebral and occur at predominantly cortical sites after age 65, and most bone loss occurs after this age [54]. Furthermore, extrapolation of the changes in bone mass found in perimenopausal women before the beginning of the menopausal estrogen drop and after its completion indicates that between menopause and the age of 75, women lose approximately 22% of their total body bone mineral; of this, 13.3% is due to aging and 7.75% to estrogen deprivation. In the femoral neck, 14% of the loss is "age-related" and only 5.3% because of estrogen deprivation [55]. In addition, a more recent analysis of cortical bone loss with high resolution peripheral CT of the radius and postmortem femurs of women between ages 50 and 80 years has revealed that most bone loss in old age is the result of increased intracortical porosity [54]. On the other hand, studies by Khosla and colleagues have suggested that while the onset of cortical bone loss in humans is closely tied to estrogen deficiency, a significant proportion of trabecular bone loss is estrogen-independent [53].

In agreement with the clinical evidence, studies in the murine model have revealed that age-related mechanisms intrinsic to bone such as oxidative stress (OS) are protagonists and age-related changes in other organs and tissues, such as ovaries, may be contributory [52].

Reactive oxygen species (ROS) influence the birth and death of bone cells

Oxidative stress (OS) has been thought for many years as a common mechanism in the pathogenesis of several degenerative disorders associated with aging. The same seems to be true for osteoporosis. Indeed, several lines of evidence implicate an increase in reactive oxygen species (ROS) in the decreased bone formation associated with advancing age, as well as the increased resorption associated with estrogen deficiency [12, 52, 56]. In line with this evidence, OS caused by increased ROS production in osteoblasts stimulates apoptosis and decreases bone formation [12, 57, 58]. On the other hand, ROS are a critical requirement for RANKL-induced osteoclast generation, activation, and survival (Fig. 25.3) [52]. In agreement with the results from the study of ROS in bone biology, it is now widely appreciated that ROS can be both: harmful byproducts of aerobic metabolism that damage proteins, lipids, and DNA leading to cell demise, as well as signalers deliberately produced by cells for the purpose of propagating intracellular signaling from cell surface receptors [52].

To protect against OS, organisms ranging from prokaryotes to mammals, scavenge ROS by a network of overlapping mechanisms including various forms of superoxide dismutases (SODs) and catalase as well as thiol-containing oligopeptides with redox-active sulfhydryl moieties, the most abundant of which are glutathione and thioredoxin. Reduction of these scavenging mechanisms along with increased mitochondrial respira-

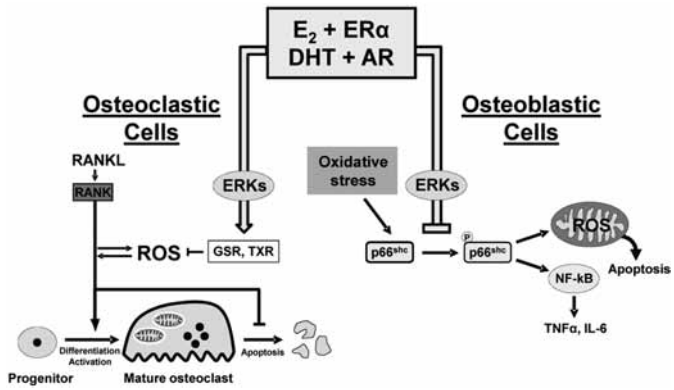

Fig. 25.3. Reactive oxygen species (ROS) influence the birth and death of osteoclasts and osteoblasts, and their effects are counterregulated by sex steroids. In osteoclasts, ROS are required for RANKL-induced differentiation, activation, and survival. On the other hand, ROS stimulate osteoblast apoptosis and attenuate osteoblastogenesis. Estrogens or androgens, acting via cytoplasmic kinases like ERKs, antagonize the production or the effects of ROS. These antioxidant actions are responsible for the ability of sex steroids to attenuate osteoclast generation and survival, promote osteoblast and osteocyte survival, and attenuate NF-κB and cytokine production. Reproduced with modifications and permission from *Endocrine Reviews* (Ref 52).

tory chain leakage and increased activity of oxidases in other cellular compartments are the three main mechanisms for OS [52]. Over the past few years, FoxO transcription factors have emerged as another important defense mechanism against OS, serving primarily to maintain the integrity of long-lived cells, including tissue stem cells. Consistent with this, global deletion of FoxOs recapitulates the effects of old age on the murine skeleton in young mice [57], suggesting that oxidative defense provides a mechanism to handle the oxygen free radicals constantly generated by the aerobic metabolism of osteoblasts and is thereby indispensable for bone mass homeostasis throughout life.

Estrogens or androgens attenuate oxidative stress in bone cells

Sex steroid deficiency, similar to aging, increases the generation of ROS and the activity of the tumor suppressor p53 and $p66^{Shc}$ (a 66-Kd isoform of the growth factor adapter Shc with a pivotal role in OS, apoptosis, and aging) in the murine skeleton; the adverse effects of the acute loss of ovarian or testicular function on bone can be prevented by antioxidants (Fig. 25.4) [12, 56]. Thus, sex steroid deficiency accelerates the effect of aging [42, 52].

Conversely, estrogens or nonaromatizable androgens decrease OS and $p66^{Shc}$ activation and antagonize ROS-induced osteoblast apoptosis, NF-κB activation, and cytokine production by attenuating a PKCβ/$p66^{Shc}$ signaling cascade in osteoblastic cells [12, 59] (Fig. 25.3). They also decrease ROS production in bone marrow [12, 60]. On the other hand, estrogens or androgens attenuate the pro-survival effects of RANKL on osteoclasts also via antioxidant mechanisms. All the antioxidant effects of estrogens are preserved in the mice bearing the ERα knock-in mutation that prevents binding to DNA ($ERα^{NERKI/-}$) and are mimicked by an estradiol dendrimer conjugate (EDC) that is not capable of stimulating the nuclear-initiated actions of ERα [37, 61]. These observations suggest that the effects of estrogens on OS and the birth and death of osteoblasts and osteoclasts do not require the binding of ERα to DNA response elements, but instead they result from the activation of cytoplasmic kinases (Fig. 25.3).

A cell autonomous effect of estrogens that favors osteoblast formation by protecting osteoblast progenitors from the adverse effects of ROS (and perhaps the generation of ROS) is consistent with the finding that ERα deletion from mesenchymal progenitors (expressing Osx1) results in reduced cortical bone mass [41].

Based on these latest advances, it appears that estrogen deficiency may not only decrease mature osteoblast survival but also hinder osteoblast generation in such a way that the osteoblast number is insufficient relative to the demand caused by the increased resorption. In females, loss of estrogen actions in osteoclasts in and of itself is sufficient for loss of bone in the cancellous compartment in which complete perforation of trabeculae by osteoclastic resorption precludes subsequent refilling of the cavities by the bone-forming osteoblasts. On the other hand, loss of estrogen actions on osteoblast generation and lifespan may be responsible for the loss of cortical bone (Fig. 25.5).

SEX STEROID DEFICIENCY AND THE DEVELOPMENT OF OSTEOPOROSIS

Both women and men lose bone as a result of age, but men are less likely to develop osteoporosis than women for two reasons. First, men gain more bone during puberty, and second they lose less bone during aging because unlike women, men do not experience an abrupt loss of estrogens.

The accelerated cancellous bone loss caused by menopause results predominantly from trabecular perforation and loss of connectivity. This phase is followed a few years later by a phase of slower bone loss that primarily affects cortical sites. This later stage occurs in both women and men and is associated with a decrease in osteoblast number and bone formation rate and reduced number of trabeculae. In line with this, decreased wall width is the most consistent histologic findings in elderly women and men with osteoporosis. Moreover, bone loss in elderly men is associated with trabecular thinning rather than perforation [62]. The dissimilarity of the effects of acute estrogen deficiency (as in menopause) and prolonged estrogen deficiency (as in elderly osteoporotic male and females) suggests that the effects of the loss of sex steroids are drastically modified and perhaps some—for example the increased osteoclastogenesis—overridden by aging mechanisms intrinsic to bone. Besides aging *per se* and estrogen deficiency, two additional age-dependent pathogenetic mechanisms contribute to increased OS and loss of bone: lipid oxidation [63] and an increase in endogenous glucocorticoids [64]. It is therefore likely that these two mechanisms also participate in the later stage of bone loss by further exaggerating OS and restraining osteoblastogenesis. In support of this contention, the upregulation of osteoblast (and osteoclast) progenitors caused by gonadectomy in mice is prevented by simultaneous administration of glucocorticoids [65].

Estrogen versus androgen deficiency in men with osteoporosis

Estrogen deficiency may be an important mechanism of the development of osteoporosis not only in females but also in males. Support for this view is provided from three types of evidence: (1) the genetic evidence from men with ERα or aromatase mutations discussed earlier [17, 20]; (2) results of short-term clinical experimentation with administration of aromatase inhibitors [27]; and (3) cross-sectional correlations between free serum estradiol levels

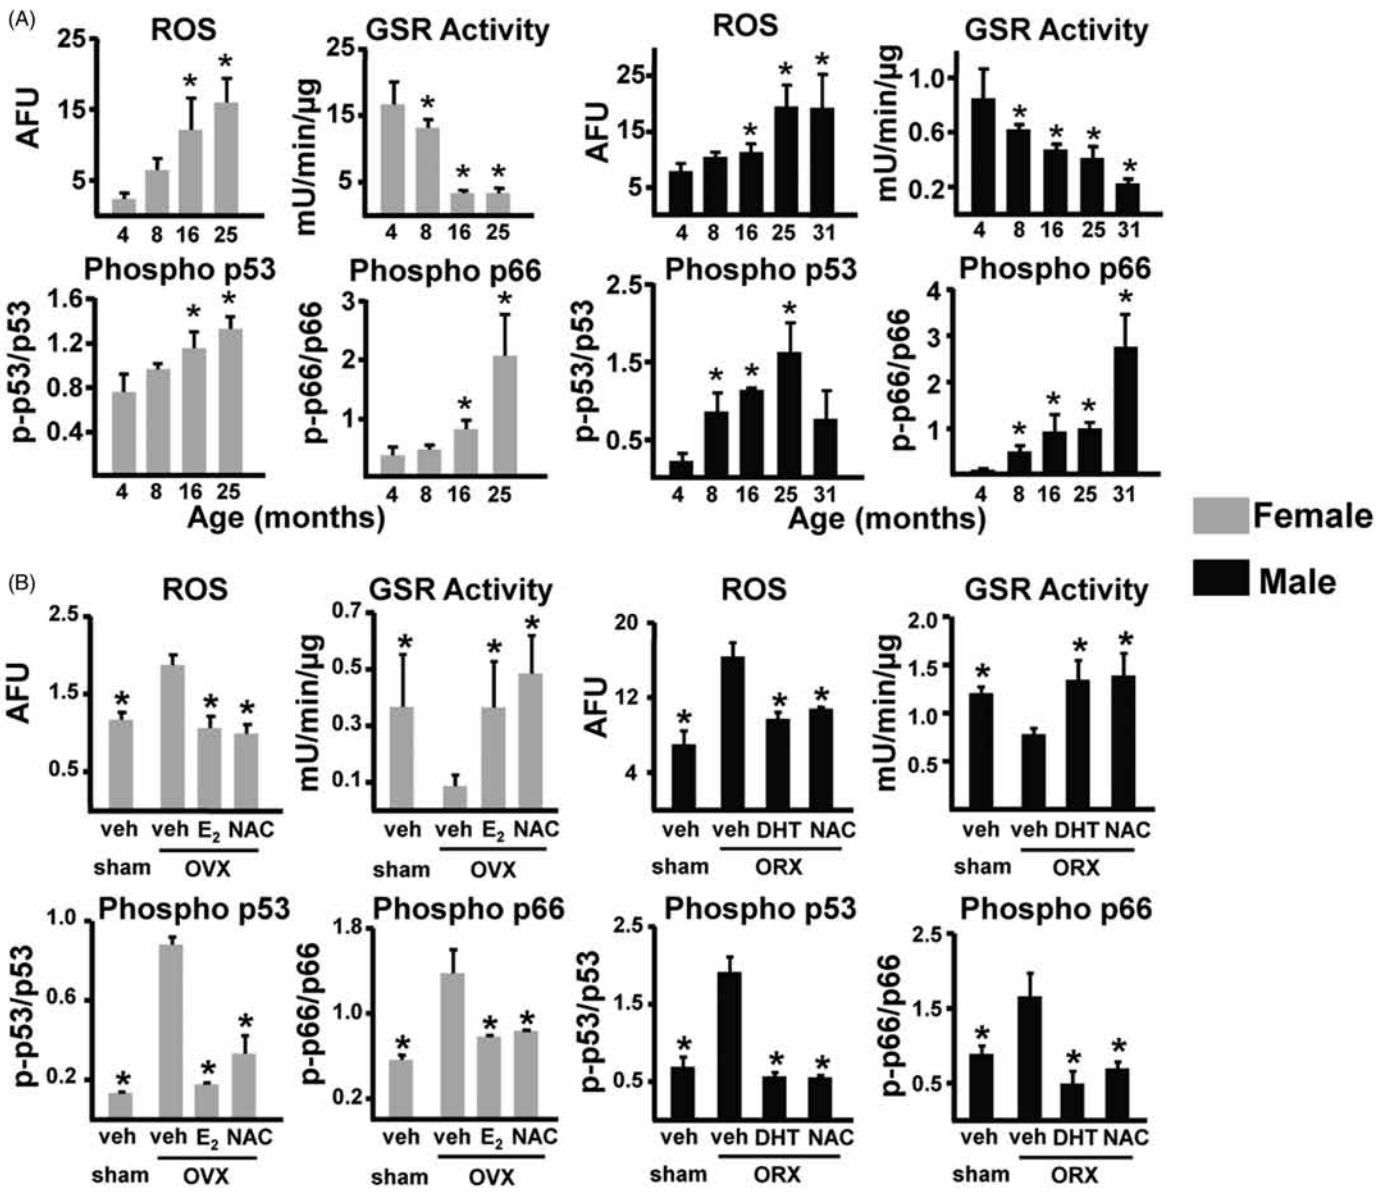

Fig. 25.4. Aging (A) and loss of estrogens or androgens (B) cause similar changes in oxidative stress in the skeleton of male and female mice. ROS and glutathione reductase (GSR) activity were measured in the bone marrow and the phosphorylation of p53 and p66 in vertebral lysates from C57BL6 mice. Ovariectomy (OVX) or orchidectomy (ORX) were performed at 5 months of age, and the measurements were made following euthanasia 6 weeks later. Reproduced with permission from *Endocrine Reviews* (Ref 52).

and bone mineral density (BMD) or bone remodeling markers [53]. However, longitudinal studies of the propositus of genetic ERα mutations indicate that these individuals experience a failure of normal bone development and growth, which is, of course, a different situation to that of the vast majority of patients with osteoporosis who have normal bone development and growth but start losing bone after the attainment of peak bone mass [66]. Furthermore, it remains unknown whether, and to what extent, small differences in estrogen or androgen levels in the circulation contribute to changes in bone markers or BMD in elderly males, especially as similar small differences do not seem to cause BMD differences in pre- or perimenopausal women [67]. More important, and as discussed above, whereas the accelerated cancellous bone loss caused by estrogen deficiency at menopause results predominantly from trabecular perforation and loss of connectivity, the later phase of slower bone loss that occurs in both elderly women and men primarily affects cortical sites [68] and is associated with a decrease in osteoblast number and bone formation rate and reduced thickness of trabeculae.

On the other hand, the important role of androgens and the AR in the homeostasis of the male skeleton in

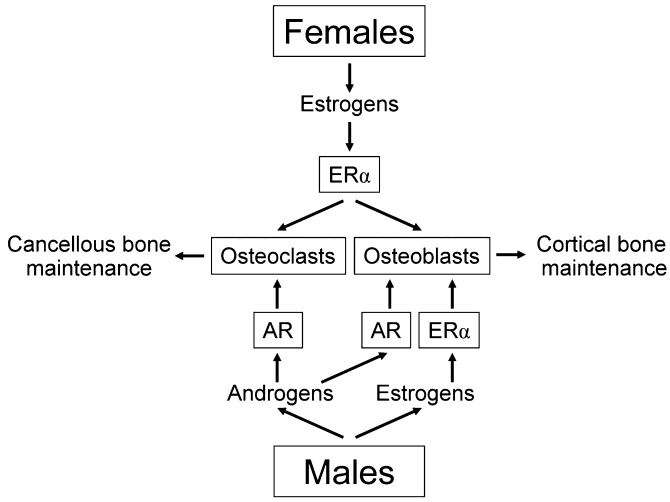

Fig. 25.5. Protective effects of estrogen and androgen on the female vs. the male skeleton. In females, estrogens protect against loss of cancellous and cortical bone mass by cell autonomous effects on osteoclasts and osteoblasts, respectively. In males, cell autonomous effects of androgens (acting via the AR) on osteoclasts are responsible for the protection of the cancellous compartment. However, cell autonomous effects of both androgens (acting via the AR) and aromatizable androgens converted to estrogens (acting via the ERα) are responsible for the protection of the cortical compartment.

humans is well manifested by the low bone mass of men with idiopathic hypogonadotropic hypogonadism or complete androgen insensitivity syndrome [69, 70]. In agreement with this, global AR deletion in male mice results in high bone turnover, increased resorption, and decreased trabecular and cortical bone volume [71]. Nonetheless, in sharp contrast to consistent findings that DHT suppresses osteoclastogenesis, stimulates mature osteoclast apoptosis, and fully protects against orchidectomy (ORX)-induced loss of bone [37, 43], osteoclastogenesis and osteoclast survival were unaffected in the systemic AR deletion model, leading the authors of that study to conclude that the increased resorption was attributed to increased RANKL production by osteoblasts. Importantly, and in contrast to the adverse effects of androgen deficiency on both trabecular and cortical bone mass, trabecular or cortical bone formation was increased in these mice. This makes it highly unlikely, if not implausible, that the bone loss was solely the result of the loss of cell autonomous effects on osteoblasts.

The uncertainty regarding the relative contribution of estrogens versus aging and OS to the development of osteoporosis in elderly men notwithstanding, ER-mediated actions of aromatizable androgens seem to play a minimal or no role in the protective effects of androgens on cancellous bone, but they may play a role in the protective effect of androgens on cortical bone. In support of the contention that the protective effect of androgens on trabecular bone cannot be the result of ERα-mediated action of aromatized androgens, deletion of the ERα selectively from mature osteoclasts or the entire osteoclast lineage in mice has no effect on trabecular bone in the male [36, 37]. On the other hand, nonaromatizable androgens prevent the ORX-induced loss of trabecular bone. Moreover, trabecular number is preserved in men with homozygous loss of function mutation of ERα, indicating that the AR can preserve the trabecular number in the absence of the ERα [66]. Consistent with an AR-mediated effect of androgens on the preservation of trabecular bone, deletion or overexpression of the AR in mature osteoblasts decreases and increases trabecular bone volume, respectively [72, 73]. Nonetheless, the effect of such genetic manipulation on trabecular bone is minimal, as compared to the global deletion of the AR, indicating that AR mediated effects of androgens on osteoclasts are the predominant mechanism of the protective effect of androgens on this site (Fig. 25.5).

In contrast to the global AR deletion, specific deletion of the AR from mature osteoblasts or osteoclasts has no effect on cortical thickness or periosteal diameter [74, 75]. The lack of an effect on cortical bone in mice that lack AR in mature osteoblasts, in the face of such an effect with global AR deletion, strongly suggests that the AR plays an important role in earlier stages of osteoblastogenesis. Support for this possibility has been provided by the selective ERα deletion in early osteoblast progenitors [41], indicating for the first time that sex steroids may positively regulate bone formation by cell autonomous actions on these early progenitors (Fig. 25.5).

To sum this section up, it remains currently unclear how much of the bone-sparing effect of androgens on the adult male skeleton results from effects of T or DHT acting via the AR as opposed to androgens converted to estrogens and acting via the ER [23]. It is also unclear to what extent the bone-sparing effect of androgens result from cell autonomous actions on osteoclasts, osteoblasts, or some other cell type, and whether their protective effects on the adult skeleton result from similar or different mechanisms to those responsible for their effects on skeletal growth. Thus, a considerable gap in the understanding of the basic and clinical aspects of androgen action on bone makes uncertain how much of the osteoporosis in old men results from sex steroid deficiency versus aging, and of the hormonal component, how much is due to true estrogen versus androgen deficiency and/or a decrease in bioavailable E_2 as opposed to T or DHT. However, several clinical studies show correlation between a decrease in bioavailable E_2, but not T, and bone mass in elderly men [53].

ROLE OF SEX STEROIDS IN THE TREATMENT OF OSTEOPOROSIS

The recognition of the serious side effects associated with natural estrogen-based therapies in the uterus, breast, and the cardiovascular system, as well as their decreased efficacy in older women the longer they are from the onset of

menopause, has nowadays significantly reduced the long-term use of estrogen replacement for the prevention or treatment of osteoporosis [76, 77]. The FDA-approved selective estrogen receptor modulator, raloxifene, obviates the adverse effects of estrogens on the uterus and breast and is effective in reducing fracture risk. However, its efficacy is lower than natural estrogens and even lower compared to FDA-approved alternative antiresorptive agents, such as the latest bisphosphonates and the anti-RANKL antibody denosumab. Currently, there is no clear understanding of how selective estrogen receptor modulators(SERMs) act as agonists in some tissues and antagonists in others. This situation hinders rational design of an ideal SERM that can be used long-term in the prevention and treatment of osteoporosis without any of the side effects associated with estrogens, including the adverse effects on clotting mechanisms and venous thromboembolic events [78, 79]. Selective AR modulators (SARMs) have been shown in preclinical studies to retain the anabolic efficacy of androgens on bone and muscle while acting as partial antagonists in the prostate [80]. However, the development of SARMs as therapeutics has been hindered by evidence that, as a class, they may have adverse effects on the heart. Therefore, the future of such compounds is at this stage uncertain.

INTRODUCTION

The parathyroid glands first appeared during evolution with the movement of animals from an aquatic environment to a terrestrial environment deficient in calcium. Maintenance of adequate levels of blood ionized calcium (1.1–1.3 mM) is required for normal neuromuscular function, bone mineralization, and many other physiological processes. Chief cells in the parathyroid gland secrete parathyroid hormone (PTH) in response to very small decrements in blood ionized calcium in order to maintain the normocalcemic state. As discussed later, PTH accomplishes this task by promoting bone resorption and releasing calcium from the skeletal reservoir; by reducing urinary calcium losses and increasing phosphate excretion; and by enhancing intestinal calcium absorption, indirectly through the renal production of the active vitamin D metabolite $1,25(OH)_2$ vitamin D. Blood ionized calcium and $1,25(OH)_2$ vitamin D contribute to the negative feedback inhibition of PTH secretion, whereas serum phosphate increases PTH secretion. Fibroblast growth factor 23 (FGF23) is the third hormone that contributes to the regulation of calcium and phosphate homeostasis; it promotes renal phosphate excretion and reduces the circulating levels of $1,25(OH)_2$ vitamin D, thus diminishing intestinal calcium absorption. The interplay between serum calcium, PTH, FGF23, $1,25(OH)_2$ vitamin D, and phosphate permit blood ionized calcium levels to be maintained within very narrow limits over a wide range of dietary calcium intake. The present chapter summarizes our current understanding of the biology of PTH secretion and action; for an historical perspective on the field, see Ref. 1.

PARATHYROID HORMONE AND PARATHYROID HORMONE-RELATED PEPTIDE

Mammalian PTH is synthesized as a pre-pro-peptide comprising 115 amino acids, but only the single chain 84 full-length polypeptide is secreted by the parathyroid glands; very limited expression has also been detected in the rodent hypothalamus and thymus. Normal development of these glands depends on the transcription factor GCM2 (Gcm2 in rodents) as well as several other upstream proteins, including SOX3, the transcription factor cascade Hoxa3-Pax1/9-Eya, GATA3, the transcription factor Tbx1, and the Shh-Bmp4 signaling network [2, 3]. Mutations in GATA3 and GCMB can be a cause of isolated hypoparathyroidism [4–7].

PTH displays considerable sequence homology with PTH-related peptide (PTHrP), which is, however, limited to the amino-terminal 1-34 region of both peptides [8]. PTH and PTHrP furthermore share some homology with TIP39 (tuberoinfundibular peptide of 39 amino acids) [9], a factor that is expressed in the brain and testes where it

contributes to nociception and male fertility, respectively (Fig. 26.1). PTHrP, originally identified as the humoral mediator of hypercalcemia of malignancy [8, 10, 11], plays important physiological roles in the regulation of endochondral bone formation, smooth muscle function, and branching morphogenesis of the mammary gland [12]. The genes encoding PTH, PTHrP, and TIP39 have a similar structure and at least *PTH* and *PTHrP* are most likely derived from a common ancestral precursor gene (Fig. 26.2).

PTH SYNTHESIS AND SECRETION

In humans, there is a single mammalian PTH gene located on the short arm of chromosome 11, which encodes the precursor molecule preproPTH. After removal of the pre-sequence comprising 25 amino acid residues and of the pro-sequence comprising 6 amino acid residues, the mature PTH peptide of 84 amino acid residues is secreted [13]. The pre-sequence functions as a signal peptide that directs the nascent polypeptide to the machinery that transports it across the membrane of the endoplasmatic reticulum, where the pre-sequence is cleaved off. The role of the pro-sequence is not as clearly defined, but it appears to be required for efficient ER transport of the polypeptide and may play a role in subsequent events such as protein folding [14]. Once produced and packaged into secretory vesicles within the

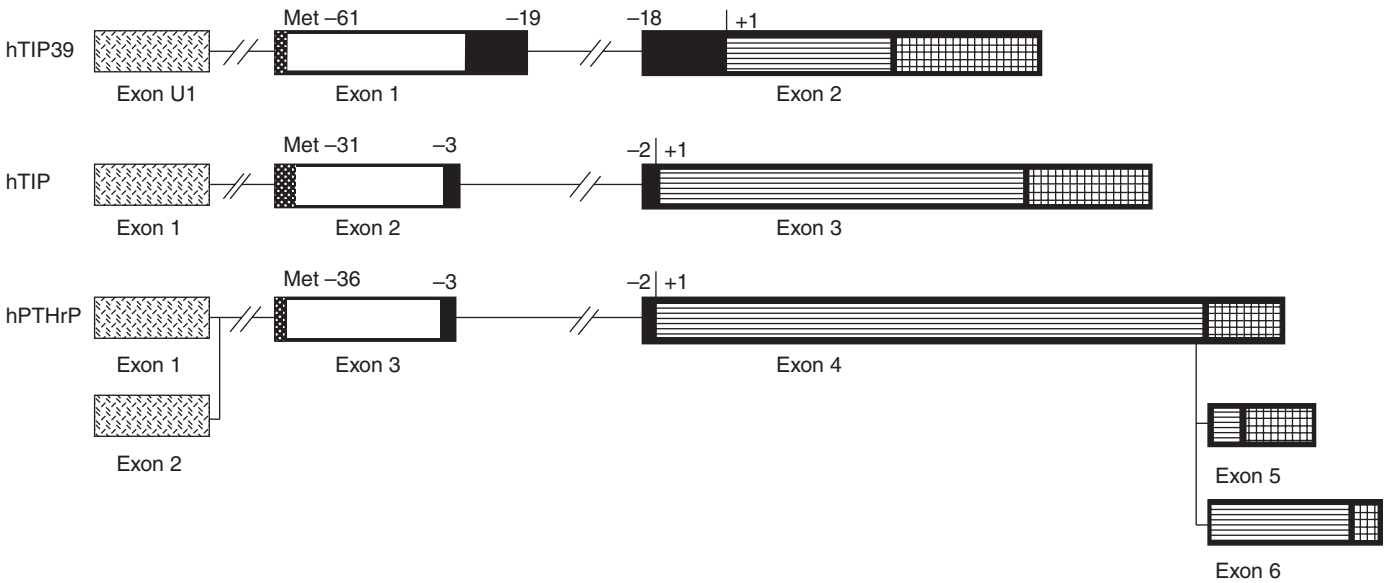

Fig. 26.2. Diagrammatic structures of the genes encoding human TIP39, PTH, and PTHrP. Boxed areas represent exons (the 5′ end of exon U1 in the TIP39 gene is not known). White boxes denote pre-sequences, black boxes are pro-sequences, gray stippled boxes are mature protein sequences, and striped boxes are non-coding regions. The small striped boxes preceding the white boxes denote untranslated exonic sequences. The positions of the initiator methionines are also indicated. +1 represents the relative position of the beginning of the secreted protein. Reproduced with permission from John, Arai, Rubin et al. (Ref. 59).

parathyroid chief cells, PTH(1-84) is subject to alternative fates. The mature hormone can be secreted through a classical exocytotic mechanism or it may be cleaved by calcium-sensitive proteases present within secretory vesicles, resulting in the production and secretion of fragments of PTH(1-84) that lack portions of amino-terminal region and are thus inactive with respect to responses mediated by the PTH/PTHrP receptor [15]. Cleavage of circulating PTH(1-84) into carboxyl fragments can also occur in peripheral tissues such as the liver and kidney [16]. Historically, cleavage of PTH(1-84) has been viewed as a mechanism for biological inactivation of the hormone, but some evidence suggests that carboxyl-terminal fragments of PTH may display unique biological properties [17].

REGULATION OF PTH SECRETION BY EXTRACELLULAR CALCIUM

The major physiological function of the parathyroid glands is to act as a "calciostat," sensing the prevailing blood ionized calcium level and adjusting the secretion of PTH accordingly (Fig. 26.3). The relationship between ionized calcium and PTH secretion is a steep sigmoidal one, allowing significant changes in PTH secretion in response to very small changes in blood ionized calcium. The midpoint of this curve ("set point") is a reflection of the sensitivity of the parathyroid gland to suppression by extracellular calcium [18].

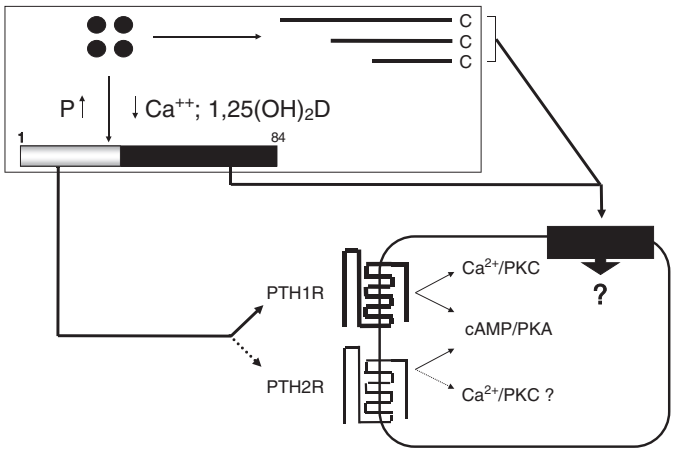

Fig. 26.3. PTH production and activation of different receptors. Intact PTH and different fragments are secreted from the parathyroid glands. Low ionized calcium and elevated phosphate increase PTH synthesis and secretion, while increased ionized calcium and $1,25(OH)_2D$ lead to a decrease; note that the regulatory actions of calcium are mediated through the calcium-sensing receptor. Different receptors interact with the amino- or carboxyl-terminal portion of intact PTH. Through its amino-terminal portion, PTH activates the PTH/PTHrP receptor (PTH1R), a G protein-coupled receptor that mediates its actions through at least two different signaling pathways: cAMP/KPA and Ca^{2+}/PKC. The closely related PTH2-receptor (PTH2R) is most likely the primary receptor for the tuberoinfundibular peptide of 39 residues (TIP39); however, at least the human PTH2R is also activated by amino-terminal PTH. Another receptor, which has not yet been cloned, interacts only with the carboxyl-terminal portion of PTH.

Alteration in blood ionized calcium affects the secretion of PTH(1-84) by multiple mechanisms. Short-term increases in extracellular ionized calcium produce increased levels of intracellular free calcium in the parathyroid cell, resulting in the activation of calcium-sensitive proteases in secretory vesicles. As a result, there is increased cleavage of PTH(1-84) into carboxyl-terminal fragments. Increased extracellular calcium also reduces the release of stored PTH from secretory vesicles, although the molecular details of this regulation are not well defined. Long-term changes in blood ionized calcium (e.g., chronic dietary calcium deficiency, resistance toward PTH) result in increased PTH mRNA expression and in the number of PTH-secreting parathyroid cells.

Extracellular calcium is "measured" at the surface of the parathyroid cell through a calcium-sensing receptor (CaSR) that is abundantly expressed at the plasma membrane of these cells [19]. Increased levels of extracellular calcium suppress PTH secretion, while diminished levels increase PTH secretion. Unlike intracellular calcium-binding proteins, which have an affinity for free calcium in the nanomolar range (consistent with intracellular levels of free calcium), CaSR is presumed to bind free calcium with an affinity in the millimolar range. The CaSR is a member of the G protein-coupled receptor superfamily, which contains calcium-binding elements in its extracellular domain and signaling determinants in its cytoplasmic regions. Binding of calcium (or calcimimetic agents such as Sensipar) to the CaSR triggers activation of heterotrimeric G proteins comprising the alpha-subunits Gq/11 and (to a lesser extent) Gi, which results in stimulation of phospholipase C and inhibition of adenylyl cyclase, respectively [20, 21]. This results in an increase in intracellular free calcium and a decrease in cyclic AMP levels in parathyroid cells. By mechanisms that are not fully defined, activation of these signaling pathways suppresses the synthesis and secretion of PTH. When blood ionized calcium falls, there is less intracellular signaling by the CaSR on the plasma membrane of parathyroid cells and PTH secretion consequently increases. The essential role of the CaSR can best be seen in humans bearing loss-of-function mutations in the CaSR gene. In the heterozygous state, such mutations cause familial hypocalciuric hypercalcemia (FHH), characterized by inappropriately elevated levels of PTH in the face of hypercalcemia [22, 23]. These individuals are quantitatively resistant to the suppressive effect of calcium on PTH secretion due to the reduced number of functional CaSRs; this disorder usually requires no surgical intervention. In the homozygous state, patients display a severe increase in PTH secretion with life-threatening hypercalcemia (neonatal severe hyperparathyroidism), which can be controlled with bisphosphonates

and possibly with calcimimetics, but usually require removal of all parathyroid glands during infancy. Mice with homozygous and heterozygous disruption of the CaSR gene display similar phenotypes [24]. Of interest, deletion in mice of the function of Gq/11, the two major G proteins associated with the CaSR, also results in neonatal severe hyperparathyroidism, confirming the role of Gq/11 in CaSR signaling [25]. Point mutations in the CaSR that induce constitutive signaling are the cause of autosomal dominant hypocalcemia [26, 27].

Limited information is available on the mechanisms by which CaSR signaling suppresses PTH gene expression. Some studies suggest that transcription of the PTH gene is negatively regulated by calcium [28], while others have provided evidence for a post-transcriptional effect of calcium that reduces PTH mRNA stability through binding of a factor(s) to the 3′ untranslated region [29]. This effect appears to be mediated by CaSR-dependent increases in the level of intracellular free calcium [30]. The identity of the relevant factor(s) remains to be established.

Under normal physiological conditions, there is minimal proliferation of parathyroid cells. However, chronic hypocalcemia elicits an increase in both the size and number of parathyroid cells [31].

It is of considerable interest that the CaSR is expressed in a number of tissues outside of the parathyroid gland including kidney, C cells of the thyroid gland, gut, bone, cartilage, and many others [26]. An important function of CaSR in the kidney is to contribute to the regulation of urinary calcium excretion independently of PTH; thus a reduction in signaling as observed in patients with FHH results in hypercalcemia and hypocalciuria due to increased calcium reabsorption in the distal tubules. Although the physiological role of the CaSR in other peripheral tissues is not well understood, recent studies with conditional knockout models suggests that the expression of CaSR in chondrocytes and osteoblasts is essential for normal endochondral bone development [32, 33].

Several pharmacological agents that interact with CaSR have been developed, and these are effective in altering second messenger signaling downstream of the CaSR [27, 34]. So-called calcimimetic drugs bind to the CaSR thereby increasing the receptor's sensitivity to extracellular calcium, increasing receptor signaling, and thus reducing PTH secretion. Calcimimetic drugs have a clinical utility in the medical management of primary or secondary hyperparathyroidism. Calcilytic drugs act as pharmacological antagonists at the CaSR, which reduce the receptor's sensitivity to extracellular calcium, thereby increasing PTH secretion.

REGULATION OF PTH SECRETION BY $1,25(OH)_2$ VITAMIN D

For many years it has been known that vitamin D deficiency causes an increase in PTH production. This is due to diminished intestinal calcium absorption, which leads to an increase in PTH secretion due to insufficient $1,25(OH)_2$ vitamin D levels, resulting hypocalcemia and thus diminished negative feedback regulation of PTH production by this biologically active vitamin D analog. $1,25(OH)_2$ vitamin D production is frequently limited in the setting of chronic renal disease (CKD). Even in the early stages of CKD, levels of FGF23 are already increased to help promote the urinary excretion of phosphate. However, elevated FGF23 levels reduce the 1-alpha hydroxylase activity and enhance the 24-hydroxylase activity, thereby decreasing $1,25(OH)_2$ vitamin D production and accelerating its metabolism into biologically inactive analogs. These changes in vitamin D metabolism contribute to the development of hypocalcemia and secondary hyperparathyroidism in CKD patients. Frank hyperphosphatemia, which usually does not develop until later in the course of CKD, contributes further to the increase in PTH secretion.

The suppression of PTH secretion by $1,25(OH)_2$ vitamin D results from the inhibition of transcription of the PTH gene [35]. This appears to involve $1,25(OH)_2$ vitamin D-induced binding of the vitamin D receptor to negative regulatory elements in the PTH gene promoter [36] and $1,25(OH)_2$ vitamin D-induced association of the vitamin D receptor with a transcriptional repressor [37]. Calcium and $1,25(OH)_2$ vitamin D act coordinately to suppress expression of the PTH gene and to inhibit parathyroid cell proliferation.

REGULATION OF PTH SECRETION BY PLASMA PHOSPHATE, α-KLOTHO, AND FGF23

It has long been known that hyperphosphatemia (as in the late stages of CKD) is associated with parathyroid hyperplasia and hyperparathyroidism. This effect of hyperphosphatemia is in part due to the binding of plasma phosphate to free calcium, which lowers blood ionized calcium thus stimulating PTH synthesis, secretion, and parathyroid cell number [38]. However, serum phosphate also directly affects the parathyroid gland, increasing PTH synthesis by promoting the stability of PTH mRNA [29].

Another regulator of parathyroid function is FGF23, which is secreted by osteocytes/osteoblasts in response to increased oral phosphate intake and possibly other factors. FGF23 acts on the kidney to reduce expression of NPT2a and NPT2c, two sodium-dependent phosphate transporters in the proximal renal tubules, thereby reducing phosphate reabsorption [39]. These actions require binding of FGF23 to its cognate FGF receptor and the co-receptor α-Klotho [40]. FGF23 appears to directly inhibit PTH secretion [41, 42] thus providing another level of complexity for the regulation of parathyroid gland activity.

MECHANISM OF ACTION OF PTH

Target cell actions of PTH are initiated by the PTH/PTHrP receptor, a member of the G protein-coupled receptor superfamily [43]. Binding of PTH to its receptor leads to at least three distinct signaling processes [12, 44]. The most important pathway is receptor-mediated activation of Gsα signaling, resulting in adenylyl cyclase activation and thus increased cellular levels of cyclic AMP, and activation of protein kinase A. The importance of this signaling pathway in the renal response to PTH is highlighted by the renal resistance associated with Gsα deficiency in patients with pseudohypoparathyroidism type Ia [45] and with a recurrent PRKAR1A mutation (the regulatory subunit of PKA) in patients with acrodysostosis [46]. The effects of PTH on the expression of key genes that regulate bone resorption and bone formation (e.g., RANKL, SOST) is mediated at least in part through the cyclic AMP pathway [47, 48]. The PTH/PTHrP receptor also couples to Gq, resulting in the activation of phospholipase C with consequent activation of protein kinase C and increased intracellular free calcium. This pathway appears to play a lesser, modulatory role in PTH action in kidney and bone [49, 50]. Binding of PTH to the PTH/PTHrP receptor also recruits the adaptor protein arrestin to the plasma membrane [51]. Arrestin has been shown to participate in the desensitization and downregulation of the PTH/PTHrP receptor [52], but arrestin also acts as a signaling molecule that may contribute to target cell responses to PTH [53]. Interestingly, analogs of PTH that recruit arrestin to the membrane without activating G protein signaling have been shown to promote bone formation *in vivo* [54].

Recent findings have uncovered new complexities in signaling by the PTH/PTHrP receptor. First, the PTH/PTHrP receptor has classically been thought to initiate signaling exclusively from its location in the plasma membrane. However, PTH(1-34) has recently been shown to remain bound to the PTH/PTHrP receptor during the process of receptor endocytosis, and this was associated with persistent Gsα activation/cyclic AMP signaling [55]. The temporal and spatial domains of PTH/PTHrP receptor signaling may be essential determinants of target cell responses. Secondly, PTH/PTHrP receptor activation may play a direct role modulating the activity of the canonical Wnt signaling pathway. The PTH/PTHrP receptor has been shown to physically interact with components of this pathway—LRP6 [56] and disheveled [57], and in both cases these interactions contributed to PTH-stimulated Wnt signaling. These provocative results may provide new insights into the mechanism of action of PTH on bone and kidney *in vivo*.

INTRODUCTION

In a 1941 case report in the *New England Journal of Medicine*, Fuller Albright first postulated that tumors associated with hypercalcemia might elaborate a parathyroid hormone (PTH)-like humor [1]. Work in the 1980s and 1990s subsequently led to the biochemical characterization of humoral hypercalcemia of malignancy (HHM) and the fulfillment of Albright's predictions by the identification and characterization of parathyroid hormone-related protein (PTHrP) [2–6]. We now understand that PTHrP and PTH are related molecules that can both stimulate the same Type I PTH/PTHrP receptor (PTHR1) [7–9]. PTHrP usually serves a local autocrine, paracrine, or intracrine role, and does not circulate. However, in patients with HHM, PTHrP does reach the circulation and mimics the systemic actions of PTH. A later chapter will discuss malignancy-associated hypercalcemia in detail. This chapter will review the normal physiology of PTHrP.

THE PTHrP GENE AND THE PTH/PTHrP GENE FAMILY

In humans, PTHrP is encoded by a single-copy gene containing eight exons and at least three promoters located on the short arm of chromosome 12 [3, 6, 8]. Alternative splicing at the 3′ end of the gene gives rise to three different classes of mRNAs coding for specific translation products of 139, 141, or 173 amino acids. The physiological significance of these different PTHrP transcripts remains unclear, and in rodents and lower vertebrates such as birds and fish, PTHrP 1-173 does not exist [7, 8, 10, 11]. PTHrP mRNA has been found in almost every organ at some time during its development or functioning. Many different hormones and growth factors regulate the transcription and/or stability of PTHrP mRNA. As with PTH, the calcium-sensing receptor (CaSR) has been found to regulate PTHrP gene expression in many cells [12, 13]. Another common theme is the observation that mRNA levels are induced by mechanical deformation [8]. The reader is referred to other reviews for a comprehensive discussion of the sites and regulation of PTHrP expression [7–9].

The PTHrP and PTH genes share structural elements and sequence homology, suggesting that they are related [3, 5, 6, 8]. The exon/intron organization of that portion of both genes encoding the pre-pro sequences and the initial portion of the mature peptides is identical. Furthermore, there is high sequence homology at the amino-terminal portion of both genes such that the peptides share 8 of the first 13 amino acids and a high degree of predicted secondary structure over the next 21 amino acids. These common sequences allow both peptides to bind and activate the same PTHR1, which ultimately

explains the ability of PTHrP to cause hypercalcemia in HHM [4]. The above-mentioned structural similarities, together with the location of the two genes on related chromosomes in the human genome (short arm of chromosome 11 for PTH; short arm of chromosome 12 for PTHrP), indicate that the two genes likely arose from a common ancestor. The PTH family also contains the PTH-L gene and the more distantly related tuberoinfundibular peptide 39 (TIP 39) gene. All of these genes were derived from a common ancestor and emerged concurrent with the evolution of vertebrates [11]. Furthermore, fish have two PTH genes, two PTHrP genes, and one PTH-L gene; amphibians have one PTH gene, one PTHrP gene, and a PTH-L gene; and mammals only retain one PTH and one PTHrP gene [10, 11]. Thus, PTHrP is a member of an ancient family of PTH-like peptides that appears to be larger and more diverse in lower vertebrates than in mammals.

PTHrP IS A POLYHORMONE

Similar to the pro-opiomelanocortin (POMC) gene, the primary translation product of PTHrP can undergo a variety of post-translational processing events resulting in an overlapping series of biological peptides [8]. The details of cell-specific PTHrP processing and the biological significance of the different PTHrP peptides are not entirely clear, but several specific secreted forms of PTHrP have been defined. First, PTHrP 1-36 is secreted from several cell types [8, 14]. In addition, longer forms of amino-terminal-containing PTHrP are secreted from keratinocytes and mammary epithelial cells, and circulate in patients with cancer and during lactation [15–17]. The amino-terminus is necessary for interaction with the PTHR1. The secretion of mid-region peptides including amino acids 38-94, 38-95, and 38-101 has also been described [8, 18]. The biology of these specific secretory forms is unclear, but the mid-region of PTHrP stimulates placental calcium transport and modulates renal bicarbonate handling, and this portion of the molecule contains nuclear localization signals (see below) [19–21]. Finally, C-terminal fragments consisting of amino acids 107-138 and 109-138 have been described. These peptides have been suggested to inhibit osteoclast function and stimulate osteoblast proliferation [8, 20].

PTHrP RECEPTORS

The amino-terminus of PTHrP binds to and activates the PTHR1, a prototypical, 7-transmembrane-containing, G-protein coupled receptor (GPCR), which is a member of class B of the large family of GPCRs [7, 22]. Like the PTHrP gene, the PTHR1 is one of a family of several related PTH receptor genes. Although PTH can bind to other receptors in this family, PTHrP can only interact with the PTHR1. This receptor has been described to couple to both $G_{\alpha s}$ and $G_{\alpha q11}$ and signal via the cyclic adenine monophosphate (cAMP) and protein kinase A pathway as well as through the generation of inositol phosphates, diacylglycerol, and intracellular calcium transients [7, 22]. The vast majority of studies *in vitro* suggest that this receptor binds PTHrP and PTH with equal affinity and that both activate the receptor in an identical manner. This is also true when amino-terminal fragments of PTH and PTHrP are infused into animals [7, 8]. However, the human PTH1R may respond differently to PTH and PTHrP. Human subjects subjected to continuous infusion of the two peptides for 3–7 days were found to be become hypercalcemic with lower doses of PTH 1-34 than PTHrP 1-36 [23, 24]. PTHrP also is less efective than PTH at stimulating the renal 1-α–hydroxylase enzyme producing 1,25-dihydroxyvitamin D. This may be explained by physical differences in the binding of the two peptides to different conformational states of the receptor so that the duration of cAMP production is shorter for PTHrP 1-36 than for PTH 1-34 [25].

The existence of biological actions for mid-region and C-terminal peptides of PTHrP implies the possibility of additional receptors for these forms of PTHrP. However, no such receptors have been identified to date.

NUCLEAR PTHrP

Immunohistochemical studies have localized PTHrP to the nucleus of many different cell types [20, 26]. There are several potential mechanisms by which PTHrP can avoid secretion and remain in the cell [20, 26]. Once in the cytoplasm, PTHrP appears to shuttle into and out of the nucleus in a regulated fashion. This is dependent on a specific nuclear localization sequence (NLS) located between amino acids 84–93 and a specific shuttle protein known as importin β1, which displaces PTHrP from microtubules and allows it to transit the nuclear pore [20, 26, 27]. Nuclear export is facilitated by a related shuttle protein known as CRM1 and likely requires a different recognition sequence in the C-terminal region of the peptide [20]. The regulation of nuclear trafficking of PTHrP is not fully understood but phosphorylation at Thr^{85} by the cell-cycle-regulated, cyclin-dependent kinase, $p34^{cdc2}$ appears to regulate nuclear import in a cell-cycle-dependent fashion [20]. The function of nuclear PTHrP remains obscure, but it has been described to bind RNA and in some cells, PTHrP localizes to the nucleolus, suggesting it may be involved in regulating RNA trafficking, ribosomal dynamics, and/or protein translation [20, 26]. Whatever the exact functions of nuclear PTHrP, this pathway appears to be necessary for life. Two groups have replaced the endogenous mouse PTHrP gene with foreshortened versions of PTHrP that exclude the nuclear localization signals [28, 29]. In both cases, this results in failure of the animals to survive more than

a couple of weeks due to a phenotype of widespread cellular senescence and growth arrest.

PHYSIOLOGICAL FUNCTIONS OF PTHrP

PTHrP has been found in at least some cells of almost all organs, and a variety of functions have been ascribed to PTHrP. The reader is referred to more comprehensive reviews for a complete discussion of these findings [8, 9]. What follows is a brief outline of areas where PTHrP has been rigorously documented to have physiological effects in intact organisms.

The skeleton

Disruption of the PTHrP gene disturbs chondrocyte differentiation in the growth plates of long bones and in costal cartilage leading to short-limbed dwarfism and a shield chest that interferes with breathing and causes perinatal death. Ablating the PTHR1 gene generates a similar phenotype and overexpressing PTHrP or a constitutively active PTHR1 within growth plate chondrocytes in transgenic mice produces the opposite effect [30–32]. These animal models have documented that amino-terminal PTHrP acts through the PTHR1 to coordinate the rate of chondrocyte differentiation in order to maintain the orderly growth of long bones during development [33]. As illustrated in Fig. 27.1, the growth plate consists of columns of proliferating and differentiating chondrocytes that progressively enlarge to prehypertrophic and then hypertrophic chondrocytes, which secrete matrix and undergo apoptosis in order to form a calcified scaffold that is remodeled into bone in the primary spongiosum. PTHrP is secreted primarily by immature chondrocytes at the top of the columns in response to another molecule known as Indian hedgehog (IHH) produced by differentiating hypertrophic chondrocytes. PTHrP, in turn, activates the PTHR1 located on proliferating and prehypertrophic cells to slow their rate of differentiation into hypertrophic cells. In this manner, IHH and PTHrP act in a local negative feedback loop to regulate the rate of chondrocyte differentiation (see Fig. 27.1) [33]. Emerging evidence suggests that PTHrP affects chondrocyte differentiation by regulating the movement of histone deacetylase 4 (HDAC4) into the nucleus in a PKA-dependent fashion, which, in turn, regulates the activity of a network of transcription factors such as Zfp521, MEF2, and Runx2 [34–36]. This may help to explain why mutations in the GNAS, HDAC4 and PTHrP genes all produce similar defects in bone development [37–39].

PTHrP is also produced in other cartilaginous sites such as the perichondrium that surrounds the costal cartilage and the subarticular chondrocyte population immediately subjacent to the hyaline cartilage lining the joint space [40, 41]. In both of these sites, PTHrP appears to prevent hypertrophic differentiation of chondrocytes

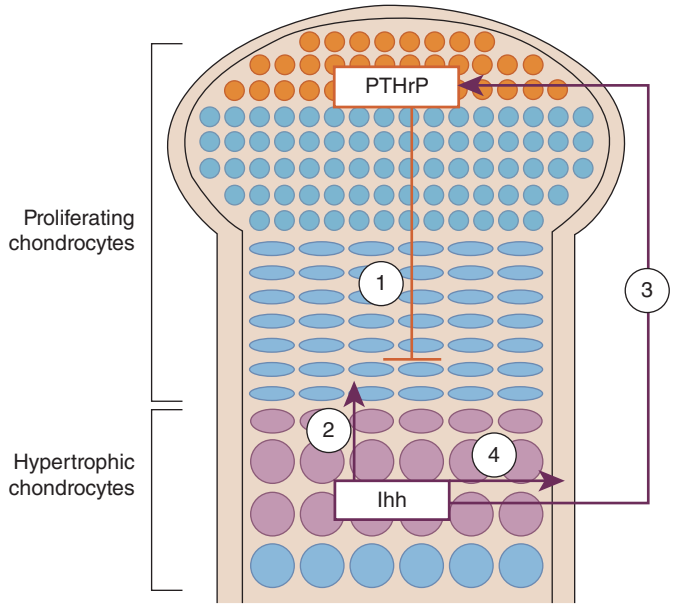

Fig. 27.1. PTHrP and Indian hedgehog (Ihh) act as part of a negative feedback loop regulating chondrocyte proliferation and differentiation. The chondrocyte differentiation program proceeds from undifferentiated chondrocytes at the end of the bone, to proliferative chondrocytes within the columns and then to prehypertrophic and terminally differentiated hypertrophic chondrocytes nearest the primary spongiosum. PTHrP is made by undifferentiated and proliferating chondrocytes at the ends of long bones. It acts through the PTH1R on proliferating and prehypertrophic chondrocytes to delay their differentiation, maintain their proliferation, and delay the production of Ihh, which is made by hypertrophic cells (1). Ihh, in turn, increases the rate of chondrocyte proliferation (2) and stimulates the production of PTHrP at the ends of the bone (3). Ihh also acts on perichondrial cells in order to generate osteoblasts of the bone collar (4). (Kronenberg HM. 2003. Developmental regulation of the growth plate. *Nature* 423: 332–336. Reprinted by permission from Macmillan Publishers Ltd. Copyright 2003.)

and the inappropriate encroachment of bone into these structures [40–42]. Similarly, recent data suggest that PTHrP is important for the maintenance of growth plate chondrocytes in mice. Disruption of the PTHrP gene in these cells after birth causes premature growth arrest due to fusion of the growth plates [43]. These experiments raise the intriguing possibility that PTHrP signaling might be involved in the fusion of growth plates during adolescence or in the loss of articular cartilage in osteoarthritis [42, 43].

In addition to cartilage, PTHrP has important anabolic functions in bone. Heterozygous PTHrP-null mice are normal at birth but develop trabecular osteopenia with age [44]. In addition, selective deletion of the PTHrP gene from osteoblasts results in decreased bone mass, reduced bone formation and mineral apposition, and a reduction in the formation and survival of osteoblasts [45]. Osteoblast cell lines in culture produce PTHrP, and its production *in vitro* can be stimulated by mechanical deformation,

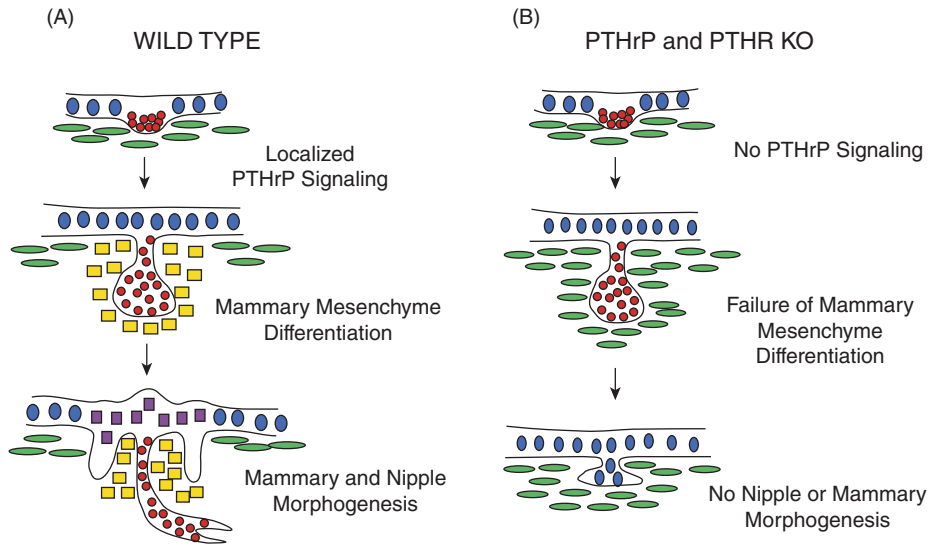

Fig. 27.2. PTHrP regulates mesenchymal cell fate during embryonic mammary development. (A) During normal mammary development, PTHrP is secreted by epithelial cells within the forming mammary bud (red circles) and interacts with the immature dermal mesenchyme (green ovals) to induce formation of the dense mammary mesenchyme (yellow squares). These cells, in response to PTHrP, maintain the fate of the mammary epithelial cells, initiate branching morphogenesis and induce the formation of the specialized nipple skin (purple squares). (B) In PTHrP- or PTHR1-knockout embryos, the mammary bud forms, but the mammary mesenchyme does not. As a result, the mammary epithelial cells revert to an epidermal fate (blue ovals), morphogenesis fails and the nipple never forms. (Adapted with permission from Foley J, Dann P, Hong J, Cosgrove J, Dreyer BE, Rimm D, Dunbar, ME, Philbrick WM, Wysolmerski JJ. 2001. Parathyroid hormone-related protein maintains mammary epithelial fate and triggers nipple skin differentiation during embryonic breast development. *Development* 128: 513–525 and the Company of Biologists Ltd.)

suggesting that it may be involved in mediating the anabolic response to skeletal loading. However, despite the clear phenotype in the osteoblast-specific PTHrP-knockout mice, there is disagreement over the PTHrP-expressing population(s) of osteoblasts in the skeleton and even if the gene is normally expressed within these cells [40, 41]. Nonetheless, the osteopenia in these animal models suggests that intermittent PTH treatment invokes an anabolic response in bone by mimicking the natural functions of local PTHrP in the skeleton.

Mammary gland

Not long after its discovery, PTHrP mRNA was found to be expressed in the lactating breast, and PTHrP protein was measured in high concentrations in milk [46, 47]. It is now known that PTHrP has important functions during breast development, is involved in regulating systemic calcium metabolism during lactation, and contributes to the pathophysiology of breast cancer.

Like other epidermal appendages, the mammary gland initially forms as a bud-like invagination of epidermal cells that grow down into a developing fatty stroma as a branching tube that becomes the mammary duct system. These processes are regulated by a series of sequential and reciprocal interactions between the epithelial cells in the bud and ducts and adjacent mesenchymal cells in the stroma [48]. In mice, as soon as the mammary bud begins to form, epithelial cells produce PTHrP, which interacts with the PTHR1 expressed on surrounding mesenchymal cells. This interaction is necessary for proper differentiation of the dense mammary mesenchyme that surrounds the embryonic mammary bud so that these mesenchymal cells can, in turn, support the proper development of the epithelial ducts [49]. PTHrP- or PTHR1-knockout mice lack mammary glands because loss of PTHrP signaling interrupts the vital crosstalk between epithelial and mesenchymal cells (Fig. 27.2). The formation of the breast in human fetuses is similar to the formation of the fetal mammary gland in mice and it also requires PTHrP [50].

PTHrP is made by breast epithelial cells during lactation and large quantities are secreted into milk [17, 46]. Although its function in milk is unclear, PTHrP is also secreted from the lactating breast into the circulation, where it participates in the regulation of systemic calcium metabolism. Milk production requires a great deal of calcium, an important source of which is the maternal skeleton. Elevated rates of bone resorption and rapid bone loss are well documented in both nursing women and rodents [51]. During lactation, elevated levels of PTHrP correlate with bone loss in humans, and circulating levels of PTHrP correlate directly with rates of bone resorption and inversely with bone mass in mice [16, 52]. In addition, disruption of the PTHrP gene in mammary glands during lactation reduces circulating PTHrP levels, lowers bone turnover, and preserves bone

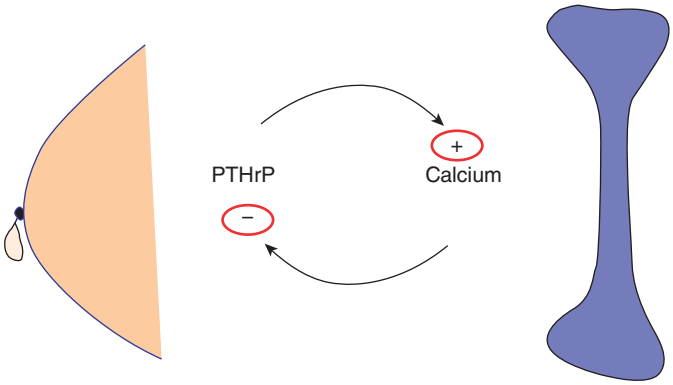

Fig. 27.3. The breast and the skeleton communicate during lactation in order to provide a steady supply of calcium for milk production. The lactating breast secretes PTHrP into the systemic circulation during lactation. PTHrP interacts with the PTH1R in bone cells in order to increase the rate of bone resorption and liberate skeletal calcium stores. Mammary epithelial cells in the lactating breast express the CaSR and suppress PTHrP production in response to increased delivery of calcium, defining a classical endocrine negative feedback loop between breast and bone.

mass, demonstrating that the lactating breast secretes PTHrP into the circulation to increase bone resorption [17]. The lactating breast also expresses the CaSR, which signals to suppress PTHrP secretion in response to increases in calcium delivery to the breast [13]. These interactions define a classical endocrine negative feedback loop, whereby mammary cells secrete PTHrP to mobilize calcium from the bone. Calcium, in turn, feeds back to inhibit further PTHrP secretion from the breast. Therefore, during lactation, the breast and bone engage in a conversation, which leads to the mobilization of skeletal calcium stores to ensure a steady supply of calcium for milk production (see Fig. 27.3). Interestingly, fish PTHrP fulfills a similar function in mobilizing calcium stored in scales to be used during egg production [10]. Thus, this reproductive function of PTHrP is ancient, and the actions of PTHrP during lactation may represent one of the principal evolutionary pressures that resulted in PTHrP and PTH retaining the use of the same PTHR1.

Placenta

During pregnancy, calcium must be actively transported across the placenta from mother to fetus. Furthermore, the responsible placental pump maintains a higher calcium concentration in the fetus as compared to the mother, so that calcium must be transported against a gradient [51]. In PTHrP$^{-/-}$ mice, this gradient is lost and PTHrP-deficient fetuses are relatively hypocalcemic, suggesting that fetal PTHrP is important in mediating placental calcium transport from the mother [21]. The source of the PTHrP is likely the placenta itself, and placental production of PTHrP has been shown to be regulated by the CaSR [53, 54]. Interestingly, experiments in sheep and mice have demonstrated that mid-region PTHrP, not amino-terminal PTHrP, is responsible for placental calcium transport [19, 21].

Smooth muscle and the cardiovascular system

PTHrP is expressed in many different smooth muscle cell beds in response to mechanical deformation and functions to relax the stretched muscle [8, 9, 55–57]. In the vasculature, PTHrP is induced by vasoconstrictive agents, as well as stretch itself, and acts as a vasodilator in resistance vessels. Given these actions, PTHrP may act as a local modulator of blood flow [58].

PTHrP regulates the proliferation of vascular smooth muscle cells. Secreted amino-terminal PTHrP can inhibit the proliferation of vascular smooth muscle cells by acting via the PTHR1 on the cell surface. However, the mid-region and C-terminal portions of PTHrP act in the nucleus to stimulate the proliferation of these cells by destabilizing a cell cycle regulatory protein known as p27^{kip1} and promoting progression through the G_1/S checkpoint [59, 60]. This pathway appears to be active during development, since the rate of proliferation of smooth muscle cells in the aorta of PTHrP$^{-/-}$ embryos is reduced [60]. Furthermore, PTHrP expression is upregulated by vascular damage following balloon angioplasty and in atherosclerotic lesions in rodents and in humans. Several studies have suggested that PTHrP plays an important role in the response of these cells to injury and may contribute to the pathophysiologic development of a neointima following angioplasty [61, 62].

Teeth

Developing teeth become surrounded by alveolar bone but must maintain a cavity or crypt that is free from bone to allow for proper morphogenesis. After teeth are formed, they must then erupt through the roof of the dental crypt in order to emerge into the oral cavity. The process of tooth eruption relies on geographically uncoupled bone turnover in which osteoclasts form over the crown of the tooth in order to resorb the overlying bone and osteoblasts at the base of the tooth propel it upward out of the crypt. In the absence of PTHrP, teeth develop but they do not erupt. PTHrP is normally produced by stellate reticulum cells and signals to dental follicle cells in order to drive the formation of osteoclasts above the crypt. In the absence of PTHrP, these osteoclasts do not appear, eruption fails to occur, and teeth become impacted [63–65].

Pancreatic islets

PTHrP is expressed by all four neuroendocrine cell types within the pancreatic islets [66]. In β cells, it is stored

within secretory granules and is co-released with insulin [67]. Pancreatic islets express the PTHR1, and β cells respond to PTHrP by activating phospholipase C and increasing intracellular calcium [68]. Overexpression of PTHrP in β cells leads to an increased β-cell mass, hyperinsulinemia, and hypoglycemia, due to the combination of increased β-cell proliferation, increased insulin production, and inhibition of β-cell apoptosis [68, 69]. PTHrP also induces proliferation and improves glucose-stimulated insulin secretion in cultured human β cells. These actions of PTHrP are mediated by a pathway involving PKC-ζ, cyclin E, and cyclin-dependent kinase 2 (cdk2) [70].

Central and peripheral nervous systems

PTHrP and the PTH1R are both widely expressed within specific neurons within the brain, including regions of the cortex, the cerebellum, the hippocampus, hypothalamus, and pituitary [71, 72]. In cultured hippocampal neurons, PTHrP is secreted in response to calcium influx through L-type calcium channels. In turn, PTHrP can act on the PTHR1 on these same neurons to dampen L-type channel activity, giving rise to the idea that PTHrP acts in an autocrine/paracrine short feedback loop to protect neurons from damage due to prolonged or repeated depolarization, so-called excitotoxicity [73]. Consistent with this idea, disruption of the PTHrP gene sensitizes mice to kainite-induced seizures [73].

In addition to neurons, PTHrP has also been shown to be expressed in glia and astrocytes [74–76]. Interestingly, the PTHrP gene is expressed in fetal and malignant glial cells but not in mature glia in the adult brain [76]. However, its expression can be induced in reactive glia in an injury model in rats [75] and in dedifferentiated Schwann cells after crush injury in the peripheral nervous system [77]. PTHrP has been shown to inhibit the differentiation of these cells, suggesting that it contributes to maintaining the dedifferentiated state necessary for nerve regeneration.

CONCLUSIONS

PTHrP was discovered as the cause of the clinical syndrome of HHM. It is evolutionarily and functionally related to PTH and shares the same PTHR1. The common use of this receptor, in turn, allows PTHrP to act as a hormone mimicking the actions of PTH during reproduction, a function preserved from fish to mammals. Although the conservation of these relationships through evolution allows PTHrP to cause hypercalcemia when it is secreted into the circulation by tumors, we have come to understand that PTHrP is generally a locally produced and locally acting growth factor that participates in normal development and physiology at many diverse sites. The power of mouse genetics has provided insight into the functions of PTHrP. However, much still remains to be learned of its normal biology.

ACKNOWLEDGMENTS

This work was supported by grants DK077565, DK55501, and CA153702 from the NIH, and BC095546 from the DOD BCRP. The author would like to thank Drs. Arthur Broadus and Rupangi Vasavada for valuable conversations during the preparation of this chapter.

Ca^{2+}-Sensing Receptor

Edward M. Brown

Introduction 224
Structure and Function of the CaSR 224
Roles of the CaSR in Tissues Maintaining Ca^{2+}_o Homeostasis 229
References 231

INTRODUCTION

Complex terrestrial organisms, including humans, maintain a virtually constant level of their extracellular ionized calcium (Ca^{2+}_o) concentration, with a normal range of 1.1–1.3 mM [1]. This provides a reliable supply of calcium ions for their numerous extracellular roles, i.e., acting as a cofactor for clotting factors, adhesion molecules, and numerous other proteins, modulating neuronal excitability and providing a source of calcium for its myriad intracellular functions [1]. In addition, salts of calcium and phosphate provide the mineral phase of the skeleton, which protects vital organs and facilitates locomotion and other movements. Bone is also a nearly inexhaustible supply of calcium and phosphate when dietary sources are insufficient for the body's requirements.

The resting level of the cytosolic calcium concentration (Ca^{2+}_i), in contrast, is about 100 nM, nearly 10,000-fold lower than that of Ca^{2+}_o [2]. Changes in Ca^{2+}_i function as a key intracellular second messenger, regulating diverse processes, such as cellular motility, differentiation, proliferation, and apoptosis as well as muscular contraction and hormonal secretion [2]. All intracellular Ca^{2+} ultimately derives from Ca^{2+} in the extracellular fluids (ECFs). Therefore, maintaining a nearly constant level of Ca^{2+}_o ensures that calcium is available for its host of intracellular roles.

The "guardian" of the near constancy of Ca^{2+}_o in mammals is a homeostatic system comprising the parathyroid glands, calcitonin (CT)-secreting C cells, kidney, bone, and intestines [1], as detailed elsewhere in this volume. Key components of this homeostatic mechanism are several types of cells that can "sense" small perturbations in Ca^{2+}_o from its normal value and respond so as to return Ca^{2+}_o to normal. The parathyroid glands play key roles in this process by secreting PTH in response to hypocalcemia, which then increases renal tubular reabsorption of Ca^{2+}, contributes to net release of Ca^{2+} from bone and enhances intestinal Ca^{2+} absorption by increasing renal synthesis of $1,25(OH)_2D_3$.

This chapter describes the properties and functions of the Ca^{2+}_o-sensing receptor (CaSR), a G-protein coupled receptor (GPCR) that plays a central role in Ca^{2+}_o homeostasis by virtue of its capacity to sense Ca^{2+}_o [1]. It is the principal mechanism in parathyroid cells, C cells, and several nephron segments in the kidney, as well as in bone and intestine for measuring the level of Ca^{2+}_o. As such, it can serve as the body's "thermostat for Ca^{2+}_o" or "calciostat" through its capacity to modulate the functions of those cell types just enumerated that participate in Ca^{2+}_o homeostasis.

STRUCTURE AND FUNCTION OF THE CaSR

The CaSR was originally cloned from bovine parathyroid gland [3] and then from several tissues of a variety of other species, including humans [4]. All exhibit highly similar amino acid sequences (≥84% identical) and pre-

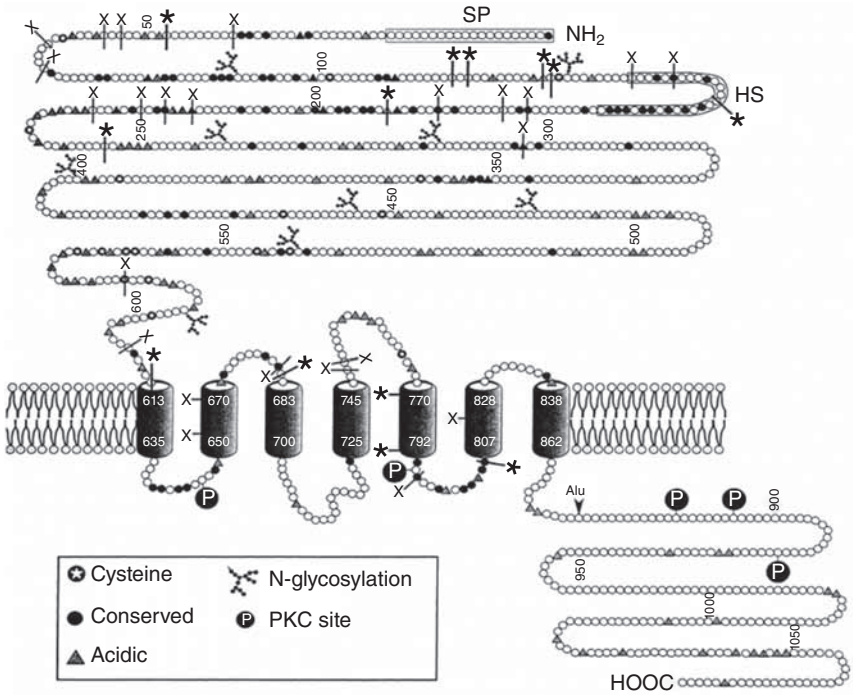

Fig. 28.1. Predicted structure of the human CaSR (see text for details). SP: signal peptide; HS: hydrophobic segment. The X's show examples of sites of naturally occurring inactivating mutations, and asterisks indicate locations of activating mutations. Reproduced in modified form with permission from Brown EM, Bai M, Pollak M. In: Avioli L, Krane SM (eds.) *Metabolic Bone Disease and Clinically Related Diseases*. San Diego: Academic Press. 1999, pp. 479–499.

dicted structures, and they represent tissue and species homologs of the same ancestral CaSR gene (so-called orthologs). Similar genes have been isolated from evolutionarily more distant species, such as salmon and dogfish shark [5], which exhibit approximately 60–70% amino acid identity to the sequence of the human CaSR. Thus the CaSR originated prior to the migration of vertebrates from the oceans onto dry land and is thought to regulate processes that maintain stability of Ca^{2+}_o in bony fish and elasmobranchs, e.g., sharks [5].

Figure 28.1 shows the predicted topology of the human CaSR protein. Its three principal structural domains include: (a) a large, 612 amino acid extracellular amino-terminal domain (ECD) containing a cysteine rich region followed by a peptide linker to the first transmembrane helix at its carboxy terminus; (b) a 250 amino acid, seven-transmembrane domain (TMD) motif characteristic of the superfamily of GPCRs; and (c) a carboxyl-terminal (C–) tail of 216 amino acids (for review, see Ref. 6).

The CaSR gene and properties of the CaSR

The human CaSR gene resides on the long arm of chromosome 3 in band 3q13.3–21. It has seven exons, the first of which encodes sequences upstream of the translational start site and contains two promoters. The remaining six exons contain the translational start site and the three domains of the CaSR just described. Exons 2–6 encode the ECD and exon 7 codes for the TMD and C-terminus [6]. Interleukins 1β [7] and 6 [8], $1,25(OH)_2D_3$ [9] and activation of the CaSR itself [10] upregulate the receptor. The high Ca^{2+}_o-evoked increases and $1,25(OH)_2D_3$-evoked increases in CaSR expression may contribute to the known inhibition of parathyroid function by these two factors. The chemokines, MCP-1 and SDF-1α, increase CaSR expression on the cell surface [11], probably by enhancing translocation of preformed receptor to the plasma membrane. The CaSR's expression is commonly downregulated in various forms of hyperparathyroidism [12].

Biogenesis and structure of the CaSR

Biogenesis of the CaSR in the endoplasmic reticulum (ER) is accompanied by cleavage of the 20 amino acid signal peptide that directs the nascent protein chain into the lumen of the ER. The receptor dimerizes in the ER through intermolecular disulfide bonds involving cysteines 129 and 131 [13]. Transport of the CaSR from the ER to the Golgi is followed by glycosylation of the receptor on a total of eight O-linked glycosylation sites, a process that is essential for surface expression of the receptor (for review, see Ref. 6). Several proteins have been identified that are important for the CaSR's efficient transport from the ER to the Golgi and, ultimately, the cell surface, including the low molecular weight, monomeric G protein, Rab1 [14], the "cargo receptor" p24a, and the so-called receptor activity modifying proteins (RAMP) 1 and 3 (for review, see Ref. 15). These may overcome the action of an ER retention signal present within the CaSR's C-terminus [6].

Following activation by its agonists, the CaSR can undergo desensitization by mechanisms involving phosphorylation of its C-terminus by G protein receptor kinases

(GRKs) and uncoupling from heterotrimeric G proteins that it activates, such as $G_{q/11}$ [16]. The receptor undergoes relatively little agonist-induced internalization [17], however, and the recycling of intracellular CaSR to the cell surface is facilitated by another monomeric G protein, Rab11a [15]. The continued availability of cell surface CaSR, resulting in part from agonist-induced insertion of intracellular CaSR into the plasma membrane (17a), is important to ensure continuous, efficient monitoring of Ca^{2+}_o by the CaSR in its role as "calciostat."

Binding of Ca^{2+}_o and activation of CaSR-mediated signaling

The ECD of the CaSR is thought to assume a bilobed configuration resembling a Venus flytrap (Fig. 28.2), based on homology modeling from the related, metabotropic glutamate receptors (mGluRs) [18]. Several of the mGluR ECDs have been crystallized and their structures solved by X-ray crystallography with and without their agonist, glutamate. Like the mGluRs, the CaSR has a binding site for its agonist, Ca^{2+}, in the crevice between the two lobes of ach monomer (Fig. 28.2) [19, 20]. Binding of calcium to this site is thought to facilitate closure of the Venus fly trap (VFT) domain and initiation of intracellular signaling through additional conformational changes on the CaSR's TMD, intracellular loops and C-tail that activate G proteins (for review, see Ref. 6). It is likely that there are additional Ca^{2+}-binding sites elsewhere in the ECD (and possibly in the TMD), which are important for the receptor's high degree of positive cooperativity, i.e., the binding of Ca^{2+} to one site enhances binding of Ca^{2+} to other sites [20]. This generates the steep slope of the relationship between Ca^{2+}_o and CaSR-mediated biological responses that is essential for maintaining near constancy of Ca^{2+}_o [1]. Within its intracellular loops and C-tail, the human CaSR harbors five predicted protein kinase C (PKC) sites. CaSR-mediated activation of protein kinase C (PKC) diminishes stimulation of phospholipase C (PLC) by the receptor, primarily by phosphorylating a key PKC site in the CaSR's C-tail at threonine 888 (T888) [21]. This PKC-induced phosphorylation of the C-tail confers negative feedback regulation of CaSR-mediated stimulation of PLC.

On the plasma membrane, the CaSR in parathyroid resides in caveolae, which are flask-shaped invaginations of the plasma membrane [22]. In this locale, the CaSR binds to caveolin-1, a key cholesterol-binding, structural protein of caveolae that interacts with multiple other proteins, including signaling proteins (e.g., G proteins) [23]. The CaSR's C-tail interacts with filamin-A, an actin-binding protein, which, like caveolin-1, acts as a scaffold for multiple proteins [24]. The CaSR's ability to activate MAPKs, i.e., ERK1/2 (see below), is dependent, in part, on its binding to filamin-A [24]. The binding of filamin-A to the CaSR's C-tail also increases the receptor's resistance to degradation. In contrast, binding of the E3 ubiquitin ligase, dorfin, to the C-tail is thought to promote proteasomal degradation of the protein [25].

CaSR agonists and CaSR signaling

The CaSR is activated by a variety of agonists in addition to Ca^{2+}_o (Fig. 28.3) (for review, see Ref. 6), including other

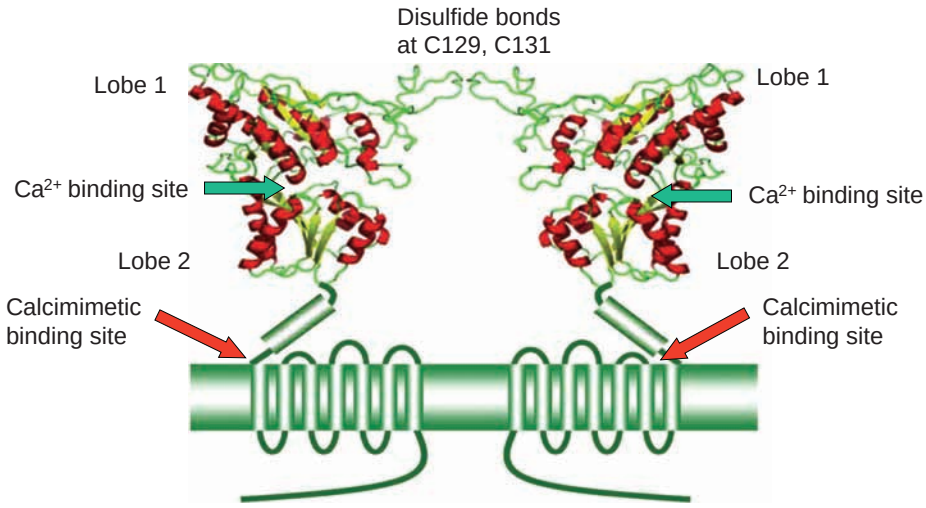

Fig. 28.2. Schematic illustration of the ECD of the CaSR based on the known structure of the ECDs of several metabotropic glutamate receptors. Note that the ECD is a dimer, with each monomer having a Venus flytrap-like conformation with a binding site for Ca^{2+} in the crevice between the two lobes of each monomer. Additional binding sites for Ca^{2+} are probably present elsewhere in the ECD. A binding site for amino acids (e.g., phenylalanine) is close to the binding site for Ca^{2+}_o depicted. Calcimimetics, such as Cinacalcet, in contrast, bind to a site in the TMD, with the amino group of the drug between the two hydrophobic ends anchored to Glu837. Reproduced in modified form from a figure originally published in the *Journal of Biological Chemistry*. Huang Y, Zhou Y, Yang W, Butters R, Lee HW, Li S, Castiblanco A, Brown EM, Yang JJ. 2007. Fig. 28.3. Multiple agonists and other factors modulating the activity of the CaSR as well as the numerous intracellular signaling pathways through which the receptor can regulate cellular function. Ca^{2+}, Mg^{2+}, aminoglycoside antibiotics, spermine and other polyamines, and amyloid beta peptides are examples of polycationic agonists of the CaSR. Aromatic amino acids and calcimimetics—drugs that activate the receptor and are used to control hyperparathyroidism—are allosteric modulators of the CaSR. The former bind to a site near a putative calcium-binding site in the receptor's ECD, while the latter bind to the CaSR's transmembrane domains; both increase its apparent affinity for polycationic agonists. AA: arachidonic acid; AC: adenylate cyclase; cAMP: cyclic AMP; $cPLA_2$: cytosolic phospholipase A_2; DAG: diacylglycerol; ERK: extracellular signal-regulated kinase; $G\alpha_i$ and $G\alpha_q$, α subunits of the i- and q-type heterotrimeric G-proteins, respectively, $Ins(1,4,5)P_3$: inositol 1,4,5-trisphosphate; $Ins(1,4,5)P_3R$: 1,4,5-trisphosphate receptor; JNK: Jun N-terminal kinase; MAPK: mitogen-activated protein kinase; MEK: MAPK kinase; PI4K: phosphatidylinositol 4-kinase; PKC: protein kinase C; PLC: phospholipase C; $PtdIns(4,5)P_2$: phoasphatidylinositol-4,5-bisphosphate. divalent (i.e., Mg^{2+} and Sr^{2+}) and trivalent cations (e.g., La^{3+} and Gd^{3+}), as well as organic polycations, such as polylysine, polyarginine, and neomycin. All of these are so-called type 1 agonists (i.e., they activate the receptor even in the absence of Ca^{2+}). Type II CaSR activators, in contrast, require the presence of extracellular Ca^{2+} for their activity [26]. These include amino acids, particularly aromatics, which bind to a site close to the Ca^{2+}-binding site between the two lobes of the ECD, and calcimimetics. The latter are drugs used to suppress parathyroid function in hyperparathyroid states [26]; they bind to a pocket within the TMD (Fig. 28.2). CaSR antagonists, so-called calcilytics [26], in contrast, inhibit the CaSR by binding to a site in the TMD overlapping, but not identical to, that binding calcimimetics [27].

Does the CaSR serve as an Mg^{2+}_o-sensor?

Some evidence supporting the CaSR's role in sensing and "setting" Mg^{2+}_o derives from experiments-in-nature that initially proved the CaSR's role as a central element in Ca^{2+}_o homeostasis. Namely, individuals with hypercalcemia owing to heterozygous inactivating CaSR mutations, viz., the syndrome familial hypocalciuric hypercalcemia (FHH), have serum Mg^{2+} levels in the high normal or mildly elevated range [28]. Conversely, persons who have activating CaSR mutations can manifest mild hypomagnesemia [1]. Therefore, inactivating and activating mutations of the CaSR reset not only Ca^{2+}_o but also Mg^{2+}_o. The regulation of Mg^{2+}_o homeostasis by the CaSR may occur, in part, in the parathyroid gland, where hypermagnesemia suppresses parathyroid hormone (PTH) release, and/or in the cortical thick ascending limb (cTAL) of the kidney, where elevated Mg^{2+}_o reduces the reabsorption of not only Mg^{2+} but also Ca^{2+} [29].

Intracellular signaling by the CaSR

Activation of the CaSR by its various agonists and activators modulates numerous signaling pathways (Table 28.1) (for reviews, see Ref. 6). These include activation of phospholipases C, A_2 (PLA_2), and D (PLD). The CaSR activates PLC via the G-proteins, $G_{q/11}$, PLA_2 through a mitogen-activated protein kinase (MAPK) (e.g., ERK1/2)- or

Table 28.1. Mechanisms of Intracellular Signaling by the CaSR*

1. Diverse extracellular ligands (di-, trivalent cations, organic polyvalent cations, amino acids, calcimimetics, calcilytics, etc.)
2. Changes in CaSR gene expression
3. Changes in CaSR desensitization, internalization, and degradation
4. Changes in forward trafficking of CaSR to the plasma membrane
5. Interaction of CaSR with scaffold proteins (caveolin-1, filamin) that bind signaling molecules (MAPK components, G proteins, etc.)
6. Activation of G proteins
   a. Heterotrimeric G proteins ($G_{i//o}$, $G_{q/11}$, $G_{12/13}$, G_s)
   b. Low molecular weight G proteins (Arf6, RhoA, Ras, Rab1, Rab11a)
7. Generation of second messengers
   a. Adenylate cyclase (forms cAMP)
   b. Phospholipase A_2 (forms arachidonic acid)
   c. Phospholipase C (forms IP_3, DAG)
   d. Phospholipase D (forms phosphatidic acid)
8. Activation of lipid kinases
   a. PI-3 kinase (forms PIP_3)
   b. PI-4 kinase (forms inositol 4-phosphate)
9. Activation of protein kinases
   a. Protein kinase A (PKA)
   b. Protein kinase B (Akt)
   c. Protein kinase C (PKC)
   d. Calmodulin-dependent kinases (CaMKII)
   e. Tyrosine kinases
   f. Mitogen-activated protein kinases (ERK1/2, P38 MAPK, JNK)

Table 28.2. Functions of CaSR in Ca^{2+}_o Homeostatic Tissues

Tissue	Function
Parathyroid cells	Inhibits PTH secretion Reduces expression of preproPTH mRNA Suppresses parathyroid cellular proliferation Inhibit PTH degradation Increase expression of CaSR and VDR
C cells	Stimulates calcitonin secretion
Kidney	Increases expression of VDR (PT) Inhibits Ca^{2+} and Mg^{2+} reabsorption (TAL) Activates TRPV5 (DCT) Stimulates acid secretion (CCD) Inhibits water reabsorption (IMCD)
Intestine	Upregulates genes involved in Ca^{2+} absorption Stimulates gastrin, gastric acid secretion Enhances cholecystokinin secretion Inhibits fluid secretion in colon
Osteoblast	Stimulates osteoblast proliferation, chemotaxis, differentiation, bone growth, mineralization
Osteoclast**	Promotes osteoclast differentiation Supports calcemic action of PTH Inhibits bone resorption Stimulates apoptosis Mentaverri
Lactating breast	Stimulates Ca^{2+} transport into milk
Placenta	Stimulates Ca^{2+} transport to fetus

**How the CaSR supports osteoclast differentiation, on the one hand (Refs. 68, 75), and inhibits osteoclast action and stimulates apoptosis (Ref. 68), on the other, has not been fully elucidated.

calmodulin-dependent mechanisms, and PLD via protein kinase C (PKC) or $G_{12/13}$. Arachidonic acid (AA) produced by PLA_2 can be further metabolized to produce biologically active products, including those arising from the P450 pathway [20-hydroxyeicosatetraenoic acid (i.e., 20-HETE)] [30], from the 12- and 15-lipoxygenases (e.g., 12- and 15-HETE) [31], and/or from cyclooxygenase (viz. PGE_2) [32]. The high Ca^{2+}_o-induced, transient elevation in Ca^{2+}_i in bovine parathyroid cells is the result of PLC activation and consequent IP_3-mediated release of intracellular Ca^{2+} stores [6]. High Ca^{2+}_o also produces sustained increases in Ca^{2+}_i via incompletely defined influx pathway(s) for Ca^{2+} that probably include activation of one or more Ca^{2+}-permeable, nonselective cation channels of the transient receptor potential (TRP) family (i.e., TRPC1)[33]. Not uncommonly, activation of the CaSR and PLC signaling initiates slow intracellular Ca^{2+}_i oscillations, which may encode information related to their amplitude and/or frequency [34]. High Ca^{2+}_o decreases agonist-evoked cAMP accumulation in parathyroid cells [6] by inhibiting adenylate cyclase via the inhibitory G protein, G_i [35]. High Ca^{2+}_o-elicited diminution of cAMP in other cells types, however, can result from inhibition of a Ca^{2+}-inhibitable isoform of adenylate cyclase [6] or increased degradation of cAMP by phosphodiesterase [36].

Another common form of CaSR signaling involves activation of MAPKs, including ERK1/2, p38 MAPK, and JNK through both PKC- and tyrosine kinase-dependent pathways [37]. Other signaling mechanisms/pathways activated by the CaSR include monomeric G proteins (e.g., Ras and RhoA), lipid kinases [phosphatidylinositol-3 kinase (PI3K) (producing PIP_3) and PI-4 kinase (PI4K)], and protein kinases [protein kinases A, B (also known as Akt), and C, as well as calmodulin kinase II (CaMKII)]. The interested reviewer is referred to recent comprehensive reviews on CaSR signaling [6, 37].

ROLES OF THE CaSR IN TISSUES MAINTAINING Ca^{2+}_o HOMEOSTASIS

Parathyroid

The parathyroid glands express arguably the highest levels of CaSR mRNA and protein in the body (Table 28.2) [38]. Abundant evidence supports the CaSR's key role as the mediator of the high Ca^{2+}_o-induced inhibition of PTH secretion. Through this action, i.e., CaR-mediated stimulation of PTH secretion in response to hypocalcemia, the CaSR in the parathyroid provides a "floor," which the Ca^{2+}_o homeostatic system utilizes to vigorously defend against hypocalcemia. Evidence supporting the CaSR's importance in Ca^{2+}_o-regulated PTH secretion is as follows: First, humans and mice homozygous for genetic inactivation ("knockout") of the CaSR exhibit severely impaired inhibition of PTH release by high Ca^{2+}_o [1, 39]. Second, calcimimetics acutely inhibit PTH secretion *in vivo* and *in vitro* [26], further documenting the CaSR's key role in regulating PTH secretion.

Despite several decades of study, the details of how the CaSR suppresses PTH release remain elusive. Recent evidence demonstrates that activating $G_{q/11}$ is essential, since mice with knockout of both of these G proteins have severe hyperparathyroidism similar to that present in mice homozygous for global knockout of the CaSR [40]. Downstream signaling pathways involved in Ca^{2+}_o-regulated PTH release may include products of the 12- and 15-lipoxygenase pathways of AA metabolism [41] and/or ERK1/2 [6, 37]. Through poorly defined mechanisms downstream of these signaling cascades, the CaSR eventually induces polymerization of the actin-based cytoskeleton, which may represent a physical barrier to the secretion of PTH-containing secretory vesicles [42]. The failure of the high Ca^{2+}_o-evoked, CaSR-mediated increase in Ca^{2+}_i to stimulate exocytosis, as it does in nearly all other secretory cells, may relate to the presence of a Ca^{2+}-insensitive isoform of synaptosomal-associated protein (SNAP-23) that participates in vesicle fusion [37].

Another CaSR-regulated process in parathyroid cells is PTH gene expression, since the calcimimetic CaSR activator, NPS R-568, decreases the elevated level of prepro-PTH mRNA [43]. The CaSR-mediated change in the level of PTH mRNA is the result of a change in preproPTH mRNA stability rather than in PTH gene transcription by a pathway involving stimulation of calmodulin (CaM) and protein phosphatase 2B (for review, see Ref. 44).

Finally, the CaSR suppresses parathyroid cellular proliferation, since individuals homozygous for inactivating CaSR mutations [1] or homozygous CaSR knockout mice [39] exhibit marked parathyroid cellular hyperplasia. Furthermore, treating rats with experimentally induced renal insufficiency with a calcimimetic mitigates the parathyroid hyperplasia that would otherwise occur in this setting [45]. The CaSR-mediated inhibition of parathyroid cellular proliferation is thought to be the result of induction of the cyclin-dependent kinase inhibitor, $p21^{WAF1}$, and downregulation of both the growth factor, TGF-α, and its receptor, the EGFR [46].

C cells

The cloning of the CaSR enabled direct documentation that C cells express the receptor [47]. Studies in CaSR knockout mice subsequently documented the mediatory role of the CaSR in high Ca^{2+}_o-stimulated CT secretion [48]. In contrast to the role of the CaSR in the parathyroid, the receptor in the C cell serves more as a "ceiling" to prevent hypercalcemia. A model for how the CaSR stimulates CT secretion [49] involves CaSR-induced activation of a nonselective cation channel, which causes cellular depolarization, thereby stimulating voltage-dependent calcium channels, elevating Ca^{2+}_i, and activating exocytosis.

Kidney

In the rat kidney, the CaSR resides along nearly the entire nephron [50], although some studies have reported a more limited distribution [51]. The highest levels of expression of the CaSR protein are at the basolateral surface of the cells of the cTAL [50]. This nephron segment plays a key role in PTH-regulated divalent cation reabsorption [52]. The CaSR also has a basolateral localization in the distal convoluted tubule (DCT), where PTH likewise stimulates Ca^{2+} reabsorption. The CaSR also resides at the base of the microvilli of the proximal tubular (PT) brush border, on the basolateral surface of the epithelial cells of the medullary thick ascending limb (mTAL) [50], on the type A (acid-secreting) intercalated cells of the cortical collecting duct (CCD) [50], and on the luminal surface of the inner medullary collecting duct (IMCD) [53]. These last four nephron segments do not participate directly in the regulation of renal Ca^{2+} handling but are sites where the CaSR could potentially modulate the handling of other solutes and/or water.

In the PT, the CaSR suppresses PTH-induced phosphaturia [54] and enhances vitamin D receptor expression [55]. The latter may participate in the direct, high Ca^{2+}_o-elicited lowering of circulating $1,25(OH)_2D_3$ levels, since activation of the vitamin D receptor (VDR) reduces production of $1,25(OH)_2D_3$ and increases production of $24,25(OH)_2D_3$.

The CaSR's location on the basolateral membrane in the cTAL supports its role as the mediator of the known inhibitory action of high peritubular but not luminal Ca^{2+}_o on Ca^{2+} and Mg^{2+} reabsorption in perfused tubular segments from this region of the nephron [54]. The CaSR does so by acting in a "lasix-like" manner to inhibit the overall activity of the Na–K–2Cl cotransporter and associated components of the mechanism by which Ca^{2+} is reabsorbed by the paracellular route in this nephron segment.

This cotransporter contributes to the generation of the lumen-positive, transepithelial potential gradient driving passive paracellular reabsorption of about 50% of NaCl, and most of the Ca^{2+} and Mg^{2+} in cTAL. Others, however, have reported discrepant findings, including high Ca^{2+}_o-induced inhibition of Ca^{2+} transport in CTAL without any concomitant decrease in NaCl or Mg^{2+} transport or reduced paracellular permeability to Ca^{2+} [54a]. Elevated levels of peritubular Ca^{2+}_o have also been reported to inhibit not only paracellular but also transepithelial Ca^{2+} transport (for review, see Ref. 54). Additional studies are needed to resolve these discrepancies. In any event, hypercalcemia-induced hypercalciuria has two distinct CaSR-mediated components: (1) inhibition of PTH release, which then reduces Ca^{2+} reabsorption, and (2) direct suppression of reabsorption of Ca^{2+} in cTAL. The direct inhibitory action of the CaSR on renal tubular Ca^{2+} reabsorption, like CaR-stimulated CT secretion, represents a "ceiling" that defends against hypercalcemia [48].

Recent data indicate that the CaSR enhances Ca^{2+} reabsorption in the DCT by stimulating the activity of the apical uptake channel, TRPV5, which is the influx mechanism for transcellular Ca^{2+} reabsorption in DCT [56]. In addition, extracellular Ca^{2+} increases the expression of key, vitamin D-inducible genes involved in transcellular Ca^{2+} transport in DCT. These include TRPV5, calbindin D_{28K}, the basolateral calcium pump, PMCA1b, and the sodium–calcium exchanger, NCX1 [57]. The contribution of these actions of Ca^{2+}_o to regulating Ca^{2+} transport in DCT under normal circumstances is not presently known. Recent studies have also shown that CaSR-induced stimulation of acid secretion by the type A intercalated cells of the CCD protects against the nephrolithiasis that occurs in hypercalciuric mice with knockout of TRPV5 [58]. The apical CaSR in the IMCD has also been suggested to defend against calcium stone formation by inhibiting vasopressin-stimulated reabsorption of water in IMCD when Ca^{2+}_o in the final urine is high, thereby diluting urinary Ca^{2+} [53].

Intestine

The CaSR is expressed throughout the rat intestine on the basal surface of the small intestinal epithelial cells, within the crypts of the large and small intestines, and in the enteric nervous system [59]. Does the intestinal CaSR contribute to systemic Ca^{2+}_o homeostasis? Ca^{2+}_o modulates several intestinal functions. Hypercalcemia reduces the absorption of dietary Ca^{2+} [60]. Recent studies have also documented apparently direct actions of dietary and/or blood Ca^{2+} on the expression of TRPV6 (the apical uptake channel in intestine that corresponds to TRPV5 in kidney), calbindin D_{9K} and PMCA1b in mice lacking the 1-hydroxylase gene and cannot, therefore, make $1,25(OH)_2D_3$. The increase in the levels of these genes in response to high dietary Ca^{2+} are of uncertain physiological relevance but suggest that the gastrointestinal (GI) tract *per se* has the ability to sense Ca^{2+}_o [57].

As noted earlier, in addition to responding to Ca^{2+}_o, the CaSR is also activated by amino acids [61]. Furthermore, it has recently been proven that the long-recognized but poorly understood stimulation of GI functions such as gastrin and gastric acid secretion [62] in the stomach and cholecystokinin in the small intestine are CaSR-mediated [63]. This likely enables the CaSR to serve as a GI "nutrient sensor," whereby it monitors levels of both minerals and amino acids in the luminal contents so as to make appropriate adjustments in the digestive process [61]. The CaSR in the enteric nervous system, which regulates secretomotor functions of the GI tract, could potentially contribute to the known capacity of hypo- and hypercalcemia to enhance and decrease, respectively, GI motility. Thus the CaSR could also participate as a nutrient sensor in the secretomotor control of GI function. Recent studies have shown that activation of the CaSR in the colon markedly reduces fluid secretion, potentially affording a novel approach to the treatment of diarrheal states, e.g., through the use of a calcimimetic agent [36].

Bone and cartilage

The level of Ca^{2+}_o within the microenvironment of bone fluctuates substantially during osteoclastic bone resorption and osteoblastic bone formation. In fact, Ca^{2+}_o underneath resorbing osteoclasts can be as high as 40 mM [64]. Moreover, Ca^{2+}_o has several actions on bone cells *in vitro* of potential physiological relevance. For instance, high Ca^{2+}_o stimulates the proliferation and chemotaxis of preosteoblasts [65], potentially enhancing their availability at sites of recent bone resorption, promotes their differentiation to mature osteoblasts, and increases their capacity to mineralize bone proteins *in vitro* [66, 67]. In addition, raising Ca^{2+}_o inhibits the activity of osteoclasts *in vitro* [68, 69]. If these actions of Ca^{2+}_o on bone cells take place *in vivo*, increases in Ca^{2+}_o could promote net transfer of Ca^{2+} into bone by enhancing bone formation and inhibiting bone resorption. Are these effects of Ca^{2+}_o mediated by the CaSR?

Some [68, 70, 71] but not all [72] investigators have detected CaSR expression in osteoblast-like and osteoclast-like cells *in vitro* and in bone sections *in vivo*. These CaSR-expressing cells include cells of both the osteoclast and osteoblast lineages. In addition, the use of dominant negative CaSR constructs or calcilytics has documented *in vitro* that the CaSR can mediate the stimulatory effects of high Ca^{2+}_o on important parameters of osteoblast function *in vitro* (i.e., proliferation [73], differentiation, and mineralization of bone [66]). *In vivo*, conditional knockout of the CaSR in cells of the osteoblast lineage produced mice with a runted phenotype that had small poorly mineralized skeletons and died after several weeks, strongly supporting a key biological role for the CaSR in osteoblasts [74].

With regard to cells of the osteoclast lineage, preosteoclast-like cells generated *in vitro* show CaSR expression, and osteoclasts derived from rabbit or mouse

bone also express the receptor [68]. In sections from murine, rat, and bovine bones, however, only a minority of multinucleated osteoclasts expressed CaSR mRNA and protein [71]. *In vivo*, the CaSR seems to play a permissive/stimulatory role in the generation of osteoclasts [68, 75]. It is also necessary to achieve the full calcemic action of PTH *in vivo* in mice [75]. It also exerts inhibitory actions, however, on osteoclast function by mediating the suppressive effects of very high levels of Ca^{2+}_o (5–20 mM) on osteoclast activity and stimulating their apoptosis [68]. It is unclear how the CaSR exerts both stimulatory and inhibitory effects on osteoclast formation/function.

Some cartilage cells in intact bone express CaSR mRNA and protein, including the hypertrophic chondrocytes of the growth plate, which are key participants in the growth of long bones [71]. Raising Ca^{2+}_o dose dependently reduces the levels of the mRNAs that encode important cartilaginous proteins, including aggrecan, the $\propto_1$ chains of types II and X collagen, and alkaline phosphatase, in a chondrocytic cell line (RCJ3.1C5.18 cells) [71]. These actions are likely CaSR mediated, as the use of a CaSR antisense oligonucleotide to lower CaSR expression reversed the action of high Ca^{2+}_o on aggrecan mRNA expression [71]. Recent data have documented that conditional knockout of the CaSR in chondrocytes of mice results in an embryonic lethal phenotype with death before day 14 of embryonic life (E14), confirming an essential role of the CaSR in chondrogenesis [74].

The CaSR in breast and placenta

Expression of the CaSR in the breast increases greatly during lactation in the mouse [76]. The receptor has two functions, relevant to Ca^{2+}_o homeostasis: (1) it promotes transport of calcium from the blood to the milk of the mother, and (2) it inhibits secretion of parathyroid hormone related peptide (PTHrP) by breast epithelial cells into the milk and, probably, into the bloodstream [76]. Thus, when maternal calcium is restricted, PTHrP will be secreted, resulting in more efficient reabsorption of Ca^{2+} by the kidney and release of skeletal Ca^{2+}. The additional Ca^{2+} made available by kidney and bone can then be transported into the milk. Because of the inverse relationship just described between Ca^{2+}_o and PTHrP, the lactating breast can to some extent be viewed as an "accessory" parathyroid gland.

The placenta plays a key role in fetal development by providing adequate quantities of calcium for the developing fetal skeleton, particularly during the third trimester in humans. This takes place by "pumping" calcium transcellularly using the same machinery used in other Ca^{2+}-transporting epithelia, including TRPV6, calbindin D_{9K}, and PMCA. The CaSR in human placenta is expressed in trophoblasts, cytotrophoblasts, and syncytiotrophoblasts [77]. The role of the CaSR in regulating placental Ca^{2+} transport was explored by Kovacs, et al. [78] utilizing mice with the knockout of exon 5 of the CaSR. As expected CaSR–/– fetuses were severely hyperparathyroid, with increased bone resorption and urinary Ca^{2+} excretion. However, placental transport in the CaSR–/– fetuses was significantly less than in both CaSR+/+ and CaSR+/– fetuses [78]. Thus the CaSR normally enhances placental Ca^{2+} transport. This takes place, at least in part, through a PTHrP-dependent pathway, since knocking out PTHrP *in vivo* decreased Ca^{2+} transport to a level similar to that in CaSR–/– fetuses [78]. That is, the CaSR can only stimulate placental Ca^{2+} transport in the presence of PTHrP, which, therefore, is presumably "downstream" of the CaSR.

In addition to the roles that it plays in tissues participating in Ca^{2+}_o homeostasis, the CaSR is expressed in and modulates the functions of numerous other cells uninvolved in mineral ion homeostasis (http://biogps.gnf.org/#goto=genereport&id=846). Examples of the CaSR's roles in some of these tissues can be found in recent reviews [6, 37].

VITAMIN D_3 PRODUCTION

Vitamin D_3 is produced from 7-dehydrocholesterol (7-DHC) (Fig. 29.1). Although irradiation of 7-DHC was known to produce pre-vitamin D_3 (pre-D_3, which subsequently undergoes a temperature-dependent rearrangement of the triene structure to form D_3, lumisterol, and tachysterol), the physiologic regulation of this pathway was not well understood until the studies of Holick et al. [1–3]. They demonstrated that the formation of pre-D_3 under the influence of solar or UVB irradiation (maximal effective wavelength between 290 and 310 μm) is relatively rapid and reaches a maximum within hours. Both the degree of epidermal pigmentation and the intensity of exposure correlate with the time required to achieve this maximal concentration of pre-D_3 but do not alter the maximal level achieved. Although pre-D_3 levels reach a maximum level, the biologically inactive lumisterol and tachysterol accumulate with continued UV exposure. Thus, prolonged exposure to sunlight would not produce toxic amounts of D_3 because of the photoconversion of pre-D_3 to lumisterol and tachysterol. Melanin in the epidermis, by absorbing UV irradiation, can also reduce the effectiveness of sunlight in producing D_3 in the skin. Sunlight exposure increases melanin production and so provides another mechanism by which excess D_3 production can be prevented. As noted, the intensity of UV irradiation is also important for D_3 production and is dependent on latitude. In Edmonton, Canada (52° N) very little D_3 is produced in exposed skin from mid-October to mid-April, while in San Juan (18° N) the skin is able to produce D_3 all year long [4]. Clothing and sunscreen effectively prevent D_3 production in the covered areas.

VITAMIN D METABOLISM

Vitamin D_3 and its plant-derived counterpart vitamin D_2 (collectively referred to as "vitamin D") are by themselves biologically inert for most of their actions. After cutaneous synthesis and transport into the general circulation, vitamin D disappears from the serum within a week [5]. Vitamin D is bound to the serum vitamin D binding protein and ferried in the circulation to sites of storage (mainly fat and muscle) [6] and to the tissues, primarily the liver, where the first step in metabolism occurs, that of conversion to the prohormone 25-hydroxyvitamin D (25OHD; Fig. 29.2). There are a number of cytochrome P450 enzymes capable of converting vitamin D to 25OHD. These enzymes exhibit a high capacity for substrate vitamin D, and release product 25OHD back into the circulation and not into the bile. As such, the serum

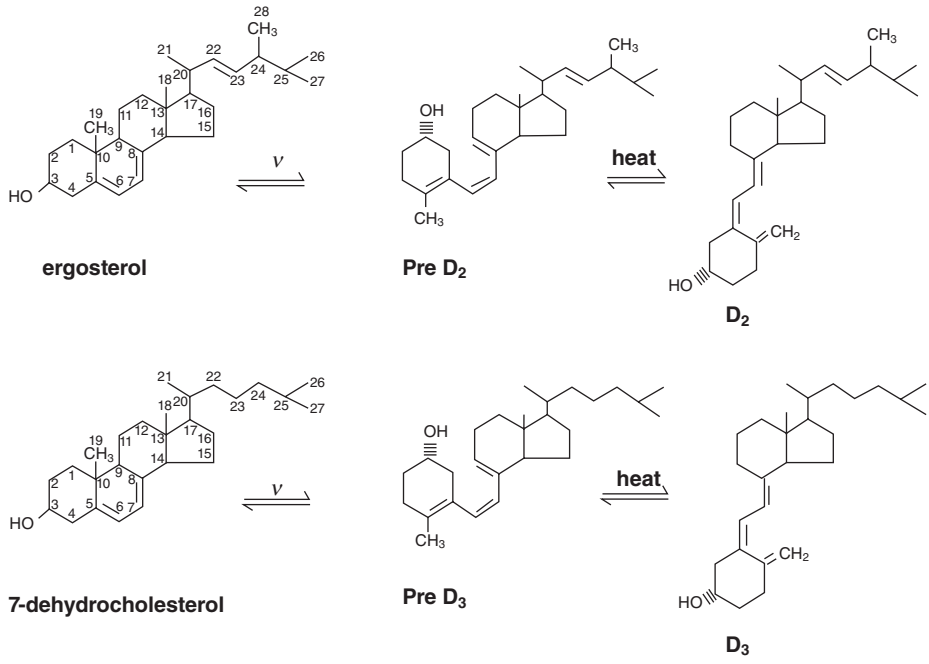

Fig. 29.1. The photolysis of ergosterol and 7-dehydrocholesterol to vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol), respectively. An intermediate is formed after photolysis, which undergoes a thermal-activated isomerization to the final form of vitamin D. The rotation of the A-ring puts the 3β-hydroxyl group into a different orientation with respect to the plane of the A-ring during production of vitamin D.

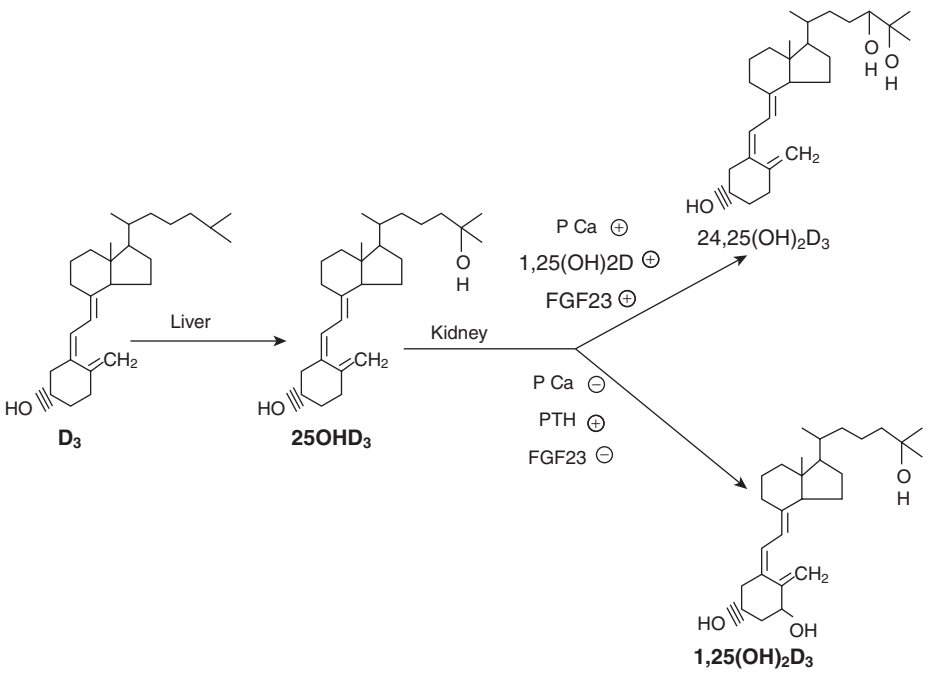

Fig. 29.2. The metabolism of vitamin D. The liver converts vitamin D to 25OHD. The kidney converts 25OHD to 1,25$(OH)_2D_3$ and 24,25$(OH)_2D_3$. Control of metabolism is exerted primarily at the level of the kidney, where low serum phosphorus, low serum calcium, low FGF23, and high parathyroid hormone (PTH) levels favor production of 1,25$(OH)_2D_3$, whereas high serum phosphorus, calcium, FGF23, and 1,25$(OH)_2D_3$ and low PTH favor 24,25$(OH)_2D_3$ production.

25OHD is the most reliable indicator of whether too little or too much vitamin D is entering the host [7]. 25OHD is biologically inert unless present in intoxicating concentrations in the blood owing to the ingestion of large amounts of vitamin D. Otherwise, it must be converted via the CYP27B1 1α-hydroxylase to 1,25-dihydroxyvitamin D (1,25$(OH)_2D$), the specific, naturally occurring ligand for the vitamin D receptor (VDR) (Fig. 29.2). CYP27B1 is a heme-containing, inner mitochondrial membrane-embedded, cytochrome P450 mixed function oxidase requiring molecular oxygen and a source of electrons for biological activity. Although the proximal renal tubular epithelial cell is the richest source of CYP27B1 and responsible for generating the relatively large amounts of 1,25$(OH)_2D$ that are required to achieve the endocrine functions of the hormone in mineral ion

homeostasis, this enzyme is also encountered in a number of extrarenal sites, including immune cells and a variety of normal and malignant epithelia [8], where it functions to provide $1,25(OH)_2D$ for intracrine or paracrine access to the VDR in these and neighboring cells. As discussed below, the VDR has an extraordinarily broad distribution among human tissues. There are four major recognized means of regulating CYP27B1: (1) controlling the availability of substrate 25OHD to the enzyme; (2) controlling the amount of CYP27B1; (3) altering the activity of the enzyme by cofactor availability; and (4) controlling the amount and activity of the alternatively-spliced, catabolic CYP24A, the 24-hydroxylase.

For the kidney, CYP27B1 substrate is provided by the endocytic internalization of filtered, megalin-bound vitamin D binding protein (DBP) carrying 25OHD into the proximal tubular cell from the urinary side of that cell. Regulation of the CYP27B1 in the proximal nephron is principally controlled at the level of transcription with circulating parathyroid hormone and FGF-23 being the major stimulator and inhibitor of CYP27B1 gene expression, respectively (see below). In the kidney, the CYP24A, also a mitochondrial P450, serves not only to limit the amount of $1,25(OH)_2D$, leaving the kidney for distant target tissues by accelerating its catabolism to 1,24, $25(OH)_3D$ but also by shunting available substrate 25OHD away from CYP27B1. In both cases, the 24-hydroxylated products are degraded by the same enzyme to side chain-cleaved, water-soluble catabolites. The CYP24A gene is under stringent transcriptional control by $1,25(OH)_2D$ itself, providing a robust means of proximate, negative feedback regulation of the amount of $1,25(OH)_2D$ made in and released from the kidney [9]. By comparison, the activity of some of the extrarenal, intracrine/paracrine-acting CYP27B1, such as in keratinocytes and disease-activated macrophages, appears to be primarily governed by the availability of extracellular substrate 25OHD to the enzyme, cytokines such as tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ), and toll-like receptor (TLR) activation. In macrophages, excess $1,25(OH)_2D$ may be produced, spilling into the circulation and causing hypercalcemia. It is postulated that this is due to the expression of an amino-terminally truncated splice variant product of the CYP24 gene that cannot be transported into mitochondria [10, 11]. The result is generation of a non-catalytically active enzyme, albeit one that can serve as a cytoplasmic reservoir for the CYP24 substrates, $1,25(OH)_2D$ and 25OHD. Also contrary to the renal CYP27B1, the extrarenal CYP27B1, at least in the macrophage, is (1) immune to control by either PTH or FGF-23 (receptors for these molecules are not expressed to any degree on inflammatory cells); (2) susceptible to induction by TLR ligands shed by microbial agents; and (3) can be upregulated by nontraditional electron donors such as nitric oxide [8]. The CYP27B1 in the keratinocyte, on the other hand, shares features of both the renal and macrophage CYP27B1 in that it is associated with a very active CYP24A, which limits the levels of $1,25(OH)_2D$ in the cell, is stimulated by cytokines such as TNF-α [12] and IFN-γ [13] but not by c-AMP, and is induced by TLR 2 activation [14].

TRANSPORT OF VITAMIN D IN THE BLOOD

In order for the hormone $1,25(OH)_2D$ to reach any of its target tissues, with the exception of the skin where it can be both produced and act locally as just described, vitamin D must be able to escape its synthetic site in the skin or its absorption site in the gut and be transported to tissues expressing one of the vitamin D-25-hydroxylase genes. From there 25OHD must travel to tissue sites expressing the CYP27B1 gene, and the synthesized $1,25(OH)_2D$ must be able to gain access to target tissues containing cells expressing the VDR in order for the genomic actions of the sterol hormone to be realized. The serum vitamin D binding protein (DBP), a member of the albumin family of proteins, is the specific chaperone for vitamin D and its metabolites in the serum [15]. It has a high capacity (less than 5% saturated with vitamin D metabolites in humans) and is bound with high affinity (nM range) by vitamin Ds, particularly the 25-hydroxylated metabolites 25OHD, $24,25(OH)_2D$, and $1,25(OH)_2D$ [16]. DBP is produced mainly in the liver and is freely filterable across the glomerulus into the urine. DBP has a serum half-life of 2.5–3.0 days, indicating that it must be largely reclaimed from the urine once filtered. Reclamation is achieved by DBP being bound by the endocytic, LDL-like co-receptor molecules megalin and cubulin embedded in the plasma membrane of the proximal renal tubular epithelial cell, with eventual transcellular transport and return to the circulation via intracellular vitamin D binding protein (IDBP) chaperones in the heat protein-70 family [17]. Interestingly, $1,25(OH)_2D_3$ infused into the DBP-null mouse is able to reach and act normally in the kidney, gut, and bone, despite failure to detect the infused hormone in the serum [18]. No human, DBP-null homozygote has yet been described suggesting that, unlike the DBP-null mouse, which is both viable and fertile [19], such a human genotype might be embryonically lethal.

INTERNALIZATION OF VITAMIN D METABOLITES

Once bound to DBP and shuttled to sites of metabolism, action, and/or catabolism, vitamin D metabolites must gain access to the interior of their target cell and arrive safely at their intracellular destination (i.e., nucleus for transaction via the VDR, inner mitochondrial membrane for access to the CYP27B1and CYP24A hydroxylases). Although possible, it seems unlikely that simple diffusion of the sterol metabolite off the serum DBP in the extracellular space and subsequent diffusion through the plasma membrane to a specific intracellular destination,

the so-called free hormone hypothesis, can account for the required specificity for targeted metabolite delivery to all cells. For example, as just described for the kidney, there likely exists a plasma-membrane anchored "acceptor" for DBP that acts to concentrate and/or endocytically internalize DBP and its cargo, with intracellular chaperones moving the cargo or metabolite(s) to specific intracellular destinations (e.g., the CYP27B1 and VDR) [20].

MOLECULAR MECHANISM OF ACTION

The mechanism of action of the active form of vitamin D, $1,25(OH)_2D$, is similar to that of other steroid hormones. The intracellular mediator of the $1,25(OH)_2D_3$ function is the VDR. $1,25(OH)_2D$ binds stereospecifically to VDR, which is a high affinity, low capacity intracellular receptor that has extensive homology with other members of the superfamily of nuclear receptors, including receptors for steroid and thyroid hormones. VDR functions as a heterodimer with the retinoid X receptor (RXR) for activation for vitamin D target genes. Once formed, the $1,25(OH)_2D_3$–VDR–RXR heterodimeric complex interacts with specific DNA sequences [vitamin D response elements (VDREs)] in and around target genes resulting in either activation or repression of transcription [21–24]. In general, for activation of transcription, the VDRE consensus consists of two direct repeats of the hexanucleotide sequence GGGTGA separated by three nucleotide pairs. The mechanisms involved in VDR-mediated transcription following binding of the $1,25(OH)_2D$–VDR–RXR heterodimeric complex to DNA are now beginning to be defined. TFIIB, several TATA binding protein associated factors (TAFs) as well as the p160 coactivators, steroid receptor activator-1, 2, and 3 (SRC-1, SRC-2, and SRC-3), that have histone acetylase (HAT) activity, have been reported to be involved in VDR-mediated transcription. In addition to acetylation, methylation also occurs on core histones. Recent studies have indicated that cooperativity between histone methyltransferases and p160 coactivators may also play a fundamental role in VDR-mediated transcriptional activation [25]. VDR-mediated transcription is also mediated by the coactivator complex DRIP (vitamin D receptor interacting protein more generally known as Mediator). This complex does not have HAT activity but rather functions, at least in part, through recruitment of RNA polymerase II [23, 26]. In addition, a number of specific transcription factors including YY1 and CCAAT, enhancer binding proteins β and δ have been reported to modulate VDR-mediated transcription [27–29]. SWI/SNF complexes that remodel chromatin, using the energy of ATP hydrolysis, are also involved in VDR-mediated transcription [30]. It has been suggested that cell- and gene-specific functions of VDR may be mediated through differential recruitment of coactivators. In addition, genome-wide studies of VDR binding sites have indicated that although many of the VDR regulatory regions are located in proximal promoters of target genes, many are also situated many kilobases upstream and downstream and in intronic and exonic sites. VDR binding to these sites has been reported to be largely but not exclusively dependent on activation by $1,25(OH)_2D$ [31]. These genome-wide studies have provided a new perspective on mechanisms involved in the regulation of gene expression by $1,25(OH)_2D$.

REGULATION OF CALCIUM AND PHOSPHATE METABOLISM

The classical actions of $1,25(OH)_2D$ involve its regulation of calcium and phosphate flux across three target tissues: bone, gut, and kidney. The mechanisms by which $1,25(OH)_2D$ operates in these tissues will be described in more detail below. However, the receptor for $1,25(OH)_2D$ (VDR) is widespread and not limited to these classical target tissues. Indeed the list of tissues not containing the VDR is probably shorter than the list of tissues that contain the VDR. Furthermore, as discussed previously, a number of these tissues express CYP27B1 and so can make their own $1,25(OH)_2D$. The biologic significance of these observations is found in the large number of nonclassical actions of active vitamin D metabolites including effects on cellular proliferation and differentiation, regulation of hormone secretion, and immune modulation. Examples of these actions will be discussed below.

With regard to the classical endocrine actions of vitamin D, $1,25(OH)_2D$ acts in concert with two peptide hormones, parathyroid hormone (PTH) and FGF23 (Fig. 29.3). In each case, feed forward and feedback regulatory loops are operative. Parathyroid hormone (PTH) is the major stimulator of $1,25(OH)_2D_3$ production in the kidney. $1,25(OH)_2D_3$ in turn suppresses PTH production directly via a transcriptional mechanism and indirectly by increasing serum calcium levels. The parathyroid gland expresses both VDR and CYP27B1 so the regulation of PTH secretion may involve endogenous as well as exogenous $1,25(OH)_2D$. Calcium acts via the calcium sensing receptor (CaSR) in the parathyroid gland to suppress PTH release. $1,25(OH)_2D$ increases the levels of CaSR in the parathyroid gland just as calcium increases the VDR in the parathyroid gland further enhancing the negative influence of calcium and $1,25(OH)_2D$ on PTH secretion. FGF23, on the other hand, inhibits $1,25(OH)_2D$ production by the kidney while increasing the expression of CYP24A, whereas $1,25(OH)_2D$ stimulates FGF23 production in bone. FGF23 requires klotho (a multifunctional protein involved in phosphate and calcium homeostasis) as a cofactor for FGF23 signaling. $1,25(OH)_2D$ also upregulates klotho and the loss of klotho results in induction of CYP27B1. Klotho-deficient mice and FGF23-deficient mice exhibit homologous phenotypes (including hyperphosphatemia and increased synthesis of $1,25(OH_2D)$, further indicating cooperation of klotho and

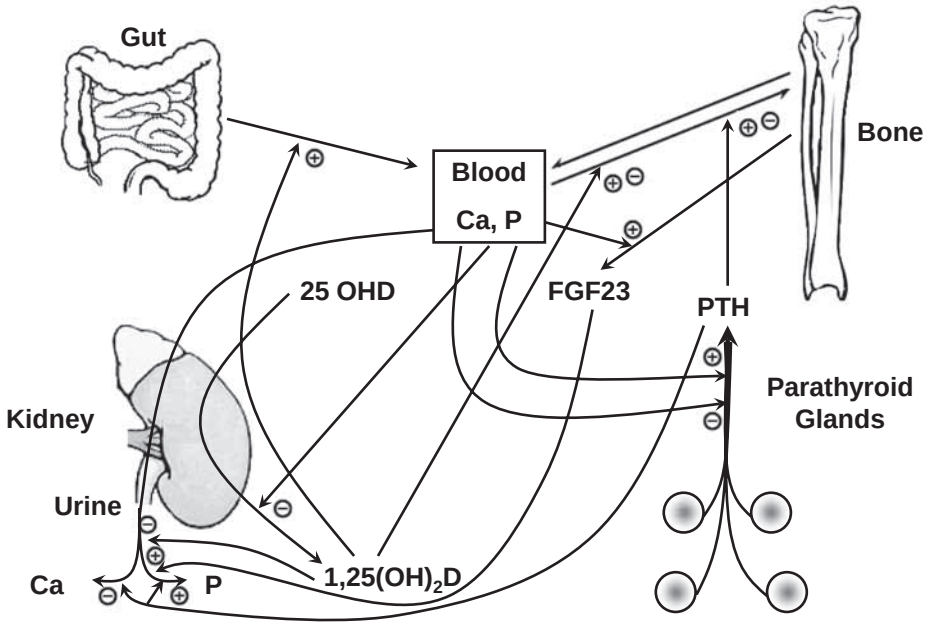

Fig. 29.3. Classical actions: Bone mineral homeostasis mineral feedback loops. $1,25(OH)_2D$ interacts with other hormones, in particular FGF23 and PTH, to regulate calcium and phosphate homeostasis. As noted in the legend to Fig. 29.2, FGF23 inhibits whereas PTH stimulates $1,25(OH)_2D$ production by the kidney. In turn, $1,25(OH)_2D$ inhibits PTH production but stimulates that of FGF23.

FGF23 [32]. Dietary phosphate also regulates FGF23 levels (high phosphate intake stimulates), an effect independent of $1,25(OH)_2D$ as demonstrated by phosphate regulation of FGF23 in the VDR null mouse. Similarly, high phosphate stimulates PTH secretion, an action independent of its inhibitory actions on $1,25(OH)_2D$ production. Whether phosphate has its own receptor, as calcium does, is unclear. FGF23 expression is found in a number of tissues including the parathyroid gland, but its greatest expression is in osteocytes, bone lining cells, and active osteoblasts. Thus, in considering the mechanisms of action of $1,25(OH)_2D$ *in vivo*, the roles of PTH and FGF23 must also be considered along with the minerals they regulate: calcium and phosphate.

CLASSICAL TARGET TISSUES

Bone

Whether $1,25(OH)_2D$ acts directly on bone or mediates its antirachitic effects indirectly by stimulation of intestinal calcium and phosphorus absorption is uncertain. VDR-ablated mice [VDR knockout (KO) mice] develop secondary hyperparathyroidism, hypocalcemia, and rickets after weaning [33, 34]. However, when VDR KO mice are fed a rescue diet containing high levels of calcium, phosphorus, and lactose, serum ionized calcium and PTH levels are normalized, and rickets and osteomalacia are prevented; these results suggest that the major effect of $1,25(OH)_2D_3$ is the provision of calcium and phosphate to bone from the stimulated intestinal absorption of calcium and phosphorous rather than a direct action of $1,25(OH)_2D$ on bone [35]. In addition, transgenic expression of VDR in the intestine of VDR KO mice results in normalization of serum calcium, bone density, and bone volume [36]. However, *in vivo* studies using CYP27B1 KO mice and CYP27B1/VDR double KO mice showed that when hypocalcemia and secondary hyperparathyroidism are prevented by a rescue diet, not all changes in osteoblast number, mineral apposition rate, and bone volume are rescued, suggesting direct skeletal effects of the $1,25(OH)_2D$-VDR system [37]. Studies performed *in vitro* also support a direct effect of $1,25(OH)_2D$ on bone [38]. Osteoblast differentiation and osteoclastogenesis can be stimulated by$1,25(OH)_2D$ [38]. The effect of $1,25(OH)_2D$ on osteoclastogenesis is indirect. VDR is not present in osteoclasts but rather in osteoprogenitor cells, osteoblast precursors, and mature osteoblasts. Stimulation of osteoclast formation by $1,25(OH)_2D$ involves upregulation of receptor activator of nuclear factor-κB ligand (RANKL) by $1,25(OH)_2D$ in osteoblastic cells and requires cell-to-cell contact between osteoblasts and osteoclast precursors [39]. The osteoclastogenesis inhibitory factor, osteoprotegerin (OPG), is a decoy receptor for RANKL that antagonizes RANKL function thus blocking osteoclastogenesis. OPG is downregulated by $1,25(OH)_2D$ [39]. $1,25(OH)_2D$ has also been reported to stimulate the production in osteoblasts of the calcium binding proteins osteocalcin and osteopontin [40, 41]. Runx2, a transcriptional regulator of osteoblast differentiation, is also regulated by $1,25(OH)_2D$ [42]. Transgenic mice overexpressing VDR in osteoblastic cells have increased bone formation, further indicating direct effects of $1,25(OH)_2D$ on bone [43]. Thus, the effects of $1,25(OH)_2D$ on bone are diverse and can affect formation or resorption.

Intestine

When the demand for calcium increases as a result of increased requirement associated with growth, pregnancy or lactation, $1,25(OH)_2D$ synthesis increases the efficiency of intestinal calcium absorption. In VDR KO mice, a major defect is in intestinal calcium absorption, suggesting that a principal action of $1,25(OH)_2D_3$ to maintain calcium homeostasis is increased intestinal calcium absorption [35]. It is thought that intestinal calcium absorption comprises two different modes of calcium transport: the saturable process, which is mainly transcellular, and a diffusional mode, which is nonsaturating. The latter requires a lumenal free calcium concentration greater than 2–6 mM and is paracellular (i.e., between neighboring intestinal epithelial cells). In the paracellular pathway, the movement of calcium is across tight junctions and intercellular spaces and is directly related to the concentration of calcium in the intestinal lumen. The saturable component of intestinal calcium absorption is observed predominantly in the duodenum. The diffusional, nonsaturable process is observed all along the intestine (duodenum, jejunum, ileum, and colon). $1,25(OH)_2D$ has been reported to affect both the transcellular and the paracellular path [44–46]. The transcellular process comprises three $1,25(OH)_2D$-regulated steps: the entry of calcium across the brush border membrane, intracellular diffusion, and the energy requiring extrusion of calcium across the basolateral membrane [44–46]. It is thought that the calcium binding protein, calbindin, which is induced by $1,25(OH)_2D$ in the intestine, acts to facilitate the diffusion of calcium through the cell interior toward the basolateral membrane. Interestingly, recent studies in calbindin-D_{9k} null mutant mice showed no change in $1,25(OH)_2D_3$-mediated intestinal calcium absorption and in serum calcium levels compared to wild-type mice [47, 48]. This observation provides evidence that calbindin alone is not responsible for $1,25(OH)_2D$-mediated intestinal calcium absorption.

Calcium extrusion from the enterocyte is also affected by $1,25(OH)_2D$. The plasma membrane calcium pump (PMCA) has been reported to be stimulated by $1,25(OH)_2D$, suggesting that intestinal calcium absorption may involve a direct effect of $1,25(OH)_2D$ on calcium pump expression [45]. The rate of calcium entry into the enterocyte is also increased by $1,25(OH)_2D$. Recently, a calcium selective channel, TRPV6, which is colocalized with calbindin and is induced by $1,25(OH)_2D$, was cloned from rat duodenum [49, 50]. It has been suggested that TRPV6 plays a key role in vitamin D dependent calcium entry into the enterocyte. Since studies in calbindin-D_{9k}/TRPV6 double KO mice have shown that intestinal calcium absorption in response to low dietary calcium or to $1,25(OH)_2D$ is least efficient in the absence of both proteins, calbindin-D_{9k} and TRPV6 may act together to affect calcium absorption [51]. It is possible that calbindin is not a facilitator of calcium diffusion (thus challenging the traditional model of vitamin D mediated transcellular calcium absorption) but acts rather as a modulator of calcium influx via TRPV6.

In addition to intestinal calcium absorption, $1,25(OH)_2D$ also acts to enhance intestinal phosphorus absorption. Although the mechanisms involved have been a matter of debate, it has been suggested that FGF23 and $1,25(OH)_2D$ stimulate the active transport of phosphorus [52, 53].

Kidney

A third target tissue involved in $1,25(OH)_2D$-mediated mineral homeostasis is the kidney. It has been reported that $1,25(OH)_2D$ enhances the actions of PTH on calcium transport in the distal tubule, at least in part, by increasing the PTH receptor mRNA and binding activity in distal tubule cells [54]. $1,25(OH)_2D$ also induces the synthesis of the calbindins in the distal tubules [44]. It has been suggested that calbindin-D_{28k} stimulates the high affinity calcium transport system in the distal luminal membrane, and calbindin-D_{9k} enhances the adenosine triphosphate (ATP)-dependent calcium transport of the basolateral membrane [44]. Similar to studies in the intestine, an apical calcium channel, TRPV5, which is colocalized with the calbindins and induced by $1,25(OH)_2D$, has been identified in the distal convoluted tubule and distal connecting tubules [49]. Calbindin-D_{28k} was reported to associate directly with TRPV5 and to control TRPV5 mediated calcium influx [55]. Thus, $1,25(OH)_2D$ affects calcium transport in the distal tubule by enhancing the action of PTH and by inducing TRPV5 and the calbindins. Another important effect of $1,25(OH)_2D$ in the kidney is the inhibition of the CYP27B1 and the induction of the CYP24 [56]. Besides calcium transport in the distal nephron and modulation of CYP27B1 and CYP24A, effects of $1,25(OH)_2D$ on sodium phosphate transporter b (NPTB)-mediated phosphate reabsorption in the proximal tubule have been suggested [57]. Depending on the parathyroid status and on experimental conditions, $1,25(OH)_2D$ has been reported to increase or decrease renal phosphate reabsorption.

NONCLASSICAL TARGET TISSUES

Parathyroid glands

The parathyroid glands (PTGs) are an important target of $1,25(OH)_2D$. As discussed previously, $1,25(OH)_2D$ inhibits the synthesis and secretion of PTH and prevents the proliferation of parathyroid-producing cells in the gland in order to maintain normal parathyroid status [58, 59]. It has also been shown that $1,25(OH)_2D$ upregulates calcium sensing receptor (CaSR) transcription [60], suggesting that $1,25(OH)_2D$ sensitizes the PTG to calcium inhibition. In addition to containing the VDR, the PTGs also express CYP27B1; as such, local production of

$1,25(OH)_2D$, as well as circulating $1,25(OH)_2D$, may contribute to PTH production and secretion.

Pancreas

The pancreas was one of the first nonclassical target tissues in which receptors for $1,25(OH)_2D$ were identified [61]. Although $1,25(OH)_2D$ has been reported to play a role in insulin secretion, the exact mechanisms remain unclear. Autoradiographic data and immunocytochemical studies have localized the VDR and calbindin-D_{28k}, respectively, in pancreatic beta cells [62, 63]. Studies using calbindin-D_{28k} null mutant mice have indicated that calbindin-D_{28k}, by regulating intracellular calcium, can modulate depolarization-stimulated insulin release [64]. In addition to modulating insulin release, calbindin-D_{28k}, by buffering calcium, can protect against cytokine-mediated destruction of beta cells [65]. These findings have important therapeutic implications for type 1 diabetes and the prevention of cytokine destruction of pancreatic beta cells as well as for type 2 diabetes and the potentiation of insulin secretion.

IMMUNOBIOLOGY OF VITAMIN D

Nonclassical regulation of immune responses by $1,25(OH)_2D$ was first reported nearly 30 years ago with the discovery of the presence of the VDR in activated human inflammatory cells [66] and the ability of disease-activated macrophages to make $1,25\text{-}(OH)_2D$ [67]. Recent studies have shown that $1,25(OH)_2D$ regulates both innate and adaptive immunity, but in opposite directions, namely promoting the former while repressing the latter.

Vitamin D and innate immunity

Innate immunity encompasses the ability of the host immune system to recognize and respond to an offending antigen. In 1986, Rook and colleagues described studies using cultured human macrophages in which they showed that $1,25(OH)_2D$ can inhibit the growth of *Mycobacterium tuberculosis* (*M.tb.*) [68]. Although this seminal report was widely cited, it is only in the last few years that more comprehensive appraisals of the antimicrobial effects of vitamin D metabolites have been published. *In silico* screening of the human genome revealed the presence of a vitamin D response element in the promoter of the human gene for cathelicidin, whose product LL37 is an antimicrobial peptide capable of killing bacteria [69]. Subsequent investigations confirmed the ability of $1,25(OH)_2D$ [70] and its precursor 25OHD [71] to induce expression of cathelicidin in cells of the monocyte/macrophage and epidermal lineage, respectively, highlighting the potential for intracrine/autocrine induction of antimicrobial responses in cells that also express the 25OHD-activating enzyme, CYP27B1. Although detectable in many cell types, functionally significant expression and activity of CYP27B1 appears to be dependent on cell-specific stimulation of a broad spectrum of immune surveillance proteins, the Toll-like receptors (TLRs). The TLRs are an extended family of noncatalytic, host cell transmembrane pattern-recognition receptors (PRRs) that interact with specific pathogen-associated membrane patterns or PAMPs shed by infectious agents and trigger the innate immune response in the host [72].

In this regard, Liu and colleagues [73] recently used DNA array to characterize changes in gene expression following activation of the human macrophage TLR2/1 dimer by one of the PAMPs for *M. tb.* Macrophages, but not dendritic cells, so treated showed increased expression of both CYP27B1 and VDR genes and gene products, and demonstrated intracrine induction of the antimicrobial cathelicidin gene with subsequent mycobacterial killing in response to 25OHD as well as $1,25(OH)_2D$. In fact, microbial killing was more efficiently achieved with the pro-hormone 25OHD than with $1,25(OH)_2D$ at similar extracellular concentrations, indicating that the robustness of the human innate response to microbial challenge is dependent upon the serum 25OHD status of the host. This concept was confirmed in these studies by the ability of 25OHD-sufficient serum to rescue a deficient, cathelicidin-driven antimicrobial response in human macrophages conditioned in vitamin D-deficient serum [74]. A similar vitamin D-directed antimicrobial generating capacity has been recently observed in wounded skin [14], suggesting that TLR-driven expression of cathelicidin, requiring the intracellular synthesis and genomic action of $1,25(OH)_2D$, is a common response feature to infectious agent invasion. While clinical evidence in support of this notion is beginning to accumulate [75], the utility of vitamin D or 25OHD as adjuvant therapy to boost the human innate immune response in a therapeutic or preventive sense needs more in depth, prospective investigation in humans. Reinforcing these events is the ability of locally generated $1,25(OH)_2D$ to escape the confines of the cell in which it is made to act on neighboring, VDR-expressing monocytes to promote their maturation to mature macrophages [76], thus acting as a feed-forward signal to further enhance the innate immune response.

Vitamin D and the adaptive immune response

The adaptive immune response is generally defined by T and B lymphocytes and their ability to produce cytokines and immunoglobulins, respectively, to specifically combat the source of the antigen presented to them by cells (i.e., macrophages, dendritic cells, etc.) of the innate immune response. As previously noted [66], the presence of VDR in activated, but not resting, human T and B

lymphocytes was the first observation implicating these cells as targets for the noncalciotropic responses to $1,25(OH)_2D$. Contrary to the role of locally produced $1,25(OH)_2D$ to promote the innate immune response, the hormone exerts a generalized dampening effect on lymphocyte function. With respect to B cells, $1,25(OH)_2D$ suppresses proliferation and immunoglobulin production and retards the differentiation of B-lymphocyte precursors to mature plasma cells. With regard to T cells, $1,25(OH)_2D$, acting through the VDR, inhibits the proliferation of pro-inflammatory interferon *gamma*-elaborating, macrophage-stimulating Th(helper)1 and chemokine-producing Th17 cells [77]. A much less robust antiproliferative effect of $1,25(OH)_2D$ is exerted on immunosuppressive Th2 and regulatory T cells (Tregs) [78], promoting their accumulation at sites of inflammation by stimulating expression of the dendritic cell-derived T cell homing molecule, CCL22 [79]. In fact, it is this generalized ability of $1,25(OH)_2D$ to quell the adaptive immune response that has prompted the use of the hormone and its analogues in the adjuvant treatment of inflammatory and neoplastic disorders.

In sum, the collective, concerted action of $1,25(OH)_2D$ is to promote the host's response to an invading pathogen while simultaneously acting to limit what might be an overzealous immune response to that pathogen, representative of the process of tolerance. Once again, a good example is that of infection with the intracellular pathogen *M. t.b.* In this case, the pathogen evokes an exceptionally robust innate immune response that is fueled by the endogenous production of $1,25(OH)_2D$ by macrophages at the site of host invasion. If substantial amounts of $1,25(OH)_2D$ escape the confines of the macrophage, then the immunostimulation of VDR-expressing, activated lymphocytes in that environment is quelled by $1,25(OH)_2D$. If the innate immune response is extreme and enough $1,25(OH)_2D$ finds its way into the general circulation, as may occur in human granuloma-forming disorders like sarcoidosis and tuberculosis, an endocrine effect of the hormone, most notably hypercalciuria and hypercalcemia, can be observed.

KERATINOCYTE FUNCTION IN EPIDERMIS AND HAIR FOLLICLES

$1,25(OH)_2D$-regulated epidermal differentiation

Locally produced $1,25(OH)_2D$ is likely to be an autocrine or paracrine factor for epidermal differentiation since it is produced in the keratinocyte by the same enzyme, CYP27B1, as found in the kidney; under normal circumstances keratinocyte production of $1,25(OH)_2D$ does not appear to be substantial enough to contribute to circulating levels of the hormone [80]. The concentration of VDR and the production of $1,25(OH)_2D$ in the skin decrease with differentiation. Stimulation of differentiation is accompanied by the rise in mRNA and protein levels of involucrin and transglutaminase [81] as well as the late differentiation markers filaggrin and loricrin [82] with promotion of an intact barrier. The mechanisms by which $1,25(OH)_2D$ alters keratinocyte differentiation are multiple and include induction of the CaSR enhancing the effects of calcium on differentiation and induction of the phospholipase C family, which provides second messengers such as diacyl glycerol and inositol tris phosphate to the differentiation process. Although the most striking feature of the VDR-null mouse is the development of alopecia (also found in many but not all patients with mutations in the VDR), these mice also exhibit a defect in epidermal differentiation as shown by reduced levels of involucrin and loricrin, loss of keratohyalin granules, loss of the calcium gradient, and disruption of lamellar body production and secretion resulting in defective barrier function. Furthermore, both VDR and $1,25(OH)_2D$ production are required for normal antimicrobial peptide expression in response to epidermal injury and infections [14].

VDR regulation of hair follicle cycling

As noted above, alopecia is a well-known part of the phenotype of many patients with mutations in their VDR [83]. Vitamin D deficiency or lack of CYP27B1 *per se* is not associated with alopecia, and the alopecia can be rescued with mutants of VDR that fail to bind $1,25(OH)_2D$ or its coactivators [84]. Recent attention has been paid to both hairless (Hr), a putative transcription factor capable of binding the VDR and suppressing at least its ligand dependent transcriptional activity, and β-catenin, which, like Hr, binds to the VDR and may regulate its transcriptional activity (or vice versa). Hr mutations in both mice and humans and transcriptionally inactivating β-catenin mutations in mice result in phenocopies of the VDR-null animal with regard to the morphologic changes observed in hair cycling. In these models the abnormality leading to alopecia develops during catagen at the end of the developmental cycle, precluding the reinitiation of anagen. Both VDR-null mice and those with disrupted wnt signaling lose stem cells from the bulge, perhaps as a result of the loss of the interaction of the bulge with the dermal papilla [85, 86]. Thus, although the mechanism by which the VDR controls hair follicle cycling is not established, hair follicle cycling represents the best example by which the VDR regulates a physiologic process that is independent of its ligand, $1,25(OH)_2D$ and so points to a novel mechanism of action for this transcriptional regulator.

NUTRITIONAL CONSIDERATIONS

Defining vitamin D sufficiency

Serum 25OHD levels provide a useful surrogate for assessing vitamin D status, as the conversion of vitamin D to 25OHD is less well controlled (i.e., primarily substrate dependent) than the subsequent conversion of

25OHD to $1,25(OH)_2D$. Levels of $1,25(OH)_2D$, unlike 25OHD levels, are well maintained until vitamin D deficiency reaches extremes because of the secondary hyperparathyroidism and so do not provide a useful index for assessing vitamin D deficiency, at least in the initial stages. Historically, vitamin D sufficiency was defined as the level of 25OHD sufficient to prevent rickets in children and osteomalacia in adults. Levels of 25OHD below 5 ng/ml (or 12 nM) are associated with a high prevalence of rickets or osteomalacia. However, there is a growing consensus that these lower limits of normal are too low. Recently, an expert panel for the Institute of Medicine (IOM) recommended that a level of 20 ng/ml (50 nM) was sufficient for 97.5% of the population, although up to 50 ng/ml (125 nM) was safe [87]. For individuals between the ages of 1 and 70 years old, 600 IU vitamin D was thought to be sufficient to meet these goals, although up to 4,000 IU vitamin D was considered safe [87]. These recommendations are based primarily on data from randomized, placebo-controlled clinical trials (RCTs) that evaluated falls and fractures; data supporting the nonskeletal effects of vitamin D were considered too preliminary to be used in their recommendations, because of the lack of RCTs for these other actions. The lower end of these recommendations has been considered too low and the upper end too restrictive by a number of vitamin D experts, but the call for better clinical data especially for the nonskeletal actions is well taken. These guidelines, at least with respect to the lower recommended levels of vitamin D supplementation, are unlikely to correct vitamin D deficiency in individuals with obesity, dark complexions, limited capacity for sunlight exposure, or malabsorption. Furthermore, a large body of data from animal and cell studies as well and epidemiologic associations supports a large range of beneficial actions of vitamin D; as a consequence, adequate RCT data in these areas may eventually alter these IOM recommendations for nonskeletal benefits of vitamin D supplementation.

Impact on the musculoskeletal system

This rethinking of the definition of vitamin D sufficiency comes from the appreciation that vitamin D affects a large number of physiologic functions in addition to bone mineralization. The levels of 25OHD are inversely proportional to PTH levels such that PTH levels increase at levels of 25OHD below 20–30 ng/ml. Intestinal calcium transport has been reported to increase significantly when the 25OHD levels are increased from 20 to 32 ng/ml. Large epidemiologic surveys demonstrate a positive correlation between 25OHD levels and bone mineral density, with no evidence for a plateau below 30 ng/ml, and vitamin D (with calcium supplementation) showed improvement in bone mineral density (BMD) in older individuals. Similarly, a positive association between 25OHD levels and muscle function (e.g., walking speed, sit-to-stand) has been demonstrated, even over the interval of 20–38 ng/ml, although the correlation is strongest at lower levels. Vitamin D supplementation with at least 800 IU improved lower extremity function, decreased body sway, and reduced falls. Most importantly, adequate levels of vitamin D and calcium supplementation prevent fractures [88, 89].

Impact beyond the musculoskeletal system

The impact of vitamin D extends beyond the musculoskeletal system and the regulation of calcium homeostasis. Vitamin D deficiency is a well-known accompaniment of various infectious diseases such as tuberculosis, and $1,25(OH)_2D$ has long been recognized to potentiate the killing of mycobacteria by monocytes. The nutritional aspect of these observations has recently been illuminated by the observation that the monocyte, when activated by mycobacterial lipopeptides, expresses CYP27B1, producing $1,25(OH)_2D$ from circulating 25OHD, and in turn inducing cathelicidin, an antimicrobial peptide that enhances killing of the mycobacterium. Inadequate 25OHD levels abort this process [73]. Vitamin D deficiency and/or living at higher latitudes (with less sunlight) is associated with a number of autoimmune diseases including type 1 diabetes mellitus, multiple sclerosis, and Crohn's disease [90]. Levels of 25OHD are also inversely associated with type 2 diabetes mellitus and metabolic syndrome, and some studies have shown that vitamin D and calcium supplementation may prevent the progression to diabetes mellitus in individuals with glucose intolerance. Improvements in both insulin secretion and action have been observed with vitamin D supplementation. The potential to prevent certain cancers may be the most compelling reason for adequate vitamin D nutrition. A large body of epidemiologic data exists documenting the inverse correlation of 25OHD levels, latitude, and/or vitamin D intake with cancer incidence [7]. Although numerous types of cancers show reduction [91], most attention has been paid to breast, colon, and prostate. A relatively small prospective 4-year trial with 1,100 IU vitamin D and 1,400–1,500 mg calcium showed a 77% reduction in cancers after the first year of study [92], including a reduction in both breast and colon cancers. In this study, vitamin D supplementation raised the 25OHD levels from a mean of 28.8 ng/ml to 38.4 ng/ml with no changes in the placebo or calcium only arms of the study. However, other trials with vitamin D metabolites or analogs for cancer prevention or treatment have yielded less promising results.

VITAMIN D TREATMENT STRATEGIES

Adequate sunlight exposure is the most cost effective means of obtaining vitamin D. Whole body exposure to sunlight has been calculated to provide the equivalent of 10,000 IU vitamin D_3 [93]. A 0.5 minimal erythema dose of sunlight (i.e., half the dose required to produce a slight reddening of the skin) or UVB radiation to the arms and legs, which can be achieved in 5–10 min on a bright summer day in light-skinned individuals, has been

calculated to be the equivalent of 3,000 IU vitamin D_3 [7]. However, concerns regarding the association between sunlight and skin cancer and/or solar aging of the skin have limited this approach, perhaps to the extreme, although it remains a viable option for those unable or unwilling to benefit from oral supplementation. Studies have demonstrated that on average for every 100 IU of a vitamin D_3 supplementation administered, the 25OHD levels rise by 0.5–1 ng/ml [93, 94]. For obese individuals or those with malabsorption (including after bariatric surgery) much higher doses are likely to be required. A number of studies suggest that 700–800 IU is the lower limit of vitamin D supplementation required to prevent fractures and falls, although as noted, the IOM has concluded that 600 IU suffices. Unfortified food contains little vitamin D with the exception of wild salmon and other fish products such as cod liver oil. Milk and other fortified beverages typically contain 100 IU/8 oz. serving. Vitamin D_2 does not appear to increase or sustain the 25OHD levels as well as vitamin D_3 in part because it is more rapidly cleared. Therefore, if vitamin D_2 is used, it needs to be given at least weekly. Toxicity due to vitamin D supplementation has not been observed at doses less than 10,000 IU per day in several studies, although the IOM report indicates that the upper limit should be restricted to 4000 IU at least in the general population. [95].

INTRODUCTION

Dual-energy X-ray absorptiometry (DXA) scanners were first introduced in the late 1980s, and DXA is now established as the most widely used method for measuring bone mineral density (BMD) [1]. An important reason for this choice is the consensus that DXA results in postmenopausal women and older men should be interpreted using the World Health Organization (WHO) T-score definition of osteoporosis of a spine, femoral neck, or total hip BMD measurement 2.5 standard deviations (SD) or more below the population mean for healthy young adults [2–5]. Other advantages of DXA include its excellent precision, low ionizing radiation dose and short scan times (Table 30.1) [6]. With the recent introduction of the WHO Fracture Risk Assessment Tool (FRAX), DXA measurements of femoral neck BMD have acquired an important role in estimating patients' 10-year risk of hip or major osteoporotic fracture [7]. DXA also has some important limitations (Table 30.1). Because DXA scans are two-dimensional (2D) projection images, they measure areal BMD (BMD_a, units g/cm^2) and the results are dependent on bone size. This is a particular problem for interpreting results in children [8] but may also explain some of the racial and gender differences in BMD_a values between adults [9]. Another limitation is that the algorithms used to convert X-ray transmission measurements into BMD_a assume that soft tissue is homogeneous in composition. In reality soft tissue is a heterogeneous mixture of lean and adipose tissue, and this is a source of measurement error [10]. As a result of these and other factors there is often significant discordance in scan findings when T-score results from different BMD_a measurement sites are compared [11, 12].

TECHNICAL ASPECTS

DXA scanners measure the attenuation through the body of X-ray beams with two different photon energies [13]. They use the principle of basis set decomposition to resolve these measurements into the areal densities of two chosen reference materials, which, if present, would give the same transmission factors for the two beams [14]. One of these reference materials is bone mineral [hydroxyapatite, $Ca_5(PO_4)_3OH$], while the second is soft tissue with a composition defined by a reference area adjacent to the bone region of interest (ROI). A DXA scan is a set of point-by-point measurements of BMD_a across the chosen anatomical site. Edge detection software is used to find the bone outline, and the pixels inside the

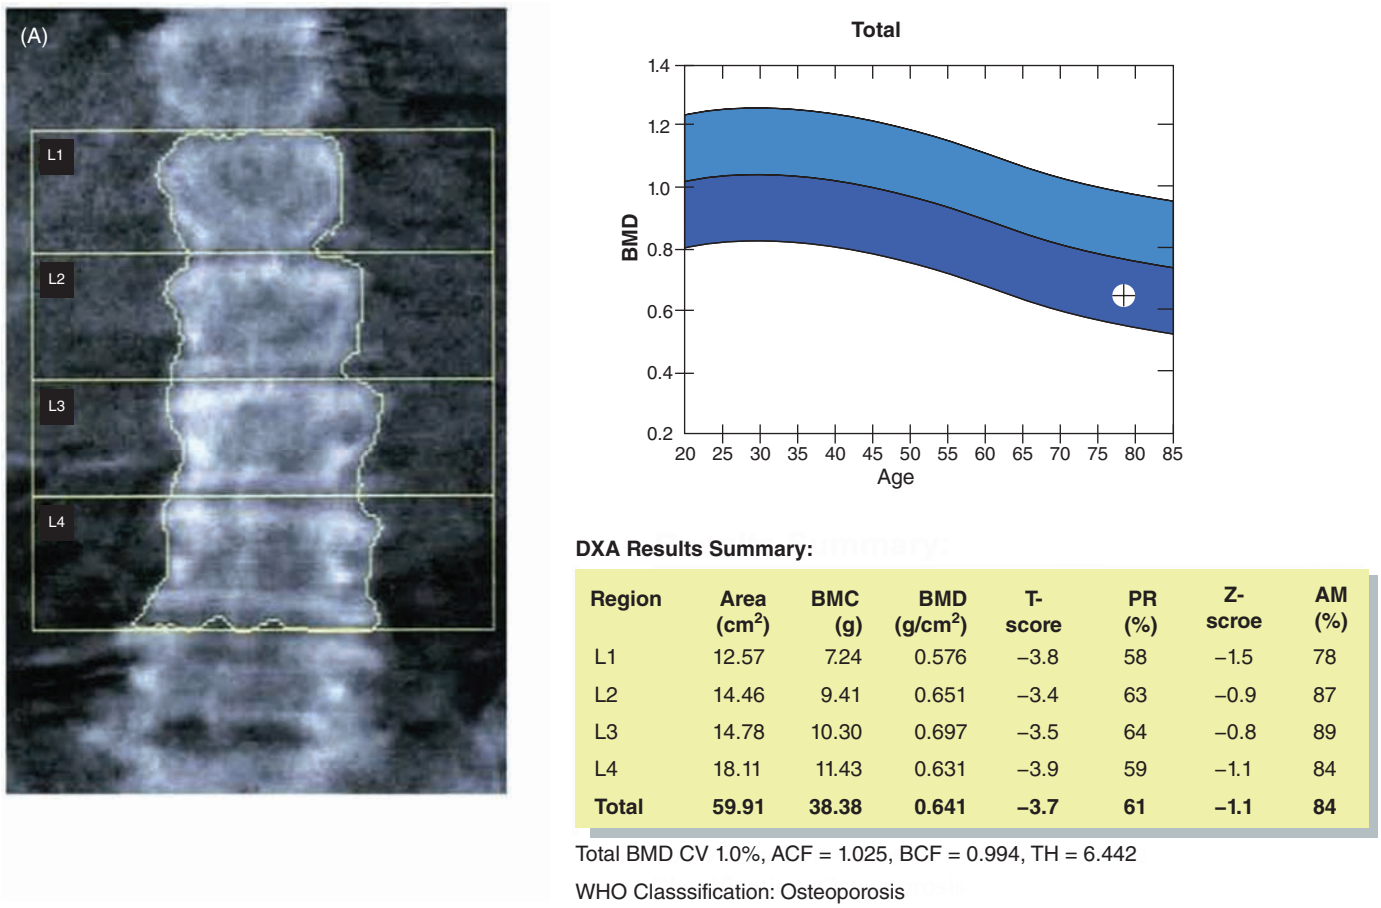
Table 30.1. Advantages and Limitations of Central DXA

Advantages
Consensus that BMD_a results can be interpreted using T-scores
Proven ability to predict fracture risk
Used in FRAX algorithm for predicting 10-year fracture risk
Proven for effective targeting of anti-fracture treatments
Good precision
Effective at monitoring response to treatment
Widely available
Stable calibration
Effective instrument quality control procedures
Short scan times
Rapid patient set up
Low ionizing radiation dose
Reliable reference ranges
Limitations
2D projection measurement affected by bone size and shape
Measurement errors caused by heterogeneity in soft tissue composition
Discordant findings between different measurement sites
Degenerative disease affects spine BMD_a in older patients
Measurements for fracture and non-fracture populations overlap
Will not differentiate low bone calcium that is due to osteomalacia or osteoporosis

bone edges are summed to find the bone area (BA; cm^2). The BMD_a result reported on the scan printout is the average BMD_a measurement within the BA. Finally, BMD_a is multiplied by BA to find the bone mineral content (BMC; g), equal to the total mass of hydroxyapatite within the bone ROI. The original DXA scanners used a pencil beam of X-rays with a single detector that scanned in a rectilinear fashion across the anatomical site with scan times of 5–10 minutes. Subsequently, fan-beam machines were introduced with an array of detectors, which resulted in shorter scan times of less than 1 minute per site and improved image quality. The radiation dose from DXA examinations is extremely low, and for a spine and hip examination is in the range of 1–10 µSv, a figure that is less than or comparable to the daily dose from natural background radiation (2.5 mSv/yr = 7 µSv/day) [15]. If adult scan modes are used for children the doses are slightly higher [16].

The accuracy error in a DXA measurement differs from patient to patient and reflects the heterogeneous distribution of adipose tissue including marrow fat at the scan site, which is different for every individual [10, 17, 18]. Precision errors (typically 1% to 2% [19]) are smaller than accuracy errors (typically 3% to 7% [10]) because when a patient is rescanned, the effect of adipose tissue on the measurement is the same. Accuracy errors are best determined by cadaver studies involving *in situ* scanning followed by ashing of bone samples to find the true mass of bone mineral [17]. Accuracy errors can also be estimated from computed tomography (CT) or magnetic resonance (MR) imaging of adipose tissue [18, 20]. It has been claimed that the accuracy errors of DXA are so large that they make the results too unreliable to be of any use [21, 22]. However, these studies were based on phantom measurements [21] that overestimated the true errors [20]. They also discount the overwhelming evidence from epidemiological studies that DXA predicts fracture risk [23–26]. Although DXA measurements are affected by accuracy errors, it should be remembered that similar questions have been raised about the accuracy of such basic clinical measurements as blood pressure and body temperature [27–30].

SCAN SITES



DXA is primarily used to scan the central skeleton to measure BMD_a of the lumbar spine and hip (Fig. 30.1) [1]. Central DXA examinations have three main roles: (1) the diagnosis of osteoporosis, (2) assessment of patients' risk of fracture, and (3) monitoring response to treatment [6]. The reasons for choosing to measure the spine and hip include the fact that the hip is the most reliable measurement site for predicting hip fracture risk [23, 24], the use of femoral neck T-score in the FRAX scheme [7], the use of spine BMD_a for monitoring treatment [31], and the consensus that osteoporosis and low bone mass (previously referred to as osteopenia) in postmenopausal women can be determined from spine and hip DXA measurements interpreted using the WHO T-score definitions of osteoporosis and low bone mass [3–5].

T-scores are calculated by taking the difference between a patient's measured BMD_a and the mean BMD_a in healthy young adults matched for gender and ethnicity, and expressing the difference relative to the young adult population SD:

$$\text{T-score} = \frac{\text{Measured BMDa} - \text{Young adult mean BMDa}}{\text{Young adult population SD}} \quad \text{(Eq. 30.1)}$$

A T-score measurement of less than or equal to –2.5 at the spine, femoral neck, or total hip sites is taken to indicate osteoporosis [3, 4]. Measurements between –2.5 and –1.0 are interpreted as showing low bone mass, while those greater than –1.0 at all three sites are classified as normal.

Manufacturers' scan printouts also report Z-scores, which are similar to T-scores except that instead of comparing the patient's BMD_a with the young adult mean it is compared with the mean BMD_a for a healthy subject matched for age, gender and ethnicity:

Region	Area (cm^2)	BMC (g)	BMD (g/cm^2)	T-score	PR (%)	Z-scroe	AM (%)
L1	12.57	7.24	0.576	–3.8	58	–1.5	78
L2	14.46	9.41	0.651	–3.4	63	–0.9	87
L3	14.78	10.30	0.697	–3.5	64	–0.8	89
L4	18.11	11.43	0.631	–3.9	59	–1.1	84
Total	**59.91**	**38.38**	**0.641**	**–3.7**	**61**	**–1.1**	**84**

Total BMD CV 1.0%, ACF = 1.025, BCF = 0.994, TH = 6.442

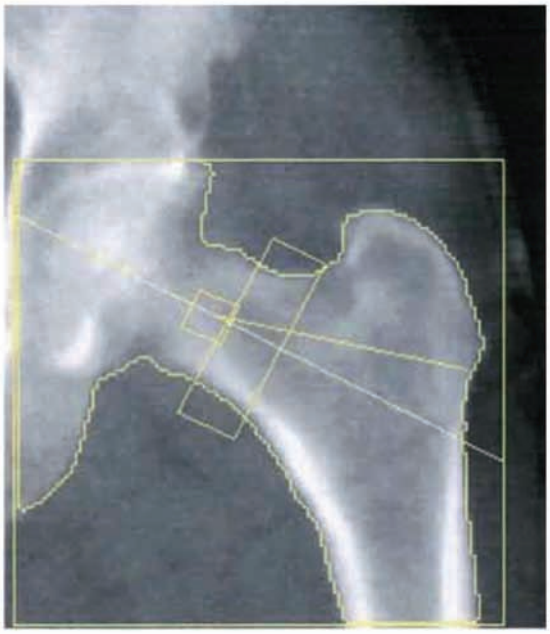
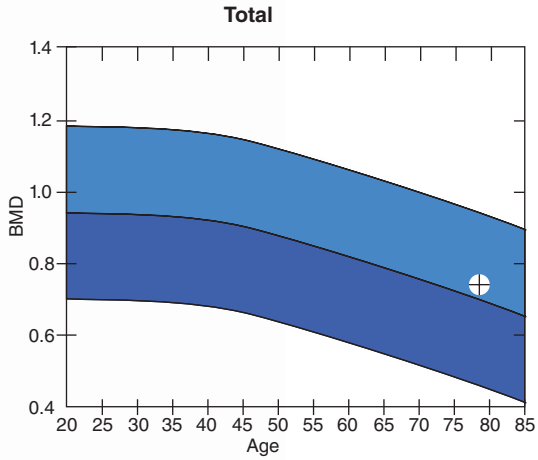
The printout shows: (left) scan image of the lumbar spine; (top right) patient's age and BMD plotted with respect to the manufacturer's reference range; (bottom right) BMD figures for individual vertebrae and total spine (L1-L4), together with the interpretation in terms of T-scores and Z-scores. (*Continued on next page.*)

$$\text{Z-score} = \frac{\text{Measured BMDa} - \text{Age matched mean BMDa}}{\text{Age matched population SD}} \qquad \text{(Eq. 30.2)}$$

Many DXA scanners can also measure forearm BMD_a. This is useful as an alternative site in circumstances when it is not possible to obtain a valid measurement at the spine or hip [3, 4]. This includes patients with bilateral hip replacement, elderly patients with severe degenerative disease in the spine, and patients whose weight exceeds the safety limit for the scanner. Forearm scans are also used to investigate patients with hyperparathyroidism by measuring cortical bone at the 33% radius site [32].



BMD_a measurements across the whole skeleton can be performed using total body scans [33]. These are usually interpreted after excluding the head from the scan analysis. They are useful in younger children with a growing skeleton in whom the adult hip scan may not be appropriate [3, 4, 34]. In adults, total body scans are most frequently used to study whole body and regional body composition by measuring BMC, and lean and fat mass [35].



A variety of peripheral DXA (pDXA) devices are available for measuring the forearm, heel, or hand. In principle, these are attractive because they offer a quick, inexpensive, and convenient method of investigating skeletal status. In practice, however, these alternative types of measurement correlate poorly with central DXA, with correlation coefficients in the range r = 0.5 to 0.65 [12]. The lack of agreement with central DXA has proved a barrier to reaching a consensus on how to interpret results from pDXA devices [36]. However, no type of DXA measurement is immune from the uncertainties caused by T-score discordance, since similar differences are observed when comparing spine and hip results [11, 12].

FRACTURE PREDICTION

The ability to identify patients at increased risk of fracture is the most important reason for performing DXA [37]. The earliest ideas for interpreting BMD_a measurements were based on the concept of a fracture threshold, a

Fig. 30.1. (*Continued from previous page.*) (B) Scan printout of a hip DXA examination. The printout shows: (left) scan image of the hip; (top right) patient's age and total hip BMD plotted with respect to the NHANES III) reference range (Ref. 43); (bottom right) BMD figures for the femoral neck and total hip regions of interest, together with the interpretation in terms of T-scores and Z-scores using the NHANES III reference range and the FRAX® evaluation of the 10-year risk of hip fracture or an osteoporotic fracture at a major site (hip, forearm, humerus, or clinical vertebral fracture).

BMD_a figure below which patients were at increased risk for suffering an insufficiency fracture [38]. However, once data from large epidemiological studies were available it became clear that the relationship between BMD_a and fracture incidence is best described by a gradient-of-risk model in which the risk increases progressively as BMD_a decreases following an approximately exponential relationship (Fig. 30.2) [23, 24]. The gradient-of-risk is described by the relative risk (RR), the increased risk of fracture for each SD decrease in BMD_a. Results from meta-analyses give RR figures between 1.5 and 2.5 (Fig. 30.3), and show that the ability of a BMD_a measurement to predict fracture is comparable to the use of blood pressure to predict stroke and serum cholesterol to predict myocardial infarction [24]. Not all types of fracture are equally well predicted by BMD_a measurements, which are best at predicting fractures at sites such as the hip, spine, forearm, humerus, and pelvis, and are relatively ineffective for fractures of the face, ankles, feet and toes [25].

The most effective BMD_a measurement site for predicting fractures is the one with the largest value of RR [6]. The reason is explained in Fig. 30.4. If we consider a specific group such as all postmenopausal women in a particular age range, the distribution of Z-scores follows

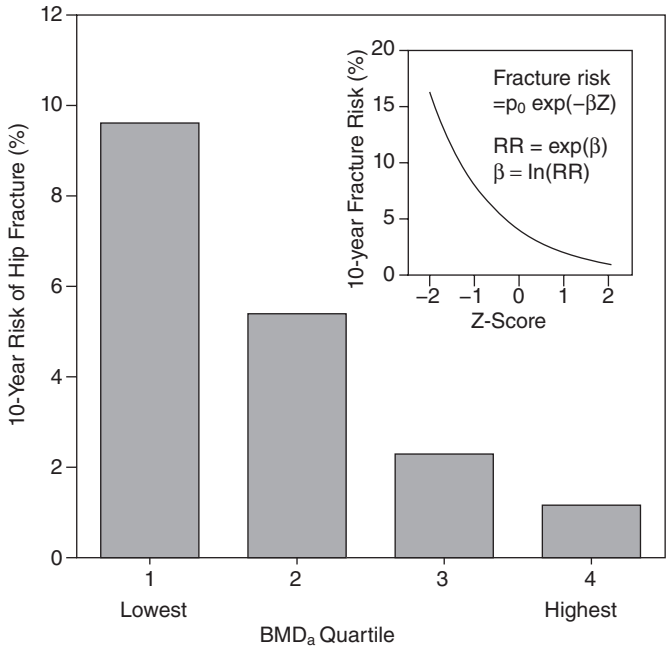

Fig. 30.2. Incidence of hip fracture risk by BMD_a quartile for femoral neck BMD_a. Data are taken from the 2-year follow-up of the Study of Osteoporotic Fractures (Ref. 23). Inset diagram: Data from fracture studies are fitted using a gradient-of-risk model, in which the fracture risk varies exponentially with Z-score with gradient β. Results are expressed in terms of the RR, the increased risk of fracture for each unit decrease in Z-score. The value of RR is found from β using the relationship RR = exp(β). Alternatively, β is found by taking the natural logarithm of RR [β = ln(RR)].

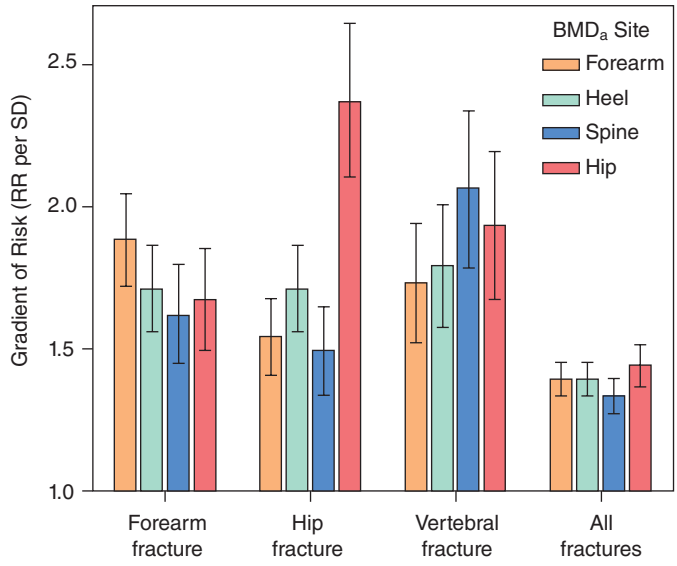

Fig. 30.3. Values of the RR (defined as the increased risk of fracture for a 1 SD decrease in BMD_a) for fractures at different skeletal sites (wrist, hip, spine, and any fracture) for BMD_a measurements made at four different sites (forearm, heel, spine, and femoral neck). The error bars show the 95% confidence intervals. Data are taken from the 10-year follow-up of the Study of Osteoporotic Fractures (SOF) study population (Ref. 25). In the SOF data the largest value of RR is for the prediction of hip fracture risk from a hip BMD_a measurement (RR = 2.4). This means that the clinically most effective type of DXA scan examination is to use hip BMD_a to predict hip fracture risk.

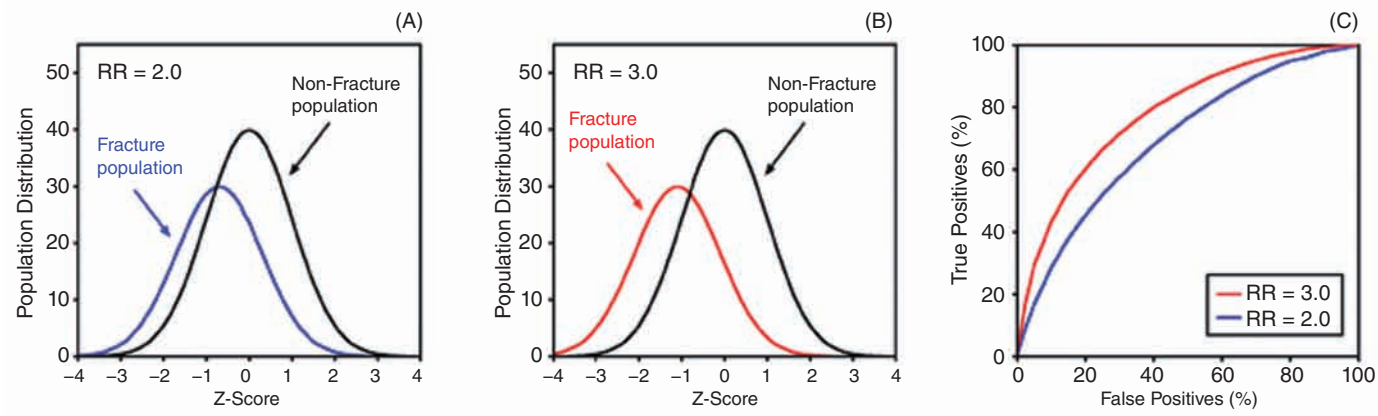

Fig. 30.4. (A) Distribution of Z-score values in a fracture population compared with an age-matched non-fracture population. The curve for the non-fracture population is a bell-shaped curve symmetrically distributed around its peak at Z = 0. The corresponding curve for the fracture population is a similar bell-shaped curve that is offset to lower (more negative) Z-scores by an amount that is greater for larger values of the RR. The curves shown are for RR = 2.0. (B) Similar to (A) but drawn for RR = 3.0. For a larger value of RR there is less overlap between the distribution curves for the fracture and non-fracture populations. (C) Plot of the ROC curves for the distribution curves shown in (A) and (B). The ROC curve shows the true positive fraction (those patients who sustain a fracture and were correctly identified as being at risk) against the false positive fraction (those patients identified as being at risk but who never actually have a fracture). The larger the value of RR the more effective BMD measurements are at discriminating the patients who will have a fracture as shown by the larger area under the ROC curve.

a bell-shaped curve. Multiplying the population distribution by the curve for increasing fracture risk leads to the conclusion that the corresponding fracture population has a similar bell-shaped curve with its peak shifted to lower Z-scores. This leads to one of the most important limitations of BMD_a measurements, namely that there is a wide overlap between the BMD_a distributions of the fracture and non-fracture populations, and that DXA is an imperfect tool for distinguishing between them [Fig. 30.4(A)]. However, the larger the value of RR the wider the separation between the two groups and the more effective BMD_a measurements are at distinguishing between patients who will have a fracture from those who will not [Fig. 30.4(B)] [6].

The clinical importance of choosing a measurement site with a large value of RR can be illustrated by using the distribution curves in Figs. 30.4(A) and (B) to draw a receiver operating characteristic (ROC) curve in which the percentage of true positive cases (patients who will suffer a fracture in the future and are correctly identified to be at risk) is plotted against the percentage of false positive cases (patients identified to be at risk but who will never have a fracture) [Fig. 30.4(C)]. Plotting ROC curves shows that the larger the RR value the greater the area under the curve (AUC) and the better the test will discriminate patients who are at the greatest risk of fracture.

SCAN ARTIFACTS

Careful visual inspection of the images included on the manufacturer's scan printout is important to ensure that BMD_a results are not affected by artifacts. For spine scans these include degenerative disc disease with osteophytes, spondylosis, osteoarthritis with hyperostosis of the facet joints, aortic calcification or vertebral fractures, which all cause BMD_a to be falsely elevated and particularly affect patients aged 65 years or more (Table 30.2) [39]. Technical artifacts include metal clips, navel rings, and buttons. The effect on scan interpretation can be assessed by noting the trend in T- or Z-score values at each vertebral level. Vertebrae significantly affected by artifacts should be excluded from the scan analysis, with the proviso that for clinical diagnosis a minimum of two unaffected vertebrae is recommended [3]. Laminectomy will cause underestimation of BMD_a at the affected level. For spine scans it is important to check that the correct vertebrae have been selected for analysis. Instead of L1-L4, scan analysis is sometimes erroneously performed for T12-L3 or L2-L5. One source of confusion is patients with abnormal segmentation [40]. In patients who have recently had an investigation with barium contrast medium it may be necessary to wait up to a month for this to clear. For patients who have recently had a radionuclide scan with technetium-99m, it may be necessary to wait 48 hours for this to decay [41, 42]. It is also important to recognize that DXA cannot differentiate between a low BMD_a that is due to osteomalacia (e.g., in vitamin D deficiency) or osteoporosis.

Table 30.2. Causes of Artifacts Resulting in Errors in DXA BMD_a

Overestimation of BMD_a
Spinal degeneration and hyperostosis (osteophytes)
Vertebral fracture
Extraneous calcification (aortic calcification, lymph nodes)
Overlying metal (clips, coins, navel rings, surgical rods)
Other overlying objects (buttons, wallets)
Sclerotic metastases
Vertebral hemangioma
Ankylosing spondylitis with paravertebral ossification
Exposure to strontium-containing medications (strontium ranelate, health supplements)
Underestimation of BMD_a
Laminectomy
Lytic metastases
Barium contrast medium in bowel
Recent radionuclide examinations

In patients with extensive degenerative disease, the spine scan may be of little diagnostic value, and in such individuals a more reliable result is obtained from the hip. Hip scans also require careful scrutiny as there is a wide range of anatomical variations, some of which cause difficulties in correctly positioning the hip ROIs. Inspection of scan images is particularly important when interpreting follow-up scans, and a visual comparison should always be made with previous studies. For the spine a check should be made that the same vertebrae were used for the analysis. For hip scans it is important that the angles of rotation and abduction of the hip are the same and that the ROI boxes are placed in a consistent manner. Follow-up scan results showing unexpectedly large rates of change should be reviewed to exclude technical factors as a cause.

SCAN INTERPRETATION USING T- AND Z-SCORES

Once a BMD_a measurement has been made, a clinical report is issued interpreting the findings for the referring clinician. The International Society for Clinical Densitometry (ISCD) has issued guidance for the interpretation and reporting of DXA scans that is free to download from the ISCD website [3]; it is also available in published articles [4]. Results are interpreted using T- and Z-scores calculated using the appropriate age-, gender- and ethnically matched reference ranges (Eqs. 30.1 and 30.2). Osteoporosis may be diagnosed in postmenopausal

women and men aged 50 or older if the T-score at the lumbar spine, femoral neck, or total hip site is –2.5 or lower [3, 4]. For the hip sites, the United States (U.S.) National Health and Nutrition Examination Survey (NHANES) III database should be used for calculating T-scores [43]. In women, the Caucasian female reference range is recommended for interpreting results for all ethnic groups, with a similar recommendation for men [3, 4]. In circumstances where it is necessary to perform a forearm scan the 33% radius (also called the 1/3 radius) site may be used [3, 4]. However, the WHO T-score definition of osteoporosis should only be applied to DXA measurements at the above-mentioned sites, since with other measurements [for example, quantitative computed tomography (QCT) or quantitative ultrasound (QUS)] it is likely to lead to the over or under diagnosis of osteoporosis [12, 44]. When applied appropriately, the WHO T-score threshold for defining osteoporosis is similar to the use of a blood pressure threshold to diagnose hypertension or serum cholesterol to diagnose hypercholesterolemia.

For premenopausal women and men younger than age 50, Z-scores rather than T-scores are preferred for scan interpretation [3, 4]. In particular, T-scores must never be used to interpret DXA results in children because of the effect of bone size on the measurements and the fact that peak bone mass has not yet been reached [8]. When Z-scores are used they should be based on reference data for the relevant population and ethnic group. A Z-score of –2.0 or lower is defined as below the expected range for age [3, 4].

SCAN INTERPRETATION USING FRAX®

A new approach to DXA scan interpretation based on using femoral neck BMD_a combined with information on clinical risk factors to estimate patients' 10-year probability of a fracture at the hip or one of the major osteoporotic sites (the latter defined as the hip, spine, forearm, or humerus) was introduced by the WHO and is designed for use in women and men aged 40 to 90 years [45]. The FRAX WHO fracture risk assessment tool is readily accessed using the website [7] and has also been incorporated into manufacturers' DXA scan reports [Fig. 30.1(B)]. A limitation of the T-score approach to making decisions about patient treatment is that factors such as age and a history of previous insufficiency fracture are independent risk factors that are as important as BMD_a in determining the 10-year risk of fracture. In the FRAX scheme a selected list of clinical risk factors (Table 30.3) is used with BMD_a to improve the ROC curve (Fig. 30.5).

The FRAX algorithm was developed based on a series of meta-analyses of data from nine different fracture studies from North America, Europe, and Asia. These enrolled a total of 46,000 men and women with 190,000 person-years of follow-up, and included 850 cases of hip fracture and 3,300 other osteoporotic fractures [45]. Once

Table 30.4. Treatment Criteria from the National Osteoporosis Foundation 2010 Guidelines*

Postmenopausal women and men age 50 and older presenting with the following should be considered for treatment:

- A hip or vertebral (clinical or morphometric) fracture
- T-score ≤–2.5 at the femoral neck or spine after appropriate evaluation to exclude secondary causes
- Low bone mineral density (T-score between –1.0 and –2.5 at the femoral neck or spine) and a 10-year probability of a hip fracture ≥3% or a 10-year probability of a major osteoporosis related fracture ≥20% based on the U.S.-adapted WHO algorithm.

*(Ref. 5).

the fracture risk algorithm had been constructed, a validation study was performed using data from 11 independent studies not used in the development of the original model involving a total of 230,000 subjects with over 1.2 million person-years of follow-up [45]. By reason of its large numbers, its international character, and the care taken in its construction and implementation, the FRAX algorithm is arguably the most important advance in bone densitometry since the introduction of DXA.

FRAX is gradually being incorporated into national guidelines on the treatment of osteoporosis. In the U.S. the National Osteoporosis Foundation (NOF) has added FRAX to the criteria for treating patients with a threshold of 3% for hip fracture and 20% for a major osteoporotic fracture (Table 30.4) [5]. In the U.K., a different treatment algorithm was issued by the National Osteoporosis Guidelines Group (NOGG), which recommended that FRAX be used in a triage scheme to select the patients who would benefit from having a DXA examination [46]. The introduction of FRAX has raised some interesting discussion and controversy [47–49]. As a result, the FRAX tool has been refined and a number of errors corrected, and at the time of writing, versions are available for use in 47 different countries. An up-to-date review of FRAX can be found in a recent position paper [50].

PRECISION ERRORS AND MONITORING BMD_a CHANGE

The use of DXA scans to monitor patients undergoing treatment is more controversial than other applications [51, 52], and good precision is essential [53]. Precision errors measure the reproducibility of BMD_a results in individual patients and can be measured by performing repeated scans on a representative group of subjects. Precision is usually expressed in terms of the percentage coefficient of variation (CV) and is typically around 1–1.5% for spine and total hip BMD_a and 2–2.5% for femoral neck BMD_a [19]. DXA scanners have excellent long-term precision because their calibration is very stable, and there are instrument quality control procedures provided by manufacturers to detect any long-term drifts should they occur. However, good precision depends on scanners being operated by skilled and appropriately trained staff and that rigorous quality assurance protocols are in place.

To reach a statistically significant conclusion when monitoring a patient, the BMD_a change needs to equal or exceed the least significant change (LSC), which is defined as 2.8 times the precision error, i.e., a change of 3–4.5% for spine and total hip BMD_a and 6–7.5% for femoral neck BMD_a [53, 54]. In general the same DXA scanner should be used for follow-up examinations to avoid even larger errors. Typically for monitoring individual patients an adequate interval of time (18–24 months) is required between measurements unless particularly large changes in BMD_a are expected, for example after large doses of oral glucocorticoids [3, 4].

VERTEBRAL FRACTURE ASSESSMENT (VFA)

Lateral views of the thoracic and lumbar spine (T4–L4) can be obtained with fan-beam DXA scanners, using dual- or single-energy scanning (dual-energy images are generally superior for visualizing vertebrae in the thoracic region), with the patient either in the supine ("C" arm scanners) or lateral decubitus position. From these images a visual assessment can be made as to whether or not vertebral fractures are present, and morphometric assessment of vertebral shape can be made [55, 56]. The method uses a lateral scan projection, with simultaneous movement of the X-ray source and detectors along the spine, so the X-ray beam is always parallel to the vertebral endplates. This avoids the "bean can" artifact of vertebral endplates due to the parallax effect of a conventional conical shaped X-ray beam, and the dose from ionising radiation is much lower (1/100th to 1/40th) than with spinal radiographs. Guidelines for indications for VFA and scan interpretation have been published by the ISCD [3, 4, 57]. The method has been shown to be satisfactory for excluding the presence of vertebral fractures [58]. However, more scientific studies are required to confirm the exact clinical role of this alternative technology to conventional spinal radiography for the identification of vertebral fractures.

DXA IN CHILDREN

The purpose of any assessment of bone size or mass in children is to provide data relevant to the current, or future, health of the skeleton. DXA is the most widely used quantitative bone imaging technique in pediatric

practice, but many aspects of its use, and the interpretation of the data obtained, remain contentious [59–67].

DXA provides estimates of bone size in two dimensions and bone mass within that envelope, the value of bone mass adjusted for size being "areal" BMD_a (g/cm^2) [8]. The manufacturer-provided reference values for BMD_a, which increase in a similar way to height and weight during childhood and adolescence, clearly indicate that DXA is not measuring true volumetric bone density, but some composite measure of bone size and mass. This is not necessarily a disadvantage since bone size, especially in the tubular bones that children are most prone to fracture, is an important predictor of bone strength. Moreover, to some extent this limitation can be overcome by using an estimated volumetric BMD [bone mineral apparent density (BMAD, g/cm^3)] in the spine and femoral neck [68, 69].

The advantages of using DXA in children are the short scan time, low radiation dose, and general widespread availability. DXA measures of BMD_a in healthy children are predictive of fracture risk both at the measurement site (in the forearm) and elsewhere; total body BMD_a less head (Fig. 30.6), adjusted for weight, height, and bone area, is the measure that has been found in a prospective cohort study at age 9.9 years to be most strongly associated with fracture risk over the following 2 years [70]. However, there are no data for the predictive value of DXA at other ages in apparently healthy children and no similar data for children with bone disease.

Children are a difficult group to study, because as they grow so their bone mass should increase [64]. They also fracture frequently—by the end of teenage years, up to half of all boys and a third of girls will have sustained a fracture [71, 72]. A single fracture in an otherwise healthy child should not therefore require investigation of skeletal health.

Most requests for DXA scans in children will be in the groups thought to be at increased risk of fracture. These include children with primary bone diseases such as osteogenesis imperfecta and idiopathic juvenile osteoporosis; chronic immobilization (cerebral palsy and Duchenne muscular dystrophy); inflammatory conditions (Crohn's disease, cystic fibrosis, and juvenile idiopathic arthritis); conditions with endocrine disturbance such as anorexia nervosa and Cushing's syndrome (but not Turner's syndrome); following chemotherapy or organ transplantation; and in thalassemia major [73]. Other requests come when a child has recurrent fractures in the absence of an obvious underlying predisposition.

Measurement sites for DXA in children are typically the lumbar spine (L1-4) and total body less head, where precision is similar to that achieved in adults [74]. The forearm and proximal femur have been used in some studies, as has the lateral distal femur where deformity and contracture preclude the use of DXA in the normal measurement sites. Normative reference data are available for spine, femoral neck, total body, and lateral distal femur [34, 62, 75]. It should be noted that inconsistencies have been reported between different reference databases that can lead to clinically relevant differences in BMD_a Z-scores [65].

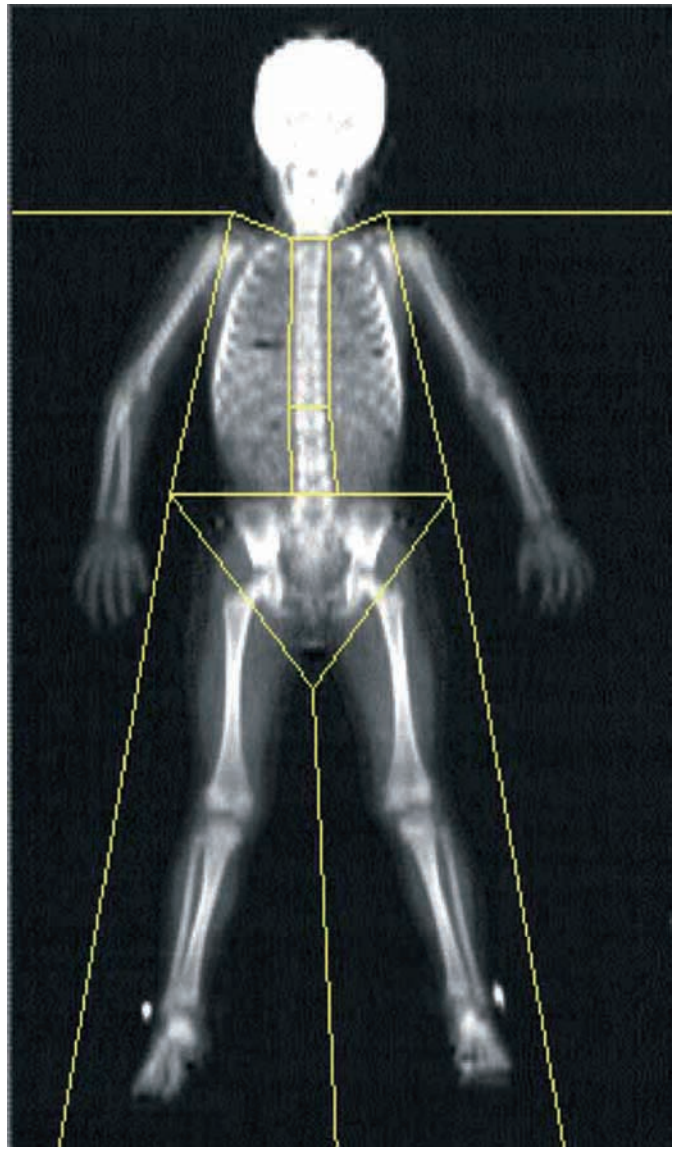

Fig. 30.6. Whole body DXA in a child is obtained in approximately 1 min on fan-beam scanners and provides total and regional information about the skeleton (less head) and body composition (lean muscle and fat mass).

Measurements are usually reported in relation to gender, age and race [62, 75]. Further adjustments have been made in research studies in apparently healthy children to account for the assumed shape of the vertebrae (cylindrical, cuboidal) to calculate BMAD [76, 77] or the expected relationship of bone size and mass with height or elements of body composition such as lean body mass [63, 67, 78–80]. Recent data suggest vertebral shape also influences BMD_a measurements [81]. Some of the current generation of scanners provide methods of adjusting for body size at both the spine and total body, but currently

there is a lack of information as to which adjustment (if any) should be used in clinical practice. It is unclear from the published data whether any one of the proposed adjustments is optimal in terms of either fracture prediction or skeletal health assessment.

In diseases and disorders in childhood where fracture risk is increased, initiation of bone mass measurement by DXA should be at the discretion of the treating clinician, and the monitoring interval should reflect the severity of the disease. There is little evidence to support monitoring at intervals of less than 6 months in any setting [74]. Although there is a known increased risk of fracture for children receiving glucocorticoid therapy, it is difficult to disentangle the effects of these on bone from the effect of the underlying disease. It does not seem appropriate at this time to suggest that measurements should be any more frequent in children receiving such therapy [73].

Interpretation of the scan results depends on the clinical context. A diagnosis of osteoporosis should not be made on the basis of a BMD_a measurement in isolation [4]. Terminology such as "low bone density for chronological age" may be used if the Z-score is below –2.0 [3, 4, 8]. If a child presents with recurrent fractures but no clinically apparent underlying disease, and BMD_a is within the expected range, reassurance can be offered. If there is an underlying problem, further monitoring and additional imaging may be required. Such a clinical setting would be a child with apparently mild osteogenesis imperfecta with BMD_a in the normal range who may have occult fractures of thoracic vertebrae; such findings have also been reported in nephrotic syndrome [82]. Normal bone mass by DXA does not, therefore, preclude the presence of vertebral fractures that merit intervention. Low BMD_a in the presence of vertebral, or recurrent, fractures resulting in loss of independent mobility and chronic bone pain should prompt evaluation of the need for active intervention, as should falling bone mass in conditions that predispose to fracture.

CONCLUSIONS

DXA is the most widely used method of measuring BMD_a in adults and children and provides precise results with very low doses of ionizing radiation. It can be used in postmenopausal women and men aged 50 years and over to diagnose osteoporosis using the WHO definition (T-score of –2.5 or less at the lumbar spine, femoral neck, total hip, or 33% radius) and aid decisions on patient management. The basic rationale for DXA examinations is their ability to identify patients at increased risk of fracture, and the new WHO FRAX fracture risk assessment tool effectively exploits this ability and sets the clinical application of bone densitometry on a sound scientific basis. DXA has some important limitations. The discordant results between different sites reflect the relatively limited information that can be derived from a 2D projection scan as well as the errors caused by variations in soft tissue composition. Although DXA has excellent precision, it is easy to overlook the significance of this lack of concordance and to mistake good precision for good diagnostic accuracy. The degree of discordance between different sites indicates that DXA measurements should be viewed as a relatively rough and ready indicator of skeletal health. One merit of the FRAX scheme is that it treats BMD_a measurements as just another type of clinical risk factor rather than a uniquely special indicator of skeletal status. Another merit of FRAX is that it provides a focus for future research by directing attention to the importance of achieving the best ROC curve for fracture risk prediction. There are particular issues with interpreting DXA results in children in whom the dependency on bone size is a limitation, and to date there is no consensus on whether size correction should be applied and which method is optimum.

INTRODUCTION

Bone mineral density (BMD) is one of the strongest predictors of fracture risk, but today's standard densitometric method, dual X-ray absorptiometry (DXA)-based measurement of areal BMD (aBMD), has limitations, particularly for characterizing changes in bone status in subjects on treatment. Quantitative computed tomography (QCT) is a potential alternative for the future because in addition to volumetric density it permits assessment of bone microstructure and calculation of whole bone strength. Technical and clinical considerations are outlined in this chapter.

METHODOLOGY

X-ray-based computed tomography (CT) provides three-dimensional (3D) morphological and compositional information. On the reconstructed CT-images, tissue contrast is predominantly determined by X-ray absorption of its heavier elements (e.g., calcium). Image gray values are expressed as a CT number measured in Hounsfield units (HUs), but for QCT, a reference phantom of known composition is scanned together with the patient, which allows conversion of HUs into calcium-hydroxyapatite (Ca-HAP) equivalent BMD. For earlier measurements that were calibrated to K_2HPO_4, a correction factor needs to be applied to express results in Ca-HAP [1], an issue important, for example, for comparison with published reference ranges. Unlike DXA, BMD measured by QCT reflects volumetric BMD, not an areal projection.

Single-energy QCT of the skeleton was initially applied to the radius in 1976 by Rüegsegger et al. [2] and Isherwood et al. [3], followed by measurements at the spine by Genant and Boyd [4]. Measured BMD is decreased by marrow fat [5, 6]. Low tube voltage settings of about 80 kVp lead to smaller fat-related accuracy errors than measurements at 120 kVp. Dual-energy QCT approaches improve the accuracy of the measurement but at the expense of poorer precision and increased radiation exposure and these approaches have not achieved a significant clinical role. The recent advent of dual source CT scanners may facilitate dual-energy QCT in the future. For a QCT measurement, first a lateral planar overview measurement of the region to be scanned is generated [Fig. 31.1(A) and (B)], which allows placement of the measurement regions at the anatomically correct positions. Until the 1990s, the measurement region consisted of multiple individual and spatially separated CT slices, each about 5–10 mm thick [single-slice QCT; Fig. 31.1(A)]. Today, spiral CT approaches yield a complete 3D dataset of the volume of interest [multislice QCT; Fig. 31.1(B)], consisting of anywhere from tens of CT slices to hundreds. This permits automated and precise placement of volumes of

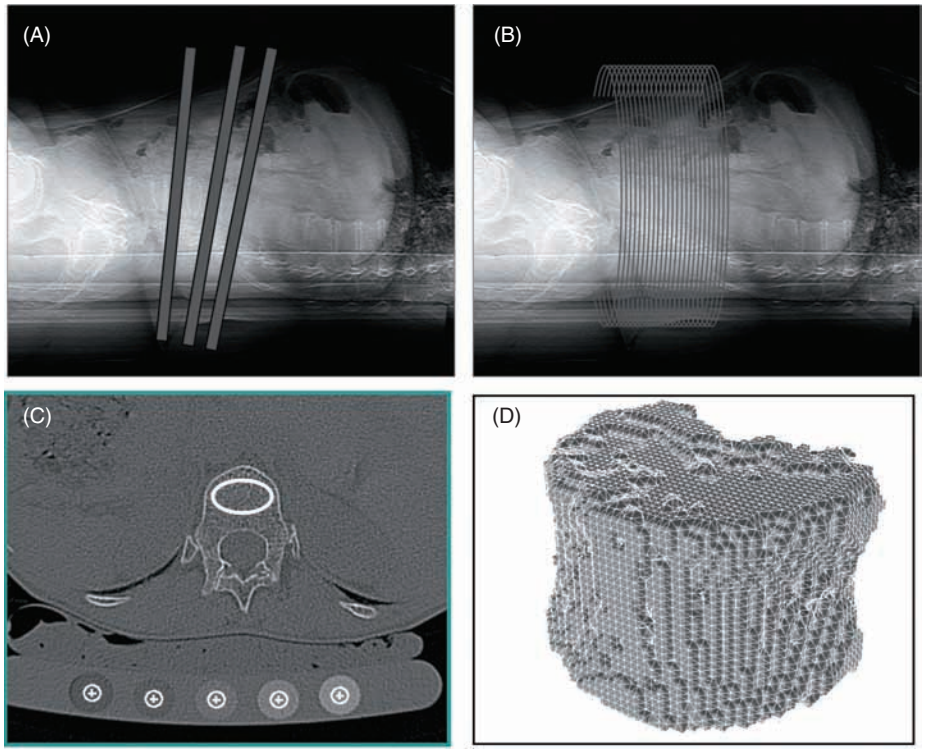

Fig. 31.1. Illustration of QCT procedure: (A) localizer image used for either tilted single slice placement at three adjacent vertebrae or (B) spiral volumetric multislice acquisition covering the same three vertebrae; (C) typical single slice technique image showing elliptical trabecular region of interest evaluated and calibration phantom underneath patient; (D) stack of images segmented along the cortical rim depicting the volume of interest evaluated in the multislice approach.

interest (VOIs) to study automatically well-defined compartments. Data acquisition is fast with scan times on the order of 1–10 s. The spatial resolution has improved substantially, approaching 100–200 µm for human studies *in vivo* at peripheral measurement sites [7]. At central measurement sites, in-plane resolution is poorer by a factor of 2, and slice thickness is greater than or equal to 300 µm.

Spinal QCT. For single-slice approaches, L1-L3 or T12-L3 are measured, and a minimum of two vertebrae should be evaluated. At 80 kVp, 140 mAs, and 8–10 mm slice thickness located at the center of the vertebrae [Fig. 31.1(C)], good precision at low radiation exposure and lower fat errors can be achieved [8]. With the more recent multislice approach [Fig. 31.1(D)] L1-L3 are measured, typically at 120 kVp, 50–120 mAs, slice thicknesses of 1–3 mm, pitch = 1. Trabecular bone is evaluated in an ellipse in the anterior part of the vertebral body or in larger regions encompassing most of the trabecular volume. The trabecular region shows high responsiveness early after menopause, and thus the assessment with QCT is superior to DXA. For accurate assessment of vertebral fragility the cortical rim should also be evaluated. It is very thin (300–600 µm) [9], but due to partial volume effects on CT images appears to be much thicker (more than 1 mm) [10]. Assessment of 3D vertebral cortical thickness and trabecular separation is substantially improved by high-resolution QCT (HRQCT) scan protocols (120 kVp, 350 mAs, a slice thickness of 0.3–0.5 mm, pitch = 1), particularly in nonaxial imaging planes (Fig. 31.2). Using gray-level based fuzzy distance transformation, the distance between trabeculae can be assessed with residual errors of less than 100 µm [11]. Differences in spatial resolution and reconstruction kernels of CT scanners represent a challenge for multicenter studies, and structural cross-calibration methods need to be developed.

Hip QCT. In recent years, QCT hip analysis software has been marketed by that is based on multislice data acquisition with 120 kVp, 100 mAs, and 3-mm slice thickness (Mindways Software Inc., Austin, TX, USA). The software allows both calculation of trabecular and cortical compartments in the femoral neck and trochanter. It has been used to study differences between cervical and trochanteric fractures [12] and for the assessment of treatment effects [13]. The software also provides fairly correct estimates of femoral aBMD results [computer tomography X-ray absorptiometry (CTXA)] calculated from their QCT data [14]. Accurate assessment of cortical thickness is important but challenging. Good results can be achieved by model-based methods [15]. This software is freely downloadable (http://mi.eng.cam.ac.uk/~rwp/stradwin/docs/thickness.htm). Other research software for flexible analysis of various VOIs within the proximal femur has been developed and used to assess changes in density and structure in disease or under treatment [16–18].

Peripheral QCT (pQCT) has mostly been carried out at the distal forearm and the distal tibia. Using a small-angle fan beam, typical single-slice pQCT X-ray tube settings are 45–60 kVp, 140–400 mAs, and at 1–3-mm slice thickness in plane pixel sizes of 100–300 µm can be

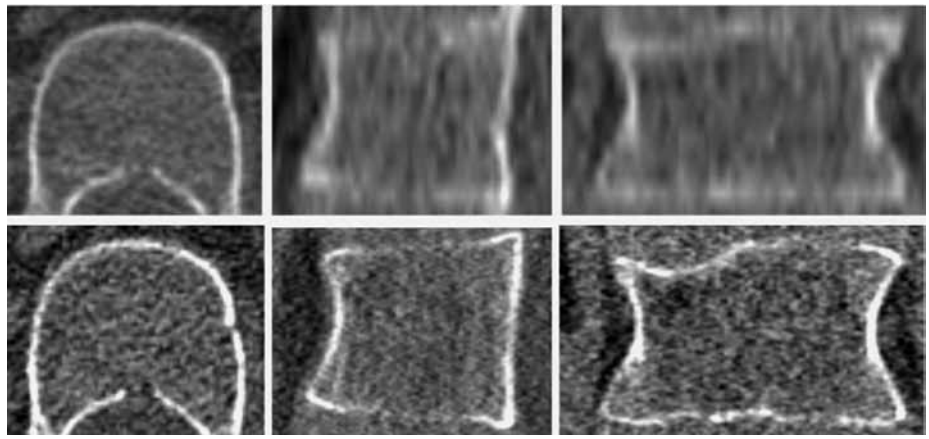

Fig. 31.2. Comparison of spatial resolution of QCT (top) and HRQCT (bottom) in the axial (left), sagittal (center), and coronal (right) planes. Protocols: QCT: 120 kVp, 100 mAs, $0.72 \times 0.72 \times 3\,mm^3$, Kernel B, threshold 250 mg/ml. HRQCT: 120 kVp, 359 mAs, $0.16 \times 0.16 \times 0.33\,mm^3$, Kernel D, threshold 250 mg/ml. Cortical thickness measured with QCT: 3.3 mm, for HRQCT: 1.9 mm; cortical density for QCT: 133 mg/ml, for HRQCT: 255 mg/ml. Microstructural assessment in 3D cannot be performed with QCT; the cortical shell can be displayed in 3D with HRQCT; for quantitative assessment, partial volume effects have to be considered.

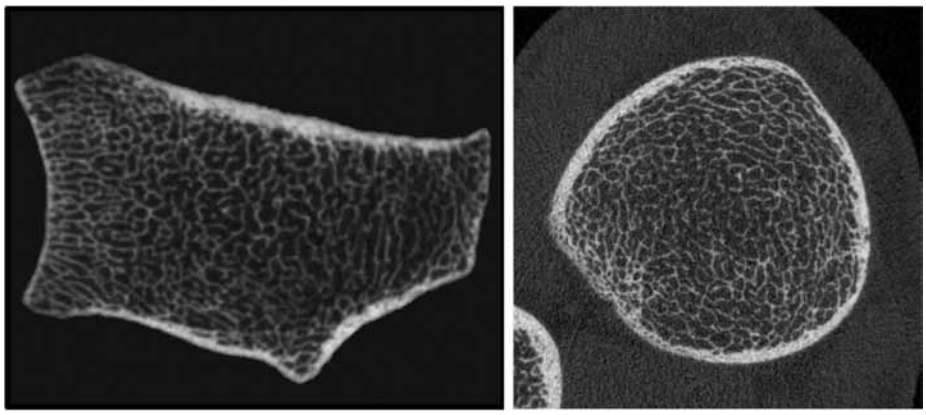

Fig. 31.3. HRpQCT of the distal forearm (left) or the tibia (right) allows visualization of trabecular microstructure and cortical porosity (courtesy Scanco Medical AG, Bruettisellen, Switzerland).

achieved. BMD is measured at the distal radius (4% or radius length, mostly trabecular) and at a more proximal location (15–65% radius length, cortical).

Recently, a **multislice high-resolution pQCT (HRpQCT)** device featuring an isotropic voxel size and slice thickness of 82 µm, sufficient to depict microstructural information, has been marketed (Fig 31.3). Measurements with a microfocus X-ray tube operated at 60 kVp, 0.9 mA are obtained at the distal radius and the distal tibia within a region of 9.02 mm length (110 slices). To calculate a variety of microstructural variables, the images are binarized. Variables include cortical thickness (derived from cortical area and perimeter) and trabecular number (Tb.N), directly determined from 3D distance transformation techniques. In its current implementation bone volume fraction (BV/TV) is NOT a microstructural variable but directly calculated from trabecular BMD, assuming a constant tissue mineral density of 1,200 mg Ca-HAP/ml. Since trabecular thickness and separation are derived from Tb.N and BV/TV, an impact of density should be noted. The precision of densitometric variables is high (less than 1%) and for most microstructural variables it is in the range of 4–5 % [19]. This method, for the first time, permits assessment of trabecular and cortical density and microstructure with high accuracy (modulation transfer function of 100 µm at 10% contrast) [20, 21]. In order to exploit this high level of spatial resolution, software for registration and microstructural characterization has been developed [22–24]; motion artifacts have to be avoided [25, 26].

Radiation Exposure. The level of desired image resolution, the location of the measurement region (proximity to radiation-sensitive organs), and the size of the measurement region determine the level of radiation exposure. By variation of the X-ray energy, radiation levels can be optimized, recognizing that the choice of the energy also affects accuracy. For earlier single-slice QCT approaches of T12-L2, low radiation levels down to 50–100 µSv have been reported [27]. For current multislice approaches the radiation exposure of QCT may vary substantially. Typical levels of effective dose are 1.5–2.3 mSv for QCT of L1-3 at 120 kVp, 100 mAs, and

3.3–3.7 mSv for HRQCT of T12 at 120 kVp, 360 mAs (values for men are slightly lower than those for women). For QCT of the hip at 120 kVp, 100 mAs the levels are 1.0–1.4 mSv for women and 2.1–3.0 mSv for men. The radiation exposure for pQCT measurements is small: about 3 µSv effective dose for radial HRpQCT [7]. Further improvements of spatial resolution are, however, restricted by high local skin radiation exposure. For comparison, typical levels of radiation exposure for DXA at the hip or spine are in the range of 0.5–5 µSv [28].

CLINICAL APPLICATION

Reference data

Pediatric spinal single-slice QCT reference data for L1-3 recently published [29] are presented in Fig. 31.4 (left). Adult reference ranges have been published for single-slice spinal QCT for a European [1] and a North American population [30] (and additional data have been published for a variety of other cohorts [31]). For these two studies QCT methods differed with regard to scanner, calibration standard, kVp, and slice thickness results depended on the model fit selected, but still BMD results deviated by less than one half of the population standard deviation (SD) [1]. Assuming that a dual-energy approach provides the most accurate data, volumetric BMD of a central slice remains fairly constant between ages 20 and 40 at about 140 mg/ml, and decreases to about 60 mg/ml at age 80, with a population SD of about 25 mg/ml [1]. Men have the same volumetric BMD at young ages, a similar population SD, and an only slightly slower decrease to a level of about 70 mg/ml at age 80 [1]. Single-energy approaches yield BMD values that are approximately 10–15% higher, depending on the kVp setting [Fig. 31.4 (right), adapted from Ref. 1]. Multislice spinal QCT BMD levels should be somewhat higher since the denser regions that are closer to the endplates are included in the volume evaluated. Some data on large cohorts have been published [32]. However, since there is no agreement on the placement of the VOIs, no standardized reference data are available yet.

For pQCT, reference ranges have been published for the single-slice approach [33]. For HRpQCT limited reference data have also been published [34]. In a multicenter setting, single and multislice approaches can be cross-calibrated using the European Forearm Phantom [35].

Diagnosis of BMD status in children

Z-scores should be used for diagnostic assessment of children. DXA as a projectional technique has many limitations for the assessment of bone status in children [36], most importantly the impact of bone size, but also variable geometry and changing tissue composition (trabecular vs cortical bone and red vs yellow marrow). QCT approaches may thus be of interest, but the radiation exposure is higher than for DXA. QCT is less affected by size, but it is more sensitive to bone marrow changes [5]. Unlike DXA, QCT allows differentiation between small bones and low BMD. If chronological age and bone age (e.g., according to Greulich-Peyl or Tanner-Whitehouse scores) differ, even QCT may not provide the complete answer, because it is not possible to distinguish low bone organ density from low tissue mineralization (e.g., in rickets). The stage of sexual development seems to be the strongest predictor of volumetric BMD [37]. Therefore, adjustment of the expected Z-score may have to be considered if pubertal status deviates from the norm.

Peripheral measurements have less of a radiation exposure problem. Moreover, pQCT of the forearm shows important relationships between bone growth and mechanical or hormonal factors impacting during adolescence. However, the many different variables generated from pQCT may confuse a clinical user. For single-slice pQCT, reference curves for trabecular or cortical bone at the 4% radius measurement site may be a good choice [38, 39]. Volumetric BMD does not change in girls and boys between ages 6 and 15 and later increases only for

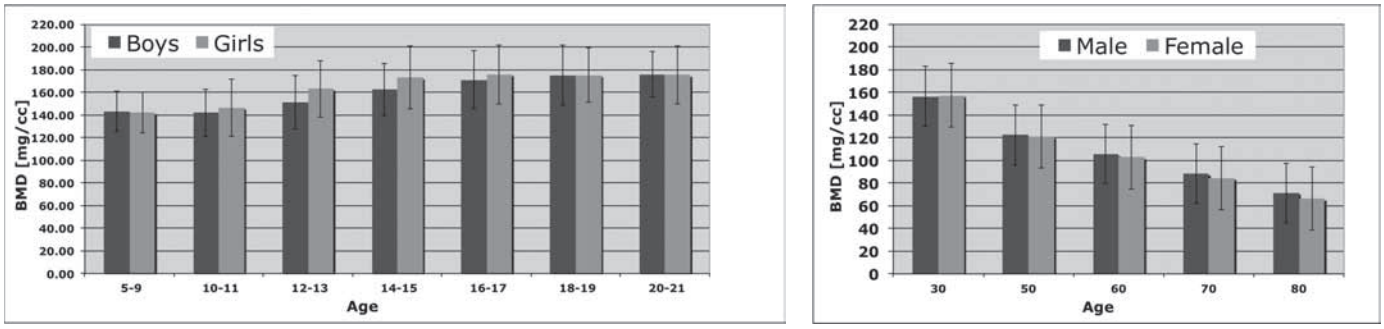

Fig. 31.4. Spinal trabecular BMD reference data measured by single-slice QCT as function of age. Published pediatric data (left, adapted from Ref. 29) were readjusted back to calibrated units of mg/ml K_2HPO_4 by applying a factor of .59, the ratio of bone density of 2.01 g/ml to mineral density of 1.183 mg/cm3 K_2HPO_4 (Ref. 109). Adult data (right) were adapted from the linear age-related fit from Ref. 1, which would closely match the pediatric data if extended to age 20). QCT was acquired in single energy mode at 80–85 kVp.

boys. However, pQCT results may also be biased: partial volume effects need to be taken in consideration, particularly at younger ages and for cortical measures. HRpQCT might be a better choice [40], but no pediatric reference data have been published to data. The techniques have recently be used to study a variety of disorders with detrimental effects on bone. For example, in children with chronic kidney disease, no significant difference compared to healthy controls was observed [41]. For both pQCT and HRpQCT, potential discordance of spinal, femoral, and peripheral BMD developments may have to be considered.

The indications for bone densitometry have been addressed in position papers by the International Society for Clinical Densitometry (ISCD) [42] and the British National Osteoporosis Society [36], but both are largely focused on DXA. QCT and pQCT can be used instead of DXA to examine with higher accuracy whether BMD deviates from age-specific reference data, but for spinal QCT, this comes at the expense of higher radiation exposure. To date, pediatric HRpQCT remains a tool for research.

Diagnosis of BMD status in adults

T-scores should be used for diagnostic assessment of adults. The diagnostic threshold given by the World Health Organization (WHO) of a T-score of –2.5 cannot be applied to QCT. Efforts have been made to define equivalent diagnostic thresholds for QCT, either based on equivalent fracture risk or equivalent fracture prevalence. However, QCT decreases faster with age than DXA. Therefore, diagnostic T-score thresholds for QCT would have to be lower than –2.5 and in order to be DXA equivalent they cannot be constant; they will decrease with age. For example, a level of 72 mg/ml for trabecular bone of the vertebrae [43], corresponding to a QCT T-score of approximately –3.2, may be DXA-T = –2.5-equivalent at age 50, but it is not low enough for older subjects. For QCT techniques using protocols that differ from those used for the above-mentioned published reference data, correction factors need to be applied. Additionally, for multislice approaches, the differences between the single and multislice regions need to be accounted for.

The correlations between spinal trabecular BMD by QCT (or spinal DXA-based BMD) and radial or tibial trabecular BMD by pQCT or HRpQCT are modest ($r = 0.4$ [44], $r = 0.3$ to $r = 0.7$ [45], respectively). Therefore, it is not possible to use pQCT or HRpQCT to accurately estimate BMD status at the spine. Because the diagnostic relevance of an abnormally low radial BMD is difficult to judge, low pQCT or HRpQCT results are not sufficient to diagnose osteoporosis.

Fracture risk assessment

QCT methods permit assessment of volumetric density and bone microstructure. Both are important determinants of bone strength [46, 47] and thus there is potential for improved fracture risk assessment [48, 49]. Bone density [44] and structure [50] vary considerably across different sites, and therefore the performance of imaging methods has to be assessed separately for each major fracture type. Results for standardized hazard ratios (sHR) and risk ratios (sRR) are expressed per standard deviation of the population variance.

Vertebral fractures

In men, spinal multislice QCT predicts incident clinical vertebral fractures significantly better than aBMD with areas under the curve (AUCs) for receiver operating characteristic (ROC) analyses of 0.83 vs. 0.76 ($p < 0.05$); age-adjusted sHRs were 5.7 (3.1, 10.3) compared to 3.2 (2.0, 5.2) [51]. For women, there is only one old prospective fracture study (in women) in which **spinal QCT** showed a predictive power similar to dual photon absorptiometry [52]. When compared to DXA in a various cross-sectional studies, single spinal QCT in general discriminated women with and without vertebral fractures at least as well as DXA [17, 44, 53–57], and in several of these studies it was significantly stronger. Recently, the stronger performance of QCT compared to DXA has also been reported for spinal multislice QCT evaluated cross-sectionally in women [58].

For **pQCT**, no prospective studies have been published on incidence of vertebral fractures. The cross-sectional studies (in women) for the single-slice approach are difficult to interpret because the authors usually tested a large number of pQCT variables, and thus it is unclear whether the observed association would hold in a retest in independent samples [44, 59–61]. For multislice pQCT, only data from one Japanese group on an older device are available, giving positive results for women [54].

For **HRpQCT**, two recent cross-sectional studies showed vertebral fracture discrimination (for densitometric and microstructural variables) in women independent of DXA for various structural variables [7, 62], but another study reported insignificant discrimination [58]. In men, a population-based study demonstrated significant age-adjusted discrimination of vertebral fractures for both density and microstructural variables, and cortical thickness contributed independently of aBMD. Two case control studies, one in men [63] and one in women [64], have reported significant association of HRpQCT variables with the *severity* of vertebral fractures; cortical thickness contributed independently of aBMD.

In summary, vertebral fracture risk prediction using QCT vBMD appears to be superior to DXA. HRpQCT measures at the radius or tibia also reflect fracture status, particularly in men and women with more severe fractures.

Hip fractures

The proximal femur is a site of substantial anatomic complexity and, therefore, 3D assessment of volumetric BMD and its distribution within the cancellous and cortical

bone envelopes by **hip QCT** appears to be warranted. Beyond density, QCT permits evaluation of a variety of structural measures identified as potential predictors of hip fracture, including hip axis length [12, 65], acetabular bone width [66], cross-sectional area [12, 66], and neck-shaft angle [12, 67]. Density and structural measures can be combined to define biomechanically motivated strength indices [12, 68]; alternatively, the distribution of BMD can be used for finite element modeling (see below) or statistical parametric mapping, in which a model-based representation of the femur depicts fracture-critical subregions for cervical or trochanteric hip fractures [69]. Hip fracture prediction by hip QCT has been assessed prospectively in men [70]. Incident fractures were best predicted by integral BMD of the femoral neck (sHR = 3.6). Combining three independent predictors, i.e., trabecular BMD, percent cortical volume, and minimum cross-sectional area, resulted in the same predictive power as femoral neck aBMD measured with DXA (sHR = 4.1). Femoral neck structure was associated with fracture incidence independent of aBMD but QCT variables did not enhance predictive power above and beyond femoral neck aBMD alone. For QCT and DXA of the proximal femur hip fracture risk, increase was large and significant only in the lowest quartile of the respective index [70]. This pattern differs from that observed for DXA in women, which is more gradual [71, 72], and, if confirmed over longer follow-up time periods, perhaps permits a more selective case-finding strategy in men. The impact of muscle and fat tissue on hip fracture risk has also been studied prospectively. A decrease in thigh muscle density measured by QCT, a measure of fatty infiltration of muscle, was associated with an increase in hip fracture risk, even after adjusting for BMD (sRR = 1.5) [73]. For women, only cross-sectional hip QCT studies have been published indicating improved fracture discrimination for multivariate models that include variables reflecting both trabecular density and cortical thickness [74].

Spinal QCT discriminated trochanteric but not cervical hip fractures [75].

For **HRpQCT of the radius and tibia**, one cross-sectional study reported significant differences of three groups of women with hip fractures with wrist fractures and a control group without fractures. In the direct comparison of women with hip fractures and controls SD decrements of cortical HRpQCT measures looked favorable when compared with aBMD of the spine and the hip [45]. However, age adjustment was not performed and thus uncertainty remains.

In summary, aBMD of the proximal femur measured by DXA remains the most powerful and best tested predictor of hip fracture risk, but multivariate QCT measurements at this site provide similar predictive power. QCT-based evaluation of macrostructure and BMD distribution permits the determination of strength indices and finite element modeling, thereby providing more detailed insight into whole bone strength under varying loading conditions. To date HRpQCT data are too limited to judge the potential.

Mixed fracture groups

Fracture discrimination in general is similar for *peripheral*, *nonvertebral*, and *clinical* fractures. Among tomography-based approaches, prospective fracture risk for *nonvertebral* fractures to date has only been published for **pQCT** of the radius and the tibia [76]. For men, sHRs ranged from 1.4 to 1.6 at the tibia and from 1.6 to 2.2 at the distal third radius site, compared to 2.3 for aBMD of the femoral neck. The predictive power of aBMD of the femoral neck was significantly improved in a multivariate model by addition of pQCT-based strength indices (the best results: the AUCs of ROC analysis improved from 0.73 for aBMD to 0.80 when adding the cross-sectional moment of inertia of the radius).

For **HRpQCT**, trabecular density and microstructure of the radius and both trabecular and cortical density and microstructure of the tibia discriminated *peripheral* fractures in men, but there was no independent contribution of microstructural variables beyond density at these sites [63]. In women, *clinical* fractures could be significantly discriminated by a large range of density and microstructural variables despite lack of discrimination with aBMD of the spine or proximal femur [77]. For prediction of *all* fractures in women, very similar discrimination was reported for density and microstructural variables, and performance seemed to be as least as good as aBMD of the total hip; several density and microstructural variables contributed independently [62]. For men, two studies from the same cohort also reported discrimination of *all* fractures based on a large variety of density and structural variables but, unlike for women, only few remained significant after adjustment for aBMD [63,78].

Spinal QCT predicted non-spine fracture in black and white women and black men, but it was not a stronger predictor than total hip aBMD from DXA [79].

In summary, nonvertebral or clinical fractures risk can be assessed by pQCT and (at a lower level of evidence) also by HRpQCT, while prospective spine or hip QCT data are scant. At peripheral measurement sites the good performance is largely achieved by density or density distribution rather than microstructure. DXA-based aBMD remains the strongest and best tested predictor, but HRpQCT with stronger performance of trabecular measures at the radius and cortical measures at the tibia may add some independent information.

Clinical interpretation

For spinal single-slice QCT, the risk of fracture at a given T-score level is smaller than for DXA because a larger fraction of the T-score reflects age-associated risk, leaving less to BMD-associated risk. Therefore, for a given level of risk, the T-score of QCT has to be lower than the DXA T-score, and that difference increases with age. Given the limited performance of spinal QCT in predicting hip fracture and the increasing prevalence of hip fractures with advancing age, the differences between risk-equivalent T-scores of DXA and QCT increase further at older age. Evidence how to use QCT for treatment decisions is

limited. A comparison of patient data with appropriate reference ranges (not yet available) would provide valuable insight. Most likely, intervention thresholds would have to be lower for QCT than for DXA if expressed as T-scores. From the perspective of evidence-based medicine, a valid DXA scan will in general still be preferable for making treatment decisions. For the future, the development of risk-based intervention criteria for QCT is indicated: Instead of using T-scores, a patient's risk could better be estimated by correcting the average age-associated risk by the QCT-associated risk derived from Z-scores and the technique's standardized gradient of risk [80]. However, this requires standardized methods, reference data, and more studies on QCT-associated fracture risk. These issues have been discussed in greater detail in the ISCD position statement on QCT [31].

Monitoring changes in bone status

A necessary requirement for monitoring is good longitudinal sensitivity (i.e., the ability of the technique to detect the changes early on). Longitudinal sensitivity is defined as the ratio of response rate divided by (long-term) precision errors [80]. Compared with DXA, precision errors of single-slice spinal CT approaches are somewhat higher, but for multislice approaches with automated placement of VOIs levels around 1%, i.e., comparable to spinal DXA, can be achieved [81]. For interpretation of changes in the individual patient, the least significant change [80], therefore, is similar to DXA. Response rates are about twice as large as for DXA for antiresorptive drugs [82] and three times as large during early osteoanabolic treatment [83, 84], and thus the monitoring time interval [80] is correspondingly shorter for QCT. As with DXA, it remains difficult to distinguish bone anabolic versus antiresorptive effects with QCT: increases in mineralization, reduction in porosity (number and size of Haversian canals), and apposition of low-mineral bone volume all result in increases in measured volumetric density. It is not clear yet to what extent QCT changes reflect the anti-fracture efficacy of drugs, but spinal BMD measured with QCT- or HRQCT-based improvements in finite element derived bone strength associated with treatment were larger than the DXA changes seen in the same patients, both for antiresorptive as well as for bone anabolic agents [84, 85].

QCT of the proximal femur has revealed differences in the specific effects bone anabolic and antiresorptive treatment on cortical and trabecular bone [86, 87]. Analysis of strength indices of specific compartments provided detailed insight into mechanism of bone anabolic action not achievable with DXA [13]. The impact of spaceflight on BMD has been investigated with QCT and a loss of 1–2.7% per month was reported [88].

The longitudinal sensitivity of **pQCT at the radius** for monitoring bisphosphonate effects is poorer than that of spinal DXA [89, 90] but treatment effects have been reported for trabecular BMD measured with pQCT [91]. Potentially, HRpQCT techniques may show improved performance. The good spatial resolution of HRpQCT permits differentiation of treatment-induced changes in the cortical and trabecular compartments. For example, in the comparison of denosumab and alendronate, comparable effects on trabecular bone but different effects on cortical bone, specifically cortical BMD and thickness, could be documented [92]. HRpQCT response to bisphosphonates in the tibia appear to be more pronounced than in the radius, driven by trabecular and endocortical changes [93]. Careful matching of the VOI is critical in longitudinal HRpQCT studies. The manufacturer-provided method, which is based on matching the outer perimeter of the bone, may yield misleading results, e.g., in the case of periosteal apposition or, more importantly, in pediatric studies. For such studies, the placement of the VOI at a fixed distance from the mid-joint line may also cause a problem since it disregards bone length. For the tibia, an 8% tibial length criterion might be a useful alternative [40].

There is growing interest in treatment effects on cortical thickness, porosity, and density. However, there are limitations to consider: The lumen of Haversian canals has an average smaller diameter of 70–80 µm [94]. Even if the Haversian cutting cone is larger with a diameter of 100–300 µm [95] and giant osteons with a diameter above 385 µm are more frequent in cases with hip fracture [96], given the 10% modulation transfer function (MTF) at 100-µm porosity, an HRpQCT-based measurement of porosity is substantially biased by partial volume effects. For the same reason, tissue mineral density (TMD) of thin cortices will be underestimated. The overall cortical treatment effects can be measured with HRpQCT but differentiation of effects on porosity, TMD, and cortical thickness is challenging. Assessment of other treatment-induced processes such as differentiation of endosteal apposition versus endosteal trabecularization, or endosteal versus periosteal apposition may be somewhat easier to achieve. For the assessment of treatment-induced microstructural changes in the trabecular compartment, directly measured Tb.N is a better measure than BV/TV since the latter, as currently implemented, only reflects BMD (see above). For HRpQCT-based assessment of the treatment effect of strontium ranelate [97], the incorporation of strontium into the bone has to be considered as an additional source of error. Beyond the overestimation of density, partial volume effects lead to biased structural measures, and thus treatment changes are difficult to interpret.

Finally, differences in the response profile of the measurement sites at the radius and tibia and the main fracture sites at the proximal femur and the vertebra need to be considered.

QCT-BASED FINITE ELEMENT MODELING

A major advantage of tomographic approaches is the feasibility to use the data as the basis for finite element (FE)

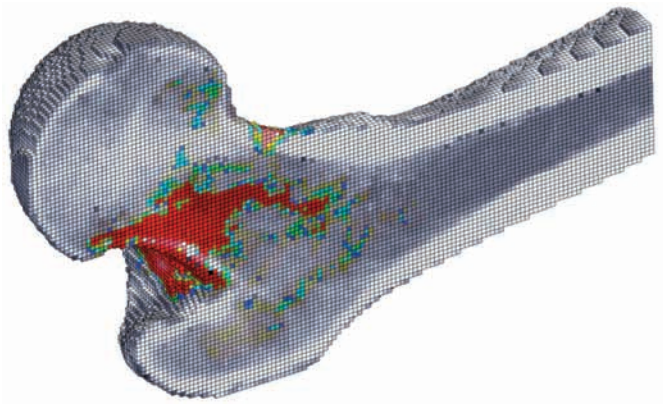

Fig. 31.5. Finite element modeling of the proximal femur (shown sectioned) under a sideways fall load. The areas of high plastic strain (red) are likely those where fractures occur first; grayscale values indicate bone mineral density. (Image provided courtesy of Tony Keaveny.)

analysis [98]. In voxel-based FE models, the bone to be modeled is segmented, and each voxel (or multi-voxel subvolume) of the segmented object is converted into a single element. These elements constitute the building blocks in a mesh that represents the entire the bone. The BMD of the mesh elements is converted into an elasticity tensor, assuming, e.g., orthotropic symmetry of bone tissue. Computer modeling then permits studying of the mechanical interaction of the elements under application of an external load. In this way the relatively simple mechanical properties of the elements can be computer-modeled to derive the complex mechanical properties of whole bones. The strains of the elements can be color-coded for visualization of the resulting strain distribution under the given load (Fig. 31.5). Linear modeling of the stress-strain relationship permits studying whole bone load-deformation processes to determine stiffness, while nonlinear modeling approaches permit to estimate whole bone strength, i.e., fracture loads.

In mechanical tests, the method has been shown to yield more accurate estimates of whole bone strength than DXA or QCT. FE analysis allows modeling of the mechanical competence of whole bones under specific loading conditions [48, 99–102]. It permits studying the respective contribution of cortical and cancellous bone compartments to whole bone strength [47], and it can also be used to identify weak regions that are most likely to fracture under loads [103]. FE analysis produces direct estimates of the forces that a specific bone can withstand. In men, spinal QCT-based FE-derived bone strength predicts incident vertebral fractures significantly better than aBMD with age-adjusted sHRs of 7.2 (3.6, 14.1) vs 3.2 (2.0, 5.2) [51] whereas for hip fractures, no improvement over DXA has yet been accomplished. In combination with estimates of the magnitude of impacting forces, it is possible to derive indices such as the "load-to-strength ratio" (also referred to as "factor or risk") [104]; at a value of greater than 1, the bone is expected to fracture. Whether this measure improves fracture risk assessment beyond FE-based estimates of bone strength remains controversial [51, 58]. Studies in recent years have shown that more detailed information about treatment effects can be obtained from FE modeling [84, 85, 105–107].

FE analysis has substantial potential and could perhaps be integrated as a surrogate marker of bone fragility. Patient-specific FE models could yield results on bone strength that are easier to interpret for clinicians and patients than T-scores. To date, however, only very few centers worldwide contribute to the development, and considerable efforts will be required before this tool will be applicable for clinical routine. Computing power is still a limiting factor, and a number of details of the modeling approach are controversial [98]. Moreover, accuracy errors affecting the underlying QCT data will also bias FE results, e.g., increases in measured BMD caused by strontium ranelate, changes in material properties in secondary osteoporosis; thus these results need to be interpreted with caution. For improved assessment of fracture risk and evaluation of treatment effects, FE models will benefit from further refinements:

- standardized assessment of different and more realistic loading configurations
- reduction of the size and adaptation of the shape of the mesh elements (current element sizes do not yet exploit the potential of HRQCT
- incorporation of the anisotropy of the trabecular network
- standardization of nonlinear modeling approaches
- benchmarking strength—density relationships
- treatment specific strength—density relationships
- addressing discrepancy of material properties across skeletal sites
- incorporation of the role of collagen and age

SUMMARY AND PERSPECTIVES

The renewed interest in QCT has two primary reasons: the deficiencies of DXA in monitoring treatment and the prospect that QCT may not only do better but also yield direct measures of strength (and, addressing the combination of these two aspects, variations in strength induced by treatment). Further refinement in imaging technology, i.e., improvement of spatial resolution (e.g., by use of flat-panel detectors [108]), improved image processing techniques, (e.g., automated placement of anatomically well-defined VOIs and gray-level-based parametric evaluation,) and progress on consensus about standardization (including imaging protocols, VOI definition, and microstructural cross-calibration procedures) may permit significant advances in the following areas:

- differentiation of changes in cortical porosity versus vs changes in TMD
- differentiation of bone anabolic versus antiresorptive effects
- differentiation of endosteal versus periosteal apposition

- improved predictive power, also for subjects already on treatment
- improved concordance of changes in BMD and treatment-induced reduction of fracture risk, i.e., better assessment of treatment efficacy in the individual patient
- incorporation of material properties

Already today, QCT is a valuable clinically applicable tool for the assessment of bone status [31]. However, prospective studies on risk assessment and clinical guidelines for appropriate use need to be expanded. In current clinical settings, a diagnostic QCT-based evaluation can only be carried out if the scanner, calibration method, and the protocol used are well characterized, and if results are compared with published reference data. Recent developments, however, document that the potential for further advances in QCT, specifically for clinical research, is very substantial.

ACKNOWLEDGMENTS

Valuable input by Judith Adams, Keenan Brown, Graeme Campbell, Christian Graeff, Tony Keaveny, Andres Laib, and Jaime Peña is gratefully acknowledged.

INTRODUCTION

Three-dimensional (3D) imaging techniques that reveal bone structure are emerging as important contenders for defining bone quality, at least partially. Techniques such as microcomputed tomography (μCT) have recently been developed and provide high-resolution images of the trabecular and cortical bone micro- and macroarchitecture. This method is routinely used in specimen evaluation and has recently been extended to *in vivo* animal and human extremity imaging. Magnetic resonance (MR) imaging has been used in addition to X-rays, computed tomography, and bone scintigraphy to detect insufficiency fractures, stress fractures, and metastatic fractures. The range of soft tissue contrast possible with different MR techniques has led to the development of techniques that differentiate osteoporotic fractures from metastatic disease, and others that identify stress fractures and related bone marrow changes. However, a more recent development in MR is in the assessment of trabecular bone and cortical bone structure that makes it possible to obtain noninvasive bone biopsies at multiple anatomic sites.

MAGNETIC RESONANCE IMAGING OF TRABECULAR BONE

Trabecular bone consists of a network of rod-like elements interconnected by plate-like elements, immersed in bone marrow composed partly of water and partly of fat. The magnetic susceptibility of trabecular bone is substantially different from that of bone marrow. This gives rise to susceptibility gradients at the bone–marrow interface. Magnetic inhomogeneity arising from these susceptibility gradients depends on the static magnetic field strength, number of bone–bone marrow interfaces, and the size of individual trabeculae [1–3]. These effects cause a rapid signal decay at a rate known as T2*. In a voxel partly occupied by bone and partly by marrow, the static inhomogeneity induced effect leads to signal cancellation within the voxel. T2* methods have been used to quantify trabecular bone, and these measures have been related to bone strength, osteoporotic status, and therapeutic response [4].

Beside the tissue composition, the small dimensions of the trabecular elements (approximately 100 μm) require

very high imaging resolutions. The suitability of an MR imaging method (acquisition and analysis) for depicting bone microstructure depends on its ability to yield images with a high enough signal in a reasonable acquisition time and its ability to derive trabecular structural measurements accurately and reproducibly from the images. The three competing factors to be considered in high-resolution MR imaging (HR-MRI) are signal-to-noise ratio, spatial resolution, and imaging time. Spatial resolution and signal-to-noise ratio (SNR) are both directly related to imaging time but are inversely related to each other. Recent technique developments in trabecular bone MRI technique reflect all these considerations, and the goal has been to increase SNR and accelerate total acquisition times.

By adjusting various times associated with switching on radio-frequency pulses, the duration of radio-frequency pulses that govern a parameter called flip angle in MR acquisitions, images with varying contrast and signal-to-noise features can be obtained. MR pulse sequences can be broadly classified into spin echo and gradient echo sequences. Ideally, 3D spin echo (SE) sequences are better suited for imaging of trabecular bone microarchitecture than gradient echo (GE)-based sequences because they are less sensitive to the thickening of trabeculae due to susceptibility differences. However, GE sequences can be employed with short repetition time (TR) because of their higher SNR efficiency and can thus acquire a 3D volume in a shorter scan time and avoid patient motion artifacts [5, 6]. 3D-SE type pulse sequences with a variable flip angle such as rapid SE excitation (RASEE) [7, 8], large-angle spin-echo imaging [9], and, subsequently, fast 3D large-angle spin-echo imaging (FLASE) [10], and a new fully balanced steady state 3D-spin-echo pulse sequence have also been developed [11]. The choice of pulse sequence for trabecular bone imaging is still a topic of active research. The availability of the sequences at multiple centers, their robustness, and total imaging time versus the anatomical coverage are typical considerations.

SNR is linearly proportional to the static magnetic field strength, perhaps making 3 T preferable over 1.5 T magnets. Phan et al. imaged the trabecular microarchitecture in 40 cadaveric calcaneus specimens at 1.5 T and 3 T, compared it with μCT as gold standard [12] and found that correlations between trabecular structural parameters derived from 3 T MR images and μCT were significantly higher ($p < 0.05$) than correlations between structural parameters obtained from 1.5 T MR imaging and μCT. Preliminary experiments conducted on a 7-T GE Signa scanner yielded a twofold increase in SNR for HR-MRI of trabecular bone [13, 14]. Figure 32.1 shows an example of an HR-MR image obtained at 3 T, in the radius, calcaneus, tibia, and femur, where the bone marrow is bright and trabecular bone is depicted as dark striations. Images such as these can be analyzed to derive structural measures of microarchitecture.

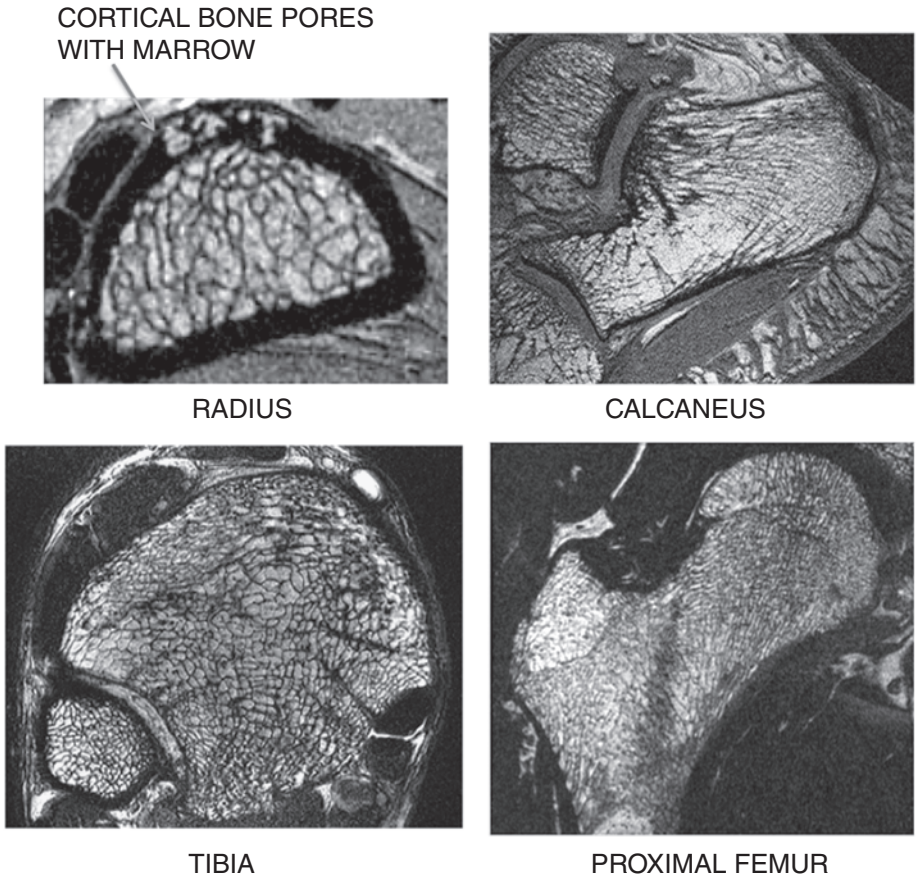

Fig. 32.1. Representative MR images showing trabecular bone in the radius, calcaneus, tibia, and femur. Cortical bone in the radius shows evidence of marrow-filled cortical porosity. Images were acquired at 3 T using a General Electric Signa scanner.

The most common structural measures analogous to quantitative histomorphometry derived from MR images include app.BV/TV, app.Tb.N, app.Tb.Sp, and app. Tb.Th [15, 16], and require the images to be subdivided into a bone and marrow component or binarized. Since the MR images are not acquired at true microscopic resolutions, Majumdar et al. [17] described these measures derived from MR images as "apparent" measurements, which, although obtained in the limited-resolution regime, is highly correlated to the "true" structure. Binarization of an MR image is not a trivial task, and mainly because of partial volume effects, multiple techniques have been developed that operate directly on the grayscale image. Recognizing the fuzzy nature of the images due to partial volume effects, Saha et al. [18] applied a fuzzy distance transform (FDT) technique, a method that obviates the need for a binary assignment of bone and marrow, for computing trabecular thickness and observed an improved robustness in the computation against loss of resolution. Mathematical formulations such as digital topological analysis techniques have also been applied to quantify the number of surface and curved edges, junctions and, interiors in the trabecular network [19].

MAGNETIC RESONANCE IMAGING OF CORTICAL BONE

MR imaging has been used to image cortical bone as well. Specifically for the proximal femur, the ability of MRI to align the image plane perpendicular to the femoral neck is a great advantage and enables more accurate acquisition of the cortical architecture [20]. MRI allows the visualization of soft tissues such as bone marrow and thus a quantification of the amount of cortical porosity that contains bone marrow.

Using advanced MRI methods with ultrashort echo times (UTE), the bone water content in the microscopic pores of the haversian and the lacuno-canalicular systems of cortical bone can be quantified. A smaller water fraction is also bound to collagen and the matrix substrate and imbedded in the crystal structure of the mineral [21]. These micropores usually have a very small size on the order of a few micrometers and are thus difficult to visualize, but the quantification of bone water using MRI could potentially provide a surrogate measure of bone porosity without resolving these individual small pores.

RELATIONSHIP OF MR-DERIVED STRUCTURE MEASURES TO BONE STRENGTH, FRACTURE, OSTEOPOROTIC STATUS, AND RESPONSE TO THERAPY

Several studies relating the measures of trabecular structure obtained using MR imaging to measures of bone strength *in vitro* have been conducted [17, 22–24]. The relationship between whole bone strength and bone structure measures have been demonstrated in radii and in the proximal femur [25, 26].

High-resolution MR images of the distal radius were obtained at 1.5 T in premenopausal normal, postmenopausal normal, and postmenopausal osteoporotic women [27]. Significant differences were evident in spinal bone mineral density (BMD), radial trabecular BMD, trabecular bone volume fraction, trabecular spacing, and trabecular number between the postmenopausal non-fracture and the postmenopausal osteoporotic subjects. Trabecular spacing and trabecular number showed moderate correlation with radial trabecular BMD but correlated poorly with radial cortical BMC.

Distance transformation techniques were applied to the 3D image of the distal radius of postmenopausal patients and structural indices such as app.Tb.N, app. Tb.Th, and app.Tb.Sp were determined without model assumptions [28]. A new metric index, the apparent intraindividual distribution of separations (app.Tb. Sp.SD), was introduced. It was found that app.Tb.Sp.SD discriminates fracture subjects from non-fracture patients as well as dual energy X-ray absorptiometry (DXA) measurements of the radius and the spine, but not as well as DXA of the hip. MR-derived measures of trabecular bone architecture in the distal radius [29] and calcaneus [30] were obtained in 20 subjects with hip fractures and 19 age-matched postmenopausal controls, in addition to BMD measures at the hip DXA and the distal radius [peripheral quantitative computed tomography (pQCT)]. Measures of app.Tb.Sp and app.Tb.N in the distal radius showed significant ($p < 0.05$) differences between the two groups, as did hip BMD measures. However, radial trabecular BMD measures showed only a marginal difference ($p = 0.05$). In the calcaneus, significant differences between both patient groups were obtained using morphological parameters, with odds ratios being slightly higher than BMD [30].

Sagittal MR images of the calcaneus were obtained in 50 men (26 patients with osteoporosis and 24 age-matched healthy control subjects) [31]. Structural parameters, especially connectivity parameters, showed significant differences between control subjects and patients ($p < .05$).

In addition, *in vivo* images have also been combined with micro-finite element analysis in a limited set of subjects. Newitt et al. [32] studied subjects in two groups: postmenopausal women with normal BMD ($n = 22$, mean age 58 ± 7 years) and postmenopausal women with spine or femur BMD –1 SD to –2.5 SD below young normal($n = 37$, mean age 62 ± 11 years). Anisotropy of trabecular bone microarchitecture, as measured by the ratios of the mean intercept length (MIL) values (MIL1/MIL3, etc.), and the anisotropy in elastic modulus (E1/E3, etc.), were greater in the osteopenic group. To date, all studies exploring the role of MRI in predicting fracture risk are based on cross-sectional studies. To establish the role of MR measures for the prediction of fracture

risk, it may be necessary to conduct prospective fracture trials.

The role of MR for assessing therapeutic effects has also been explored. Ninety-one postmenopausal osteoporotic women were followed for 2 years (n = 46 for nasal spray calcitonin; n = 45 for placebo) [33]. MRI measurements of trabecular structure were obtained at the distal radius and calcaneus in addition to DXA–BMD at the spine/hip/wrist/calcaneus (obtained yearly). MRI assessment of the trabecular microarchitecture at individual regions of the distal radius revealed preservation (no significant loss), in the treated group compared with significant deterioration in the placebo control group.

Trabecular bone structure of the tibia was studied in 10 men with severe, untreated hypogonadism and age- and race-matched eugonadal men. Two composite topological indices were determined: the ratio of surface voxels (representing plates) to curve voxels (representing rods), which is higher when architecture is more intact; and the erosion index, a ratio of parameters expected to increase upon architectural deterioration to those expected to decrease, which is higher when deterioration is greater. The surface/curve ratio was 36% lower ($p = 0.004$), and the erosion index was 36% higher ($p = 0.003$) in the hypogonadal men than in the eugonadal men [34]. In contrast, bone mineral density of the spine and hip were not significantly different between the two groups. After 24 months of testosterone treatment, BMD of the spine increased 7.4% ($p < 0.001$), and BMD of the total hip increased 3.8% ($p = 0.008$). Architectural parameters assessed by MRI also changed: The surface-to-curve ratio increased 11% ($p = 0.004$) and the topological erosion index decreased 7.5% ($p = 0.004$) [35].

Until recently, *in vivo* MRI of trabecular microarchitecture was limited to peripheral sites such as distal tibia and femur, radius, and calcaneus because of SNR limitations. However, the main sites of osteoporotic fractures are nonperipheral regions such as the vertebral bodies (spine) and the proximal femur (hip). HR-MRI has only recently been applied to the proximal femur [36] by using SNR efficient sequences, high magnetic field strength (3 T), and phased array coils.

APPLICATIONS USING MR-DERIVED CORTICAL BONE MEASURES

Although significant work has been done using MRI to measure trabecular bone structure, there is relatively little work on the macroarchitectural geometry of the cortex, which may play an equally important role for bone strength. Recently, Gomberg [20] investigated cortical shell geometry of the femur, further expanding the potential role of MR in characterizing bone. In a recent study, images of the distal radius and the distal tibia of 49 postmenopausal osteopenic women (age 56 ± 3.7) were acquired with both HR-pQCT and MRI [37]. It was found that the amount of cortical porosity did not vary greatly between subjects but the type of cortical pore containing marrow versus not containing marrow varied highly between subjects.

Bone water quantification measurements have been previously conducted in sheep and human cadaveric specimens, and the method's sensitivity to distinguish subjects of different ages and disease states has been evaluated [38]. The data were compared with areal and volumetric BMD from DXA and pQCT, respectively. The bone water content was calibrated with the aid of an external reference (10% H_2O in D_2O doped with 27 mmol/L MnCl2), which was attached anteriorly to the subject's tibial midshaft. Excellent agreement ($R^2 = 0.99$) was found in the specimen between the water displaced by using D_2O exchange and water measured with respect to the reference sample. Measurements *in vivo* revealed that the bone water content was increased 65% in the postmenopausal group compared to the premenopausal group [39]. Patients with renal osteodystrophy had 135% higher bone water content than the premenopausal group whereas conventional BMD measurements showed an opposite behavior, with much smaller group differences.

SUMMARY

Imaging trabecular and cortical microarchitecture and characterizing the features of trabecular and cortical bone has been an area of fertile and ongoing research. Beyond relating microarchitecture to the biomechanical properties of bone in specimens, advances have been made to extend these measures *in vivo* in human subjects. In this context, the relationship between, age, fracture status, and even post-therapeutic response has been studied. New advances in peripheral CT, MR (non-ionizing, peripheral sites, calcaneus, and femur) are ongoing and evolving at a rapid pace, and with the establishment of robust analysis methodologies and normative databases, they have the potential for further clinical utilization in the coming years.

INTRODUCTION

Radionuclide bone imaging remains the most widely used method for detection of benign and metastatic involvement of the skeleton. Current gamma cameras systems are able to perform high-resolution imaging in short scan times (whole body acquisitions or localized views of the skeleton). The radiation dose from bone scintigraphy is relatively low [0.005 mSv/MBq, giving a typical radiation dose of 3–5 mSv equivalent to 20–25% of that from a computed tomography (CT) scan from neck to pelvis]. More recently, single photon emission CT (SPECT) imaging has become widely available and is becoming routine in nuclear medicine, leading to improved sensitivity and specificity for lesion detection as a result of tomographic data. Currently, hybrid SPECT/CT and positron emission tomography (PET)/CT scanners are the newest additions to the diagnostic armamentarium.

Bisphosphonate compounds such as methylene diphosphonate (MDP), labeled with ^{99m}Tc, are the most commonly used radiopharmaceuticals for bone scintigraphy. Their exact mechanism of localization in bone is not fully understood. However, it is likely that they are adsorbed onto the surface of hydroxyapatite crystals at sites of active mineralization. The degree of accumulation in bone is dependent on local blood flow but is influenced more strongly by the degree of osteoblastic activity and hence bone formation. In general, pathologic processes that involve bone result in increased local bone turnover, with both osteoblast and osteoclast activity being increased. As osteoblastic and osteoclastic activity is coupled in most bone pathology, increased uptake of bone tracers is present in most bone pathology.

BONE METASTASES

Radionuclide bone imaging is routinely used for detecting bone metastases in high-risk or symptomatic patients with prostate, breast, and some other cancers. The success of imaging bone lesions depends on the osteoblastic response, which usually accompanies bone destruction by a metastasis. However, rarely with aggressive metastases where bone is unable to mount sufficient osteoblastic response there may be false negatives, and this is most commonly seen in multiple myeloma. The radionuclide imaging of bone metastases is extensively reviewed elsewhere [1–3] and is beyond the scope of this chapter.

OSTEOPOROSIS

The bone scan has no role in the diagnosis of osteoporosis *per se* but is most often used in established osteoporosis to aid with the diagnosis of vertebral or other fractures

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

Fig. 33.1. A ^{99m}Tc-MDP bone scan showing typical linear uptake in vertebral fractures. The different intensities suggest they occurred at different times.

(e.g., sacrum, pelvis, or rib) and has a valuable role in the evaluation and management of patients with back pain [4]. The characteristic appearance of a vertebral fracture is of intense, linearly increased tracer uptake at the affected level (Fig. 33.1). Although the bone scan may become positive immediately after a fracture, this varies between skeletal sites, and in the spine it can take up to 2 weeks to become abnormal [5]. The level of uptake diminishes gradually over a period of time, with the scan normalizing between 3 and 18 months after the incident, the average being between 9 and 12 months. The degree of intensity is therefore also useful in assessing the age of fractures.

In general, if a patient is complaining of back pain with multiple vertebral fractures on radiographs but has a normal bone scan, this essentially excludes a recent fracture as a cause for the patient's symptoms. In these clinical scenarios, other causes of pain should be considered and may well be identified on the bone scan (e.g., facetal joint disease).

Vertebral fractures are defined on the basis of morphometry, but morphometric abnormalities are not specific to fracture and, for example, may be caused by congenital vertebral anomalies [6]. The bone scan may therefore have a role in deciding whether a morphometric abnormality is related to a fracture, provided that it is acquired within several months of the start of symptoms (it is generally positive for 6–18 months, with fading intensity). Similarly, edema on MRI scans indicates an acute fracture (often important to decide upon vertebroplasty or kyphoplasty), and other radiological features may be able to differentiate benign from malignant causes of vertebral collapse when this is considered to be a clinical issue [7, 8].

The radionuclide bone scan, being highly sensitive, is useful in identifying unsuspected osteoporotic fractures at other sites such as ribs, pelvis, and hip. It also has an important role in assessing suspected fractures where radiography is unhelpful, either because of poor sensitivity related to the anatomic site of the fracture (e.g., sacrum) or because adequate views are not obtainable because of the patient's discomfort or mobility.

A radionuclide bone scan also may be valuable in patients in whom back pain persists for longer than one would expect after a vertebral fracture (e.g., because of additional unsuspected vertebral fractures). In addition, we are increasingly becoming aware that osteoporotic patients with chronic back pain may have unsuspected abnormalities affecting the neighboring facet joints [9]. It is not known whether this is related to physical disruption of the joint at the time of vertebral collapse or is caused by subsequent secondary degenerative or inflammatory changes. To identify abnormalities in the facet joints, SPECT imaging is essential.

PAGET'S DISEASE

The radionuclide bone scan is invaluable in Paget's disease, both for diagnosis and to define the extent of skeletal involvement. It provides a simple way to evaluate the whole skeleton with greater sensitivity than radiographic skeletal surveys [10]. Characteristically, affected long bones show intensely increased activity, which starts at the end of a bone and spreads either proximally or distally, often showing a "V" or "flame-shaped" leading edge (Fig. 33.2). Another clue that a scintigraphic abnormality is caused by Paget's disease rather than other focal skeletal pathology is that a whole bone is often involved, and this is most often evident in the pelvis, scapula, and vertebrae. The common differential diagnosis is fibrous dysplasia. However, lack of preservation of bony outline in fibrous dysplasia can help differentiate it from Paget's disease.

The role of the bone scan with regard to treatment response assessment is not well defined. A radionuclide bone scan can be obtained 3 to 4 months after therapy, and it is important to note that pagetic lesions may often respond in a heterogeneous manner, even in individual patients. After intravenous bisphosphonate therapy, some bones may completely normalize, whereas the majority show some improvement, and a small proportion remain unchanged [11].

The bone scan may provide a sensitive means to assess persistent metabolically active disease or to identify reactivation of disease, influencing decisions on the timing of further treatment, although there is no evi-

Fig. 33.2. A ^{99m}Tc-MDP bone scan (anterior and posterior images) showing intense activity in a number of skeletal sites typical of Paget's disease.

dence to support such an approach. However, it may be of particular use in patients with monostotic disease where biochemical markers are less sensitive [12]. It is important to be aware that the bone scan appearances can be unusual, and indeed bizarre, after successful bisphosphonate treatment, with resultant heterogeneous uptake sometimes mimicking metastatic disease, and hence knowledge of the relevant history and previous treatments is essential for correct interpretation. Several quantitative methods have been reported to evaluate the absolute skeletal uptake of the tracer, but none have been found to be of sufficient value to be used in routine clinical practice [13].

The radionuclide bone scan may occasionally identify complications of Paget's disease. Although osteosarcoma complicating Paget's disease is very rare (less than 1%), clues that sarcomatous change may have occurred include a change to heterogeneous and irregular uptake within an area of bone, perhaps with some photon-deficient areas corresponding to bone destruction. However, the bone scan may be misleading in the event of fracture or sarcomatous change or both. Thus, in general, the radionuclide bone scan is not reliable in the diagnosis of skeletal complications of Paget's disease, and complementary radiological correlation is necessary.

The radiopharmaceutical ^{18}F-fluorodeoxyglucose (FDG) PET evaluates tissue glucose metabolism and can differentiate benign from malignant tissue in many tumors. In principle, it could be a useful tool in distinguishing the benign changes of Paget's disease from associated osteosarcomas. However, it is important to be aware that some FDG uptake may be seen in patients with more active Paget's disease [14]. The bone-specific PET tracer ^{18}F-fluoride has a similar mechanism of uptake to ^{99m}Tc-diphosphonates. It is reported to be useful to measure the activity of Paget's disease of bone and as a promising noninvasive tool to monitor the therapeutic efficacy of bisphosphonate regimens in Paget's disease [15]. Although it essentially provides the same information as a conventional bone scan, quantitative accuracy is superior with PET.

HYPERPARATHYROIDISM

Most cases of primary hyperparathyroidism are asymptomatic and are unlikely to be associated with changes on bone scintigraphy. The diagnosis is made biochemically, and the bone scan therefore has no routine role in diagnosis. However, bone scans are often used to help differentiate the causes of hypercalcemia—in particular, hyperparathyroidism versus malignancy, and so typical features of metabolic bone disorders may be recognized. A bone scan may show a number of features in hyperparathyroidism, but the most important is the generalized increased uptake throughout the skeleton, identified as increased contrast between bone and soft tissues. Indeed, renal activity normally clearly seen on a bone scan may not be evident. This appearance has been termed a "superscan" because of the apparent high-quality images. Other typical features that have been described include a prominent calvarium and mandible, beading of the costochondral junctions (rosary beads), and prominent uptake in the sternum (the "tie" sign), sometimes with horizontal lines ("striped-tie" sign) [16]. Severe forms of hyperparathyroidism may be associated with ectopic calcification, which may lead to uptake of bone radiopharmaceuticals in soft tissues.

Nuclear medicine is the most frequently used modality for localizing abnormal parathyroid glands before surgery. Most commonly, it is performed using dual-phase ^{99m}Tc-sestamibi imaging (early and delayed imaging at 15 min and 2–3 hours, respectively) [17]. The current radionuclide tracer of choice for radionuclide localization of parathyroid adenomas is ^{99m}Tc-sestamibi. However, it is less useful in patients with secondary hyperparathyroidism, where the predominant pathology is often hyperplasia rather than adenoma.

The most frequent cause of false-positive results in ^{99m}Tc-sestamibi parathyroid imaging is the solid thyroid nodule (either solitary or multinodular gland), thyroid carcinoma, lymphoma, and other causes of lymphadenopathy. False-negative results may arise from the failure of ^{99m}Tc-sestamibi imaging to identify some smaller parathyroid lesions, which relates to system resolution and to the amount of tracer uptake by the parathyroid tissue. The addition of ^{99m}Tc-sestamibi SPECT to radionuclide scintigraphy is reported to increase the sensitivity and accuracy. More recently, ^{99m}Tc-sestamibi SPECT/CT has been used in the localization of adenomas. However, it has been reported to offer no significant additive value over conventional SPECT for identifying a normally located parathyroid adenoma, but it may assist in localizing ectopic parathyroid adenomas [18].

PET imaging using ^{11}C-methionine is reported to correctly localize abnormal parathyroid glands in patients with recurrent hyperparathyroidism for whom conventional nuclear medicine techniques have failed [19]. However, its role in routine practice is debatable because short-lived tracers that require a cyclotron for production will not be available in most centers.

RENAL OSTEODYSTROPHY

Renal osteodystrophy is caused by a combination of several metabolic bone disorders as a consequence of chronic renal dysfunction and often shows the most severe cases seen on the bone scan. It may be made up of osteoporosis, osteomalacia, adynamic bone, and secondary hyperparathyroidism in varying degrees. The most common bone scan appearance is a superscan reflecting hyperparathyroidism (Fig. 33.3). A clue in dif-

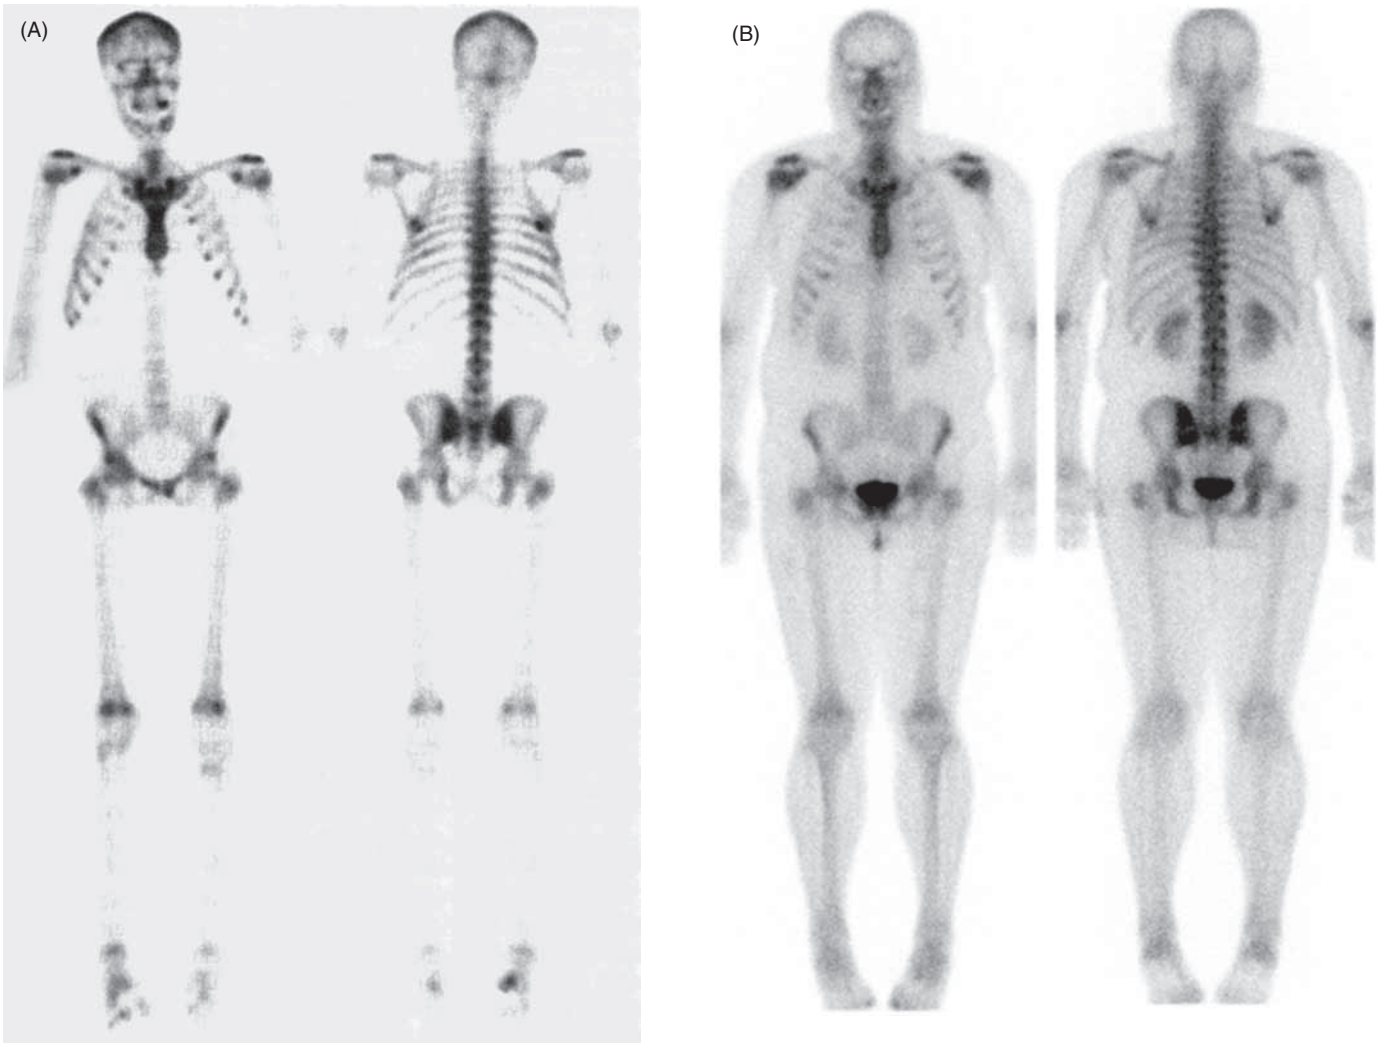

Fig. 33.3. (A) A ^{99m}Tc-MDP bone scan showing increased uptake throughout the skeleton (increased bone:soft tissue ratio) in a patient with chronic renal failure and biochemistry consistent with osteomalacia. (B) A normal bone scan is presented for comparison.

ferentiating this type of scintigraphic pattern from others is that there may be a lack of bladder activity. Although scintigraphic patterns may indicate the presence of renal osteodystrophy, the bone scan generally simply reflects the degree of hyperparathyroidism and cannot replace histologic analysis to assess the underlying determinants. Adynamic bone characteristically shows poor skeletal uptake of tracer, and the bone scan may therefore help differentiate this from the disorders with accelerated turnover.

OSTEOMALACIA

Patients with osteomalacia usually show similar features on a bone scan as described in hyperparathyroidism, although in the early stages of the disease, they may appear normal. Tracer avidity may reflect diffuse uptake in the osteoid, although it is more likely that it is caused by the secondary hyperparathyroidism that is present. The presence of focal lesions may represent pseudofractures or true fractures. Although osteomalacia may be suspected from the biochemistry, it is a histologic diagnosis. However, the typical bone scan features may be helpful in supporting the diagnosis. The detection of pseudofractures with this technique is more sensitive than that with radiography [20, 21].

CONCLUSION

The radioisotope bone scan remains a valuable method in the evaluation of malignant and metabolic bone diseases, providing functional and potentially quantitative information on bone metabolism. Recent advances in hybrid anatomical/functional imaging will consolidate the roles of radioisotope imaging in skeletal disease. In particular, hybrid SPECT/CT provides an opportunity to more accurately assess specific clinical problems, such as persistent back pain in osteoporotic patients.

INTRODUCTION

A major objective of fracture risk assessment is to enable the targeting of interventions to those at need and avoid unnecessary treatment in those at low risk of fracture. Historically, fracture risk assessment was largely based on the measurement of bone mineral density (BMD), since osteoporosis is defined operationally in terms of bone mass [1, 2]. Whereas BMD forms a central component in the assessment of risk, the accuracy of risk prediction is improved by taking into account other readily measured indices of fracture risk, particularly those that add information to that provided by BMD. Several risk prediction models have been developed, but the most widely used is FRAX®.

INPUT AND OUTPUT

FRAX® is a computer-based algorithm (http://www.shef.ac.uk/FRAX) developed by the World Health Organization Collaborating Centre for Metabolic Bone Diseases and first released in 2008 [3, 4]. The algorithm, intended for primary care, calculates fracture probability from easily obtained clinical risk factors (CRFs) in men aged 50 years or older, and postmenopausal women. The output of FRAX is the 10-year probability of a major osteoporotic fracture (hip, clinical spine, humerus, or wrist fracture) and the 10-year probability of hip fracture (Fig. 34.1).

Fracture probability is derived from the risk of fracture as well as the risk of death. Fracture risk is calculated from age, body mass index, and dichotomized risk factors comprising prior fragility fracture, parental history of hip fracture, current tobacco smoking, long-term oral glucocorticoid use, rheumatoid arthritis, excessive alcohol consumption, and other causes of secondary osteoporosis. Femoral neck BMD can be optionally input to enhance fracture risk prediction. Apart from rheumatoid arthritis and long-term use of glucocorticoids, the other secondary causes of osteoporosis considered (Table 34.1) are conservatively assumed to contribute to increased fracture risk because of low BMD.

The relationships between risk factors and fracture risk have been constructed using information derived from the primary data of population-based cohorts from around the world, including centers from North America, Europe, Asia, and Australia, based on a series of meta-analyses to identify clinical risk factors for fracture that provide independent information on fracture risk [3]. The use of primary data for the model construct permits the determination of the predictive importance in a multivariable context of each of the risk factors, as well as interactions between risk factors, and thereby optimizes

the accuracy by which fracture risk can be computed [5, 6]. The fracture risk assessment with the combined use of these clinical risk factors with and without the use of BMD has been validated in independent cohorts with a similar geographic distribution with in excess of 1 million patient years [7–9].

Fracture probability is computed taking both the risk of fracture and the risk of death into account. The inclusion of the death hazard is important because those with a high immediate likelihood of death are less likely to fracture than individuals with longer life expectancy (Fig. 34.2). In addition, some of the risk factors affect the risk of death as well as the fracture risk. Examples include increasing age, low body mass index (BMI), low BMD, glucocorticoids, and smoking. Other risk tools calculate the risk of fracture without taking into account the possibility of death [9, 10]. Fracture probability varies markedly in different regions of the world [11]. Thus, the FRAX® models are calibrated to those countries where the epidemiology of fracture and death is known. Models are currently available for 52 countries and 24 languages. Ethnic-specific models are available in the U.S. and Singapore.

FRAX has been widely used for the assessment of patients since the launch of the website in 2008, and currently makes about 11,000 calculations per working day. Following regulatory review by the U.S. Food and Drug Administration, FRAX was incorporated into dual energy X-ray absorptiometry (DXA) scanners to provide FRAX probabilities at the time of DXA scanning. For those without Internet access, handheld calculators and an application for the iPhone and iPad have been developed by the International Osteoporosis Foundation (http://itunes.apple.com/us/app/frax/id370146412?mt=8).

PERFORMANCE CHARACTERISTICS

For the purpose of risk assessment, a characteristic of major importance is the ability of a technique to predict fractures. This is traditionally expressed as the increase in relative risk per standard deviation (SD) unit decrease in risk score—termed the "gradient of risk." The gradient of risk (GR) is shown in Table 34.2 for the use of the clinical risk factors alone, femoral neck BMD and the combination.

The use of clinical risk factors alone provides a gradient of risk that lies between 1.4 and 2.1, depending upon age and the type of fracture predicted. These gradients are comparable to the use of BMD alone to predict frac-

Table 34.1. Secondary Causes of Osteoporosis Associated With an Increase in Fracture Risk*

Secondary Cause	Example
Glucocorticoids	Any dose, by mouth for 3 months or more
	High doses of inhaled glucocorticoids
	Cushing's disease
Rheumatoid arthritis	
Chronic liver disease	Alcoholism
Untreated hypogonadism	Bilateral oophorectomy or orchidectomy,
	Anorexia nervosa
	Chemotherapy for breast cancer
	Tamoxifen in premenopausal women
	Aromatase inhibitors
	GnRH inhibitors for prostate cancer
	Hypopituitarism
Prolonged immobility	Spinal cord injury
	Parkinson's disease
	Stroke
	Muscular dystrophy
	Ankylosing spondylitis
Organ transplantation	
Type 1 and 2 diabetes	
Thyroid disorders	Untreated hyperthyroidism
	Overtreated hypothyroidism
Gastrointestinal disease	Crohn's disease
	Ulcerative colitis
Chronic obstructive pulmonary disease

tures [13, 14], indicating that clinical risk factors alone are of value in fracture risk prediction and might be used, therefore, in the many countries where DXA facilities are sparse [15]. Nevertheless, there are substantial gains in the use of the clinical risk factors in conjunction with BMD, particularly in the case of hip fracture prediction. At the age of 50, for example, the gradient of risk with BMD alone is 3.7/ SD, but with the addition of clinical risk factors is 4.2/SD. Although the improvement in GR with the addition of BMD appears relatively modest, particularly in the case of other osteoporotic fractures, it

Table 34.2. Gradients of Risk (HR/per SD Change in Risk Score) (with 95% confidence intervals) With the Use of BMD at the Femoral Neck, Clinical Risk Factors, or the Combination*

	Gradient of Risk		
Age (years)	Clinical Risk Factors Alone	BMD Only	Clinical Risk Factors + BMD
(a) Hip fracture			
50	2.05 (1.58–2.65)	3.68 (2.61–5.19)	4.23 (3.12–5.73)
60	1.95 (1.63–2.33)	3.07 (2.42–3.89)	3.51 (2.85–4.33)
70	1.84 (1.65–2.05)	2.78 (2.39–3.23)	2.91 (2.56–3.31)
80	1.75 (1.62–1.90)	2.28 (2.09–2.50)	2.42 (2.18–2.69)
90	1.66 (1.47–1.87)	1.70 (1.50–1.93)	2.02 (1.71–2.38)
(b) Other osteoporotic fractures			
50	1.41 (1.28–1.56)	1.19 (1.05–1.34)	1.44 (1.30–1.59)
60	1.48 (1.39–1.58)	1.28 (1.18–1.39)	1.52 (1.42–1.62)
70	1.55 (1.48–1.62)	1.39 (1.30–1.48)	1.61 (1.54–1.68)
80	1.63 (1.54–1.72)	1.54 (1.44–1.65)	1.71 (1.62–1.80)
90	1.72 (1.58–1.88)	1.56 (1.40–1.75)	1.81 (1.67–1.97)

should be recognized that GRs are not multiplicative. For example, at the age of 70, BMD alone gave a GR of 2.8/SD for hip fracture. For the clinical risk factors the GR was 1.8/SD. If these two tests were totally independent, the combined GR would be $\sqrt{(2.08^2 + 1.8^2)} = 3.3$. The observed GR (2.9) falls short of the theoretical upper limit, since there is a significant correlation between the clinical risk factor score and BMD.

LIMITATIONS

FRAX should not be considered as a gold standard in patient assessment, but rather as a reference platform. The same argument applies to BMD testing. Thus, the result should not be uncritically used in the management of patients without an appreciation of its limitations as well as its strengths. In some instances, limitations (e.g., to experts in bone disease) are perceived as strengths to others (e.g., primary care physicians).

Assessment with FRAX takes no account of current or prior treatment, though the effect of treatment on the estimated fracture probability is modest, related in part to treatment-induced increases in BMD [16]. FRAX also takes no account of dose responses for several risk factors. For example, two or more prior vertebral fractures carry a much higher risk than a single prior fracture [17]. A prior clinical vertebral fracture carries an approximately twofold higher risk than other prior fractures. Dose responses are also evident for glucocorticoid use, smoking, and alcohol consumption [3, 18]. Since it is not possible to model all such scenarios with the FRAX algorithm, these limitations should temper clinical judgement.

In the case of glucocorticoids, simple arithmetic procedures have been formulated that can be applied to conventional FRAX estimates of probabilities of hip fracture and a major osteoporotic fracture to adjust the probability assessment with knowledge of the dose of glucocorticoids (Table 34.3). For example, an individual at the age of 60 years taking a high dose of glucocorticoids and with a probability of a major fracture of 18% would have the FRAX estimate uplifted by 15%, giving a revised probability of 21% (17 × 1.25). In contrast, if the patient were exposed to a low dose, the revised estimate would be 15%.

A further limitation is that the FRAX algorithm uses T-scores for femoral neck BMD from DXA and does not accommodate other sites or technologies. The lumbar spine is frequently measured by DXA for the assessment of patients and, indeed, is incorporated into many clinical guidelines [20–23]. It is also the site favored for monitoring treatment. There is, therefore, much interest in the incorporation into FRAX of measurements at the lumbar spine. Whereas this is not possible at present, some guidance is available in cases where there is a large discordance between the T-score at the femoral neck and the lumbar spine [24]. It has been proposed that the FRAX estimate for a major fracture is increased/decreased by one-tenth for each rounded T-score difference between the lumbar spine and femoral neck. An example is a case in which the T-score for femoral neck BMD is –2.2 SD with a FRAX-calculated fracture probability of 19% and a T-score of –3.5 SD at the lumbar spine. In this case, the T-score discordance is 1.3 SD (3.5 – 2.2). If the figure is rounded off (to 1.0 SD), the estimated probability with the inclusion of lumbar BMD is upward revised by 10% (19 + 1.9) to 21%.

INTERVENTION AND ASSESSMENT THRESHOLDS

The use of FRAX in clinical practice demands a consideration of the fracture probability at which to intervene,

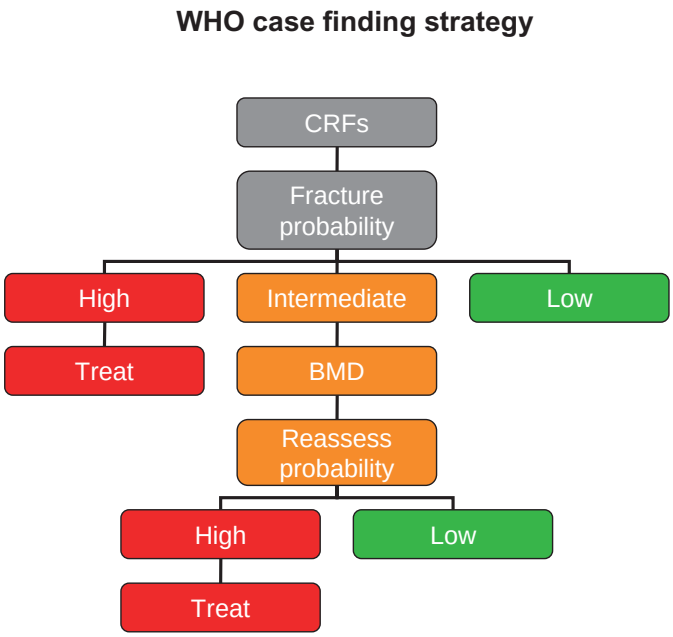

Fig. 34.3. Management algorithm for the assessment of individuals at risk of fracture (Ref. 25)]. With kind permission from Springer Science+Business Media B.V.

both for treatment (an intervention threshold) and for BMD testing (assessment thresholds). A general approach is shown in Fig. 34.3 [25]. The management process begins with the assessment of fracture probability and the categorization of fracture risk on the basis of age, sex, body mass index, and clinical risk factors. On this information alone, some patients at high risk may be offered treatment without recourse to BMD testing. Many guidelines recommend treatment in the absence of information on BMD in women with a previous fragility fracture (a prior vertebral or hip fracture in North America) [21, 23, 26]. Many physicians would also perform a BMD test, but frequently this is for reasons other than to decide on intervention, for example, as a baseline to monitor treatment. There will be other instances where the probability will be so low that a decision not to treat can be made without BMD. An example might be the woman at menopause in good health with no clinical risk factors. Thus, not all individuals require a BMD test. The size of the intermediate category in Fig. 34.3 will vary in different countries. In the U.S., this will be a large category, whereas in a large number of countries with limited or no access to densitometry [15], the size of the intermediate group will necessarily be small. In other countries (e.g. the U.K.), where provision for BMD testing is suboptimal, the intermediate category will lie between the two extremes.

FRAX has been accommodated to a greater or lesser extent in many assessment guidelines including those from Austria, Belgium, Canada, Europe, France, Greece, Hungary, Ireland, Italy, Japan, Netherlands, Poland, Singapore, Sri Lanka, Sweden, Switzerland, the U.K., and the U.S. The setting of intervention thresholds is problematic from an international perspective since the risk of fracture, the cost of fracture, the cost of treatment, reimbursement, and willingness to pay varies in different countries. Thus, probability-based guidelines differ in detail. Guidelines variously use an age-dependent fracture probability or a fixed probability threshold applied to all relevant ages. Examples of each are provided in the guidelines of the U.K. and North America, illustrated below in the case of postmenopausal women.

GUIDELINES IN THE U.K.

The U.K. guidance for the identification of individuals at high fracture risk, developed by the National Osteoporosis Guideline Group (NOGG) [25–27], recommends that postmenopausal women with a prior fragility fracture may be considered for intervention without the necessity for a BMD test. In women without a fragility fracture but with a FRAX risk factor, the intervention threshold set by NOGG is at the age-specific fracture probability equivalent to women with a prior fragility fracture. The same intervention threshold is applied to men, since the effectiveness and cost-effectiveness of intervention in men is broadly similar to that in women for equivalent risk [28, 29].

The NOGG management strategy considers two additional thresholds (Fig. 34.4):

- a threshold probability below which neither treatment nor a BMD test should be considered (lower assessment threshold)
- a threshold probability above which treatment may be recommended irrespective of BMD (upper assessment threshold)

In other words, some patients at high risk may be offered treatment without recourse to BMD testing. Conversely, some patients at low risk will be denied treatment without a BMD test. An attraction of the approach is that efficient use is made of BMD testing. For example, the NOGG strategy requires only 3.5 scans at the age of 50 years to identify one case of hip fracture, whereas the former guidelines of the Royal College of Physicians required 14. The lower number of BMD tests means that the acquisition costs for identifying a fracture case and the total costs (acquisition and treatment) per fracture averted are also lower [30].

The justification for this parsimonious approach derives from the correlation between fracture probability (without BMD) and BMD. It has been shown in several studies that the reclassification of high risk to low risk (and vice versa, from low risk to high risk) with the incorporation of BMD in the FRAX calculation is more or less confined to those close to an intervention threshold. Indeed, more than 80% of women who are reclassified have probabilities without BMD within 5% of the

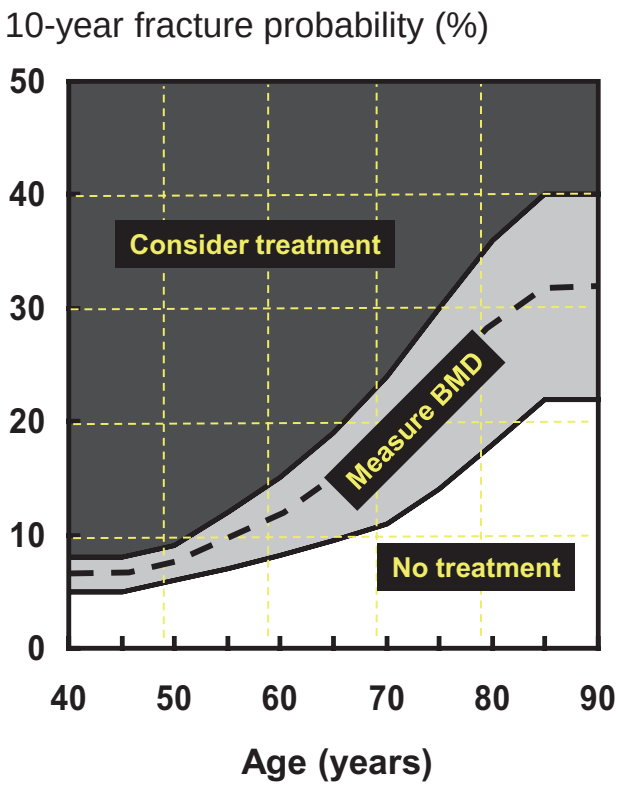

Fig. 34.4. Assessment guidelines of the National Osteoporosis Guideline Group based on the 10-year probability of a major fracture (%). The dotted line denotes the intervention threshold, which increases with age. Where assessment is made in the absence of BMD, a BMD test is recommended for individuals where the probability assessment lies in the lightly shaded region (adapted from Ref. 25).

treatment threshold. This figure rises to about 95% for probabilities without BMD within 10% of the treatment threshold. Thus, a BMD test is only required in individuals whose fracture probability lies within about 10% of the intervention threshold, thereby avoiding unnecessary testing in about 50% of eligible women without a prior fragility fracture [31].

GUIDELINES IN NORTH AMERICA

In the U.S. and Canada, the national guidelines recommend treatment for postmenopausal women who have had a prior spine or hip fracture and for women with a BMD at or below a T-score of -2.5 SD [20, 21, 23, 26]. Thus, as for the U.K., they recognize high-risk groups in whom treatment can be recommended without FRAX, but the high-risk groups differ (a prior fragility fracture in the U.K.). Conversely, the guidelines do not recommend treatment in postmenopausal women with a T-score of greater than –1.0 SD. In the U.K., the exclusion group is women without a clinical risk factor. Thus FRAX in North America becomes relevant only in women with a T-score between –1 and –2.5 SD. Treatment is recommended in such patients in whom the 10-year probability of a major fracture equals or exceeds 20% or (in the U.S. but not Canada) when the 10-year probability of a hip fracture equals or exceeds 3%.

Thus there are similarities and differences with the U.K. and North American guidelines. The similarities are that both guidelines select high-risk patients in whom treatment is recommended and low-risk groups in whom treatment is not recommended (though the categories differ somewhat). The differences lie in the intervention thresholds (fixed or age dependent) and the use of BMD in the intermediate group (all women in North America, assessment thresholds in the U.K.). Neither approach is right nor wrong, but both are imperfect and will remain so until fracture risk prediction can be improved still further.

GUIDELINES WITHOUT BMD TESTING

Many regions of the world have little or no access to BMD. In these circumstances, FRAX without BMD can be used. The clinical risk factors used in FRAX are not totally independent of BMD. Indeed there is a weak but significant correlation between the clinical risk factor score for hip fracture (assessed without BMD) and BMD at the femoral neck. This indicates that the selection of individuals with the use of FRAX, without knowledge of BMD, will preferentially select those with low BMD, and that the higher the fracture probability, the lower will be the BMD. When a fixed intervention threshold is chosen, the high-risk group has a BMD that is approximately 1SD lower than in the low-risk group [31].

As noted above, the prediction of fractures with the use of clinical risk factors alone in FRAX is comparable to the use of FRAX without BMD to predict fractures is suitable, therefore, in the many countries where DXA facilities are sparse. Notwithstanding, intervention thresholds still need to be determined.

OTHER APPLICATIONS OF FRAX

Several studies have examined the relationship between FRAX-based probability of fracture and efficacy of bone-active agents used in the treatment of osteoporosis. In some, but not all instances, efficacy (relative risk reduction) has been shown to be greater in patients with the higher baseline fracture probabilities [32]. This has implications for targeting treatments to high-risk patients in that the dividends in terms of fractures saved is amplified. This also has implications for health economic assessment and conventional meta-analyses of interventions used in osteoporosis [33].

CONCLUSION

FRAX represents a significant advance in the assessment of both women and men at risk for fracture and allows the tailoring of pharmacologic interventions to high-risk subjects. While FRAX does not define intervention thresholds, which depend on country-specific considerations, it provides a platform to assess fracture probability, which is needed to make rational treatment decisions by clinicians and public health agencies. The tool is, however, far from perfect, but better than BMD alone. The widespread use and interest in FRAX, and its adoption into management guidelines, has fueled interest as to how models can be improved, extended to other countries, and in particular, how the limitations of FRAX should temper clinical judgement.

INTRODUCTION

Bone turnover is characterized by two opposite activities: bone formation and bone resorption [1]. During bone remodeling (after growth arrest and during aging), bone formation is preceded by bone resorption. Both activities are coupled at a basic multicellular unit (BMU) [also called bone remodeling unit (BRU)]. During bone resorption, dissolution of bone mineral and catabolism of bone matrix by osteoclasts results in the formation of resorptive cavity and the release of bone matrix components. Then, during bone formation, osteoblasts synthesize bone matrix, which fills in the resorption cavity and undergoes mineralization.

There are two groups of biochemical bone turnover markers (BTMs), markers of bone formation and markers of bone resorption (Table 35.1). Recently, an expert panel convened by the International Osteoporosis Foundation and International Federation of Clinical Chemistry and Laboratory Medicine proposed that PINP and serum CTX-I become the referent markers of bone formation and resorption, respectively [2]. PINP is derived from post-translational cleavage of type I procollagen molecules before assembly into fibrils. Circulating PINP originates primarily from bone, does not show circadian variation, and increases rapidly during bone formation-stimulating therapy. Serum CTX-I is a product of the breakdown of type I bone collagen. It is present predominantly in bone and rapidly decreases during antiresorptive treatment. However, it has a strong circadian rhythm, and blood for its measurement has to be collected in the fasting state in the morning. CTX-I occurs in its native (α) and β-isomerized forms, which may undergo racemization (D- and L-forms). Bone AP and TRACP5b are enzymes reflecting the metabolic activity, respectively, of osteoblasts and osteoclasts. Other BTMs are bone matrix components released into the blood during formation or resorption.

ANALYTICAL AND PREANALYTICAL VARIABILITY

The analytical variability (assessed by the intra-assay and inter-assay coefficients of variation) depends on the BTM, the measurement method, and the technician's expertise [3]. Several methods for measurements of BTMs are available (radioimmunoassay, immunoradiometric assay, enzymatic immunoassay, chemiluminescence). The use of monoclonal antibodies permits specific measurements of the molecules. Automated analyzers permit a rapid, convenient, fully automated, and precise measurement of BTM levels both in research projects and in clinical practice [4]. Moreover, miniaturized point-of-care (POC)

Table 35.2. Determinants of the Preanalytical Variability of Bone Turnover

Modifiable determinants
Circadian variation
Menstrual variation
Seasonal variation
Fasting and food intake (particularly serum CTX-I)
Exercise and physical activity
Determinants that cannot be easily modified
Age
Sex
Menopausal status
Vitamin D deficit and secondary hyperparathyroidism
Short- and long-term day-to-day variation
Diseases characterized by an acceleration of bone turnover
Primary hyperparathyroidism
Thyrotoxicosis
Acromegaly
Paget's disease
Bone metastases
Diseases characterized by a dissociation of bone turnover
Cushing's disease
Multiple myeloma
Diseases characterized by a low bone turnover
Hypothyroidism
Hypoparathyroidism
Hypopituitarism
Growth hormone deficit
Renal impairment (depending on the stage)
Recent fracture
Depression
Chronic diseases associated with limited mobility
Stroke
Hemiplegia
Dementia
Alzheimer's disease
Sarcopenia
Medications
Oral corticosteroids
Inhaled corticosteroids (only osteocalcin)
Aromatase inhibitors (antiaromatases)
Oral contraceptives
Gonadoliberin agonists
Anti-epileptic drugs
Thiazolidinediones
Heparin
Vitamin K-antagonists

devices permit rapid measurement of urinary creatinine-corrected NTX-I [5].

The preanalytical variability has a strong effect on the BTM levels [6]. It comprises a large number of factors (Table 35.2), which may coexist in one person. Circadian rhythm has a strong impact on the BTM variability, especially serum bone resorption markers that peak in the second half of the night and have their nadir in the afternoon [7]. The amplitude is higher for CTX-I than for other BTMs. Food intake has a strong effect on bone resorption. This postprandial decrease in serum CTX-I is most probably stimulated by glucose, which induces the intestinal synthesis of glucagon-like peptide 2 [8]. Therefore, blood should be collected in standardized conditions, preferably in the fasting state in the morning. For urinary collection, the choice between a spot (preferably second morning void) and 24-hour collection is a trade-off between accuracy and feasibility. The spot sample may be easily collected with minimal patient burden. The 24-hour collection reflects the overall bone turnover. However, the 24-hour BTM excretion not corrected for creatinine may be artifically underestimated when renal function is not in a steady state. The excretion of BTM per mg of urinary creatinine may be artifically overestimated in the case of lower creatinine excretion due to sarcopenia. The BTM amount per glomerular filtrate volume assumes that the glomerular filtration is the same as that of creatinine and that there is no tubular reuptake of the BTM.

Bone metabolism is influenced by the vitamin D and calcium status, especially in the elderly. BTM levels are typically increased in the institutionalized and homebound vitamin D-deficient elderly who have lower 25-hydroxycholecalciferol (25OHD) and higher parathyroid hormone (PTH) concentrations compared to those who are ambulatory. As 25OHD is lowest during winter, especially in the elderly who rarely go out, the seasonal variation of the BTM levels is the most evident in this group. In contrast, the seasonal variability is minimal in young vitamin-D sufficient people.

BTM levels are usually increased in patients with bone metastases and their levels are correlated with the spread

of bone metastases [9, 10]. ICTP and α-α-CTX-I (the native form of CTX-I) are considered the most sensitive markers of bone involvement [9–11].

BTM levels are influenced by a recent fracture [12, 13]. During the first hours after fracture, OC decreases because of stress-related cortisol secretion. Subsequently, bone formation and resorption increase reflecting the healing of the fracture. BTM levels are typically remain elevated for 4 months after fracture, and then decrease for up to 1 year.

Endogenous and exogenous corticosteroids inhibit bone formation [14]. The decrease in the OC level is most rapid and followed by a delayed and milder decrease in PICP and PINP. Bone resorption can increase; however, data are less consistent. Low-dose prednisone (5 mg/day) decreases bone formation but not bone resorption. Inhaled corticosteroids decrease OC levels in a dose- and drug-dependent manner without significant effect on other BTMs [15].

Aromatase inhibitors (used in the treatment of breast cancer) reduce the residual secretion of estrogens. GnRH agonists (used in the treatment of prostate cancer) inhibit the secretion of androgens and decrease the level of 17β-œstradiol. Consequently, both groups of drugs lead to an accelerated bone turnover and bone loss. In both cases, the expected increase in bone turnover is not observed with concomitant bisphosphonate treatment.

Premenopausal women taking oral contraceptives have lower BTMs; however, changes in BTM levels slightly depend on the composition of combined oral contraceptives [16].

Thiazolidinediones promote the differentiation of mesenchymal cells into adipocytes and may even suppress osteoblast formation. They decrease bone formation whereas bone resorption remains stable or slightly increases [17]. PINP and bone ALP, expressed by early stages of osteoblasts, decrease promptly, earlier than OC, expressed by mature osteoblasts.

BTMS AND REFERENCE VALUES

Reference intervals for BTMs have been reported from a number of studies with differing results. The reference values depend on the selection of subjects (age, sex, method of recruitment, inclusion and exclusion criteria), geographical region (including cultural habits), method of measurement, expertise of the laboratory, and the statistical approach. Given these concerns, reported reference values should interpreted with caution in clinical practice.

BONE TURNOVER RATE AND BONE LOSS

In young adults, the quantity of bone replaced at every BMU is approximatly equal to the quantity of bone removed by resorption. After menopause and in diseases associated with accelerated bone loss, levels of bone resorption markers increase rapidly. Bone formation increases to fill in the higher number of resorption cavities, increasing serum levels of bone formation markers. As the quantity of bone formed is lower than the quantity of bone resorbed, there is a net bone loss at the BMU level. Therefore, the increased number of BMUs is the principal determinant of the postmenopausal BTM levels and bone loss.

In most studies, higher baseline BTM levels are associated with a faster subsequent bone loss. However, for a given BTM level, there is a large scatter of individual values of bone loss [18]. Thus, from a pathophysiological point of view, the rate of bone turnover seems to determine the subsequent bone loss. In contrast, from a clinical point of view, BTMs cannot be used for the prediction of the accelerated bone loss at the individual level.

BONE TURNOVER RATE AND FRACTURE RISK

Some, but not all, prospective cohort and case-control studies suggest that increased BTM levels predict fractures independently of age, bone mineral density (BMD), and prior fracture [19–21]. This association has been found in postmenopausal and elderly women, but not in men or in frail elderly where incident falls were the strongest predictor of fracture. BTM levels are predictive mainly of major osteoporotic fractures (vertebra, hip, multiple fractures), but not for minor peripheral osteoporotic fractures. BTMs predict fractures during short-term follow-up (less than 5 years) but not in the longer studies. Fracture risk is predicted mainly by urine bone resorption markers and, in some studies, bone ALP, but not by other bone formation markers (OC, PICP, PINP) or older nonspecific markers (total ALP, hydroxyproline).

High bone turnover is associated with lower BMD, faster bone loss, and poor bone microarchitecture in the trabecular compartment (trabecular perforations and loss, poor trabecular connectivity) and in the cortical compartment (cortical thinning, increased porosity) [22]. Consequently, remaining bone may sustain higher stress, leading to a more rapid fatigue of bone tissue and further deterioration of its material mechanical properties. Resorption cavities trigger stress risers, leading to a local weakening of a trabeculum [23]. High bone turnover is also associated with a higher fraction of recently formed partly mineralized bone, which may have suboptimal mechanical resistance. Shorter periods between remodeling cycles leave less time for the post-translational modifications of bone matrix proteins (such as cross-linking and β-isomerization of type I collagen). In one study of postmenopausal women, reduced isomerization of type I collagen, assessed by urinary α/β ratio of CTX-I, was associated with higher fracture risk independently of other predictors [24].

The potential clinical utility of BTMs is substantial; they may help identify women who will benefit the most from antiosteoporotic treatment and may improve the cost-effectiveness of treatment. However, both positive and negative data on BTMs and fracture risk should be interpreted cautiously. As mentioned above, BTM results may be inaccurate with fluctuation in renal function and improper collection. In particular, urinary bone resorption markers may be overestimated in patients with low muscle mass and high risk of falling.

Although promising, the clinical use of the BTMs for fracture prediction requires additional standardization concerning the time of collection of biological samples, choice of the BTM, expression of urinary markers, definition of the clinically valid thresholds, as well as choice of the type of fracture and of the duration of follow-up for which BTMs may be valid.

BONE TURNOVER RATE AND MONITORING

BTMs reflect the metabolic effect of drugs on bone turnover, help to establish the adequate dose, predict treatment-related increases in BMD and treatment-related reduction in fracture risk. Thus, BTMs have the potential to be helpful in the clinical management of osteoporosis.

Metabolic effect

Treatment-related changes in BTM levels depend on the mechanism of action of the drug. Antiresorptive drugs inhibit bone resorption and rapidly decrease levels of bone resorption markers. As bone formation continues in BMUs activated before treatment, bone formation markers are stable and decrease when osteoblasts fill in the lower number of BMUs formed during treatment. BMD increases rapidly during the early period, when bone resorption is reduced and bone formation is still at the baseline level. Changes in BTMs during antiresorptive therapy depend on the route of administration and dose of the drug, degree of inhibition of bone resorption, and the cellular mechanism of action of the drug. For instance, intravenous bisphosphonates or subcutaneous denosumab (monoclonal anti-RANKL antibody) decrease BTM levels faster than orally administered agents.

Inhibitors of cathepsin K (CatK), currently under development for clinical use, are an interesting group of antiresorptive drugs with regard to the effect on BTMs [25, 26]. CatK is a cysteine protease expressed by osteoclasts and degrades collagen under acidic conditions. CatK inhibitors decrease bone resorption by inhibiting the catabolism of type I collagen.

During bone resorption, collagen is degraded first by matrix metalloproteinases (MMPs), then by CatK. MMPs release CTX-MMP (C-telopeptide of type I collagen generated by MMPs, ICTP) [27]. Then, CatK degrades CTT-MMP to release CTX-I and generates NTX-I at the N-terminal end. Therefore, CatK inhibitors decrease the levels of CTX-I and NTX-I. In contrast, CTX-MMP is not further catabolized and its serum level increases. Thus, serum CTX-MMP does not reflect the suppression of bone turnover by CatK inhibitors.

Unlike bisphosphonates and denosumab, CatK inhibitors do not decrease the number of osteoclasts, only their activity. Therefore, TRACP5b concentration, which reflects the number of osteoclasts, decreases during the treatment with bisphosphonates or denosumab, but remains stable or even increases during the treatment with the CatK inhibitors [26-28]. In addition, the existing osteoclasts send signals to osteoprogenitor cells stimulating osteoblasts recruitment and differentiation [29]. Therefore, the decrease in bone formation is less prominent during the treatment with CatK inhibitors in comparison with the treatment by bisphosphonates or denosumab.

Potent bone formation-stimulating drugs, such as recombinant human PTH(1-34) (teriparatide) and PTH(1-84), induce a rapid increase in bone formation (especially PINP) followed by an increase in bone resorption [30, 31]. In the early phase of treatment, bone formation is increased, whereas bone resorption still remains low. It is during this phase, called the "anabolic window," that BMD increases most rapidly, mainly in trabecular bone. Recent data show that, in healthy subjects, the humanized sclerostin monoclonal antibody induces a rapid, dose-dependent increase in bone formation and a milder, transient decrease in serum CTX-I [32]. Strontium ranelate slightly increases bone ALP and slightly lowers serum CTX-I at the beginning of the therapy, and then both plateau throughout treatment [33].

BTMs and new treatments for osteoporosis

BTMs may be useful to establish the optimal dose of antiosteoporotic drugs because the treatment-related changes in BTMs are more rapid compared with BMD. In general, higher doses of antiresorptive agents as associated with greater reductions in BTM levels, and greater reductions in BTM levels are associated with greater increases in BMD. Transdermal 17β-estradiol, SERMs, and oral bisphosphonates induce a dose-dependent decrease in bone resorption (maximal after 3 months) and bone formation (maximal after 6 months), followed by an increase in BMD. A similar but more rapid trend was observed for an oral CatK inhibitor. The first dose of intermittent treatment with subcutaneous denosumab or intravenous bisphosphonates induces a very rapid dose-dependent decrease in bone resorption [34]. During treatment with bone formation-stimulating PTH(1-84), dose-dependent increases in BMD and BTM levels are found mainly for the lumbar spine and bone formation markers [35].

BTMs may also be useful for the assessment of the therapeutic equivalence of various doses of the same

drug. Similar decreases in BTM levels in two groups of patients treated with different regimens of the same drug suggest that both regimens have similar efficacy [36, 37].

BTMs and therapeutic efficacy of antiosteoporotic treatment

Relative reduction of the risk of non-spine fracture induced by alendronate was greater in postmenopausal women with a higher baseline concentration of PINP (highest tertile) [38]. However, a similar trend was not found for spine fracture or for other BTM. Relative fracture risk reduction induced by risedronate or teraparatide did not depend on pretreatment BTM levels [39, 40]. However, in both studies, untreated women with higher BTM levels had a higher incidence of fractures. Therefore, the absolute fracture risk reduction (number of avoided fractures) was greatest for women with high pretreatment bone turnover.

The change in BMD induced by the antiresorptive treatment is a suboptimal surrogate measure of the anti-fracture efficacy. In contrast, the early decrease in BTM levels (6–12 months) is associated with the long-term increase in BMD and anti-fracture efficacy (2–3 years) of the antiresorptive therapy [41, 42]. For a given decrease in BTM levels and for a given BTM level during treatment, the incidence of vertebral fracture was similar in the active treatment and placebo groups [42, 43]. Although early teriparatide-induced increases in BTM levels correlated positively with the subsequent increase in BMD, especially with the increase in trabecular volumetric BMD [44], short-term changes in BTMs were not associated with fracture risk.

BTMs after discontinuation of antiosteoporotic treatments

Bisphosphonates are accumulated in bone and not metabolized. Therefore, the lower the cumulative dose of bisphosphonates, the sooner the BTMs return to the baseline. After the withdrawal of alendronate, which had administered for several years, BTMs increased and BMD decreased, but slowly and moderately [45]. In contrast, hormone replacement therapy, denosumab, and CatK inhibitors do not accumulate in bone. Therefore, their withdrawal is followed by a rapid increase in the BTM levels that may even attain levels exceeding pretreatment levels [46, 47]. This increase is followed by a decrease in BMD and potentially an increase in fracture risk. Withdrawal of PTH(1-84) after 1 year of treatment was followed by a return of BTM levels to baseline values and a decrease in trabecular volumetric BMD [48].

After discontinuation of denosumab followed by 12 months without treatment, re-treatment with the same agent rapidly decreased levels of BTMs to the values similar to those in patients who received continuous treatment [47]. After discontinuation of teriparatide followed by 12 months without treatment, re-treatment with the same agent induced an increase in BTM levels [49]. However, the increase was much lower compared with the initial treatment in the treatment-naïve subjects.

Additional studies are needed to determine if changes in BTMs after discontinuation of antiosteoporosis treatments are associated with subsequent fracture risk.

Combination therapy and BTMs

Several combinations of two different antiosteoporotic drugs have been studied in postmenopausal women. Alendronate and PTH(1-84) administered jointly rapidly decreased bone resorption (serum CTX-I) but less so than alendronate alone and temporarily increased bone formation (PINP, bone ALP) but less than PTH(1-84) alone [50]. Then, bone formation decreased and remained slightly below baseline levels. The time course of BTM levels during this therapy was more strongly determined by alendronate, which is consistent with the similar changes in BMD in the combination therapy group and in the group receiving alendronate alone.

The effect of PTH treatment on BTMs after antiresorptive treatment depends on the degree of inhibition of bone turnover, which itself depends on the antiresorptive drug and duration of therapy. Following prolonged treatment with alendronate, the increase in BTM levels induced by teriparatide was delayed and smaller than after raloxifene therapy [51]. In the women treated with risedronate, BTMs were higher, and teriparatide induced a greater increase in BTMs than in those treated with alendronate [52]. Alendronate administered after PTH(1-84) induces a marked decrease in BTM levels that are indistinguishable from those in women treated with alendronate alone [48, 53]. This strong inhibition of bone turnover may prevent the resorption of bone formed under PTH(1-84) treatment, which results in an additional increase in BMD.

In postmenopausal women who had been treated with alendronate for at least 6 months, administration of denosumab induced an additional decrease in BTM levels followed by an additional increase in BMD [54].

BTMs and treatment monitoring at the individual level

The goal of monitoring of antiresorptive therapy is to assess the degree of decrease in bone turnover. Changes in the BTM level that exceed the least significant change ($2.8 \times$ the inter-assay coefficient of variation of the BTM assay) exceed random BTM varibility and likely represent a true biologic effect of treatment. Ideally, the BTM level during the treatment should be below the mean for premenopausal women.

Poor adherence during antiosteoporotic treatment leads to a higher risk of fracture [55]. In postmenopausal

women taking risedronate, NTX-I monitoring did not improve the persistence compared with usual care. The better the adherence the greater the average decrease in bone turnover, but it remains unclear if the association is sufficiently strong to be clinically useful [56]. Interestingly, persistence with the antiresorptive treatment was significantly better in women who received positive information corresponding to a substantial decrease in the NTX-I level [57, 58].

Available data are not sufficient to evaluate whether BTM measurement may be useful for the identification of patients at high risk of atypical subtrochanteric fracture or osteonecrosis of the jaw [59, 60]. Similarly, according to the available data, it is not possible to establish a threshold value of BTMs warranting discontinuation or reinitiation of treatment.

BONE TURNOVER MARKERS IN MEN

In boys, the growth spurt starts later and lasts longer than in girls. Therefore, young men enter the phase of consolidation (formation of peak BMD after growth arrest) later than women. Men have longer bones because they are taller than women. They also have wider bones even after adjustment for body size. At 20–25 years of age, men have BTM levels higher than women because they have more active bone turnover (later consolidation) in longer and wider bones. Then, BTMs decrease and attain their lowest levels between 50 and 60 years of age [61–63]. After the age of 60, bone formation markers remain stable or increase slightly. Bone resorption increases after the age of 60. In older men, urinary DPD and serum CTX-MMP increase with age, whereas serum CTX-I remains stable, which may reflect relative activities of various enzymes involved in the degradation of type I collagen [62, 64].

Men with high bone turnover have lower BMD as well as poor cortical microarchitecture [62, 65]. It indicates that age-related bone loss in men results at least in part from increased bone resorption. Elderly men with high BTM levels have a faster subsequent bone loss; however, this association is relatively weak [66–68]. In a nested case-control study, increased CTX-MMP level was associated with higher incidence of clinical fracture [69]. However, large prospective cohort studies showed that BTMs do not indepently predict osteoporotic fractures in elderly men [66, 67]. Interestingly, similarly to women, the higher α/β ratio of CTX-I was predictive of fragility fracture in older men independently of other predictors [70].

BTMs and antiosteoporotic treatment in men

Testosterone replacement therapy (TRT) inhibits bone turnover in overt hypogonadism (but not in men with borderline decreased testosterone concentration), if the normal concentration of bioavailable testosterone has been achieved [71, 72]. During TRT, bone resorption decreases promptly, but a decrease in urinary excretion per milligram creatinine may be partly related to the increase in muscle mass. Bone formation increases at the beginning of the TRT (direct stimulatory effect), levels off, and finally decreases, reflecting the general slowdown of bone turnover.

Oral (administered daily, weekly, or monthly) and intravenous bisphosphonates decrease BTM levels to a similar degree as in postmenopausal women [73–76]. These effects were observed in older osteoporotic men, in men with hypogonadism, in HIV-infected men, in men after cardiac transplantation, and in men after stroke. However, in men receiving androgen–deprivation therapy for prostate cancer, the decrease in BTM levels induced by denosumab is less than in postmenopausal women [77].

In men, teriparatide increased bone formation (PINP) after 1 month and bone resorption after 3 months of treatment [78]. In contrast, in eugonadal osteoporotic men, discontinuation of teriparatide was followed by a progressive decrease in the BTM levels [79]. In men treated with alendronate for 6 months, administration of teriparatide induced an increase in bone formation markers (but less than in men treated with teriparatide alone) and a slight increase in the serum NTX-I concentration which returned to baseline [80].

CONCLUSIONS

BTMs improve our understanding of the relationship between bone turnover, BMD, bone fragility, and the effect of antiosteoporotic treatment (biological mechanism, time course, anti-fracture efficacy). Data on BTMs show that the rate of bone turnover (spontaneous or modified by the therapy) is indepenently associcated with bone fragility in postmenopausal and elderly women (particularly urinary resorption markers). From a clinical point of view, there is optimism that measurement of BTMs may help to identify postmenopausal women at high risk of fracture and may improve persistence with antiresorptive treatment. It suggests that the use of BTMs may improve the cost-effectiveness of the antiosteoporotic treatment.

INTRODUCTION

Histological examination of undecalcified transilial bone biopsy specimens is a valuable and well-established clinical and research tool for studying the etiology, pathogenesis, and treatment of metabolic bone diseases. In this chapter, we will review the underlying organization and function of bone cells; identify a set of basic structural and kinetic histomorphometric variables; outline an approach to interpretation of findings, with examples from a range of metabolic bone diseases; describe techniques for obtaining, processing, and analyzing transilial biopsy specimens; identify clinical situations in which bone histomorphometry can be useful; and relate histomorphometric measures to data from other methods for assessing bone properties and bone physiology.

ORGANIZATION AND FUNCTION OF BONE CELLS

Intermediary organization of the skeleton

In what he termed the intermediary organization (IO) of the skeleton, Frost [1] described four discrete functions of bone cells: growth, modeling, remodeling, and fracture repair. Although each involves osteoclasts and osteoblasts, the coordinated outcomes differ greatly. Growth elongates the skeleton; modeling shapes it during growth; remodeling removes and replaces bone tissue; and fracture repair heals sites of structural failure.

The remodeling IO, which predominates during adult life, is the focus of this chapter. Coordinated groups of bone cells (i.e., osteoclasts, osteoblasts, osteocytes, and lining cells) comprise the basic multicellular units (BMUs) that carry out bone remodeling. Basic structural units (BSUs) are the packets of new bone that BMUs form [2]. All adult-onset metabolic bone disease involves derangement of the remodeling IO.

Bone cells

Osteoclasts, large-to-giant cells that are typically multinucleated, resorb bone (both its matrix or osteoid, and mineral). They excavate shallow pits on the surface of cancellous bone, and they appear at the leading edge of tunnels ("cutting cones") in Haversian bone. Light microscopy discloses an irregular cell shape, foamy, acidophilic cytoplasm, a perimeter zone of attachment to the bone, a ruffled border that appears in the fluid cavity between the cell and the mineralized bone matrix, and positive staining for tartrate-resistant acid phosphatase (TRAP).

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

Osteoblasts form new bone at sites of resorption. They produce the collagenous and noncollagenous constituents of bone matrix and participate in mineralization [3]. Under light microscopy, they appear as plump cells lined up at the surface of unmineralized osteoid. As the site matures, the cells lose their plump appearance.

Osteocytes, derived from osteoblasts, remain at the remodeling site, and are buried as bone formation advances at remodeling sites. They reside individually in small lacunae within the mineralized bone matrix. Their cytoplasmic processes extend through a fine network of narrow canaliculi to form an interconnected network that extends throughout living bone. This network is well situated to monitor the local strain environment and local microdamage, and to initiate organized bone cell work in response to changes in strain or microdamage.

Lining cells, also of osteoblast origin, cover cancellous and endocortical bone surfaces. By light microscopy, they appear as elongated, flattened, darkly stained nuclei. The localization and initiation of remodeling probably involves these cells.

Bone remodeling process

Remodeling occurs on cancellous and Haversian bone surfaces. The first step is activation of osteoclast precursors to form osteoclasts that then begin to excavate a cavity. After removal of about 0.05 mm^3 of bone tissue, the site remains quiescent for a short time. Then, activation of osteoblast precursors occurs at the site, and the excavation is refilled. The average length of time required to complete the remodeling cycle is approximately 6 months [4]: about 4 weeks for resorption and the rest for formation.

The healthy bone remodeling system accesses the required building materials within a favorable physiologic milieu to replace fully a packet of aged, microdamaged bone tissue with new, mechanically competent bone. However, overuse can overwhelm the capacity of the system to repair microdamage (the stress fractures that occur in military recruits are an example). The healthy bone remodeling system modifies bone architecture to meet changing mechanical needs. However, the system also promptly reduces the mass of underused bone (the bone loss of extended bed rest, paralysis, or space travel are examples). All bone loss occurs through bone remodeling. The bone remodeling system responds to nutritional and humoral as well as mechanical influences. Among the effects of vitamin D deficiency in adults, for example, is impaired mineralization of bone matrix. Finally, as other chapters describe, bone remodeling involves complex signaling processes between and within bone cells, and metabolic bone diseases of genetic origin involve defects at this level. Figures 36.1–36.3 present representative photomicrographs from human transilial biopsy specimens. An extensive atlas has also been published [5].

BASIC HISTOMORPHOMETRIC VARIABLES

Bone biopsy specimens for histomorphometric examination are ordinarily obtained at the transilial site and shipped to specialized laboratories for processing and microscopic analysis. Later sections of this chapter outline these procedures. Of the dozens of measurements and calculations that have been devised, we provide here descriptions of several frequently used variables. Together they describe a basic set of structural and kinetic features. Nomenclature is as approved by a committee of the American Society of Bone and Mineral Research [6].

Structural features

Core width (C.Wi) represents the thickness of the ilium (i.e., distance between periosteal surfaces, in millimeters) at the point of biopsy. Cortical width (Ct.Wi) is the combined thickness, in millimeters, of both cortices. Cortical porosity (Ct.Po) is the area of intracortical holes as percent of total cortical area.

Cancellous bone volume (BV/TV) is the percent of total marrow area (including trabeculae) occupied by cancellous bone. Wall thickness (W.Th) is the mean distance in micrometers between resting cancellous surfaces (i.e., surfaces without osteoid or Howship's lacunae) and corresponding cement lines.

Trabecular thickness (Tb.Th) is the mean distance across individual trabeculae, in micrometers, and trabecular separation (Tb.Sp) is the mean distance, also in micrometers, between trabeculae. Trabecular number (Tb.N) per millimeter is calculated as (BV/TV)/Tb.Th. These variables can be used to evaluate trabecular connectivity [7]. Other measures of trabecular connectivity include the ratio of nodes to free ends [8], star volume [9, 10], and trabecular bone pattern factor (TBPf) [11].

Eroded surface (ES/BS) is the percent of cancellous surface occupied by Howship's lacunae, with and without osteoclasts. Osteoblast surface (Ob.S/BS) and osteoclast surface (Oc.S/BS) identify the percent of cancellous surface occupied by osteoblasts and osteoclasts, respectively. Osteoid surface (OS/BS) is the percent of cancellous surface with unmineralized osteoid, with and without osteoblasts. Osteoid thickness (O.Th) is the mean thickness, in micrometers, of the osteoid on cancellous surfaces.

Kinetic features

A fluorochrome labeling agent, taken orally on a strict schedule before biopsy, deposits a fluorescent double-label at sites of active mineralization and allows rates of change to be determined [12]. Mineralizing surface (MS/BS) is the percentage of cancellous surface that is mineralizing and thus labeled. The most accurate version of MS/BS includes surfaces with a double-label plus one-half of those with a single-label [13]. Clear definition of MS/BS is crucial, because it is used to calculate bone formation rates, bone formation periods, and mineralization lag time.

Mineral appositional rate (MAR), is the rate (in µm/day) at which new bone mineral is being added to cancellous surfaces. MAR represents distance between labels at doubly labeled surfaces divided by the marker interval (span in days between the midpoints of each labeling period). This and all measurements of thickness must be corrected for obliquity (i.e., the randomness of the angle between the plane of the section and the plane of the cancellous surface) by use of a scaling factor [7].

Activation frequency (Ac.f) is the probability that a new remodeling cycle will begin at any point on the cancellous bone surface. Bone formation rates (BFR/BV and BFR/BS) are estimates of cancellous bone volume (in mm^3/mm^3/year) and cancellous bone surface (in mm^3mm^2/mm/year), respectively, that are being replaced annually; BFR/BS = Ac.f × W.Th [14]. Formation period (FP) is the time in years required to complete a new cancellous BSU. Mineralization lag time (Mlt) is the interval in days between osteoid formation and mineralization. The most accurate version of Mlt is calculated as O.Th/MAR×MS/OS. Microcrack density (Cr.d.) is the number of microcracks per area if mineralized bone area (#/mm^2), and microcrack length (Cr.L) is the average length (in millimeters) of visualized microcracks [15]. Apoptosis can be quantified as the percent of total osteocytes that are identified as apoptotic using special stains [16].

INTERPRETATION OF FINDINGS

Reference data

In 1988, Recker et al. [4] published the results of a study to establish reference values for histomorphometric variables in postmenopausal white women. The 34 healthy subjects were evenly distributed into three age groups: 45–54, 55–64, and 65–74 years. They ranged broadly in age at menopause and in years past menopause at the time of biopsy. A comparative study of 12 blacks and 13 whites, aged 19–46 years, has also been published [17].

In 2000, Glorieux et al. [18] reported histomorphometric data from 58 white subjects in each of five age groups: 1.5–6.9, 7.0–10.9, 11.0–13.9, 14.0–16.9, and 17.0–22.9 years. Biopsy specimens were obtained during corrective orthopedic surgeries, but the subjects had been ambulatory and otherwise healthy. The report includes within-subject coefficient of variation (CV) derived from analysis of adjacent duplicate biopsy specimens in eight subjects.

A recent paper from our center reported Ac.f in several sets of transilial biopsy specimens. In 50 paired transilial biopsy specimens taken during perimenopause and in early postmenopause, a year after last menses, median

values for Ac.f increased from 0.13/year to 0.24/year, respectively ($p < 0.001$). Ac.f. was higher still (median, 0.37; $p < 0.01$) in another group of ostensibly normal women who were postmenopausal by an average of 13 years [19]. Others have published reference databases [20–23].

Replacement of normal marrow elements

A variety of hematopoietic cells and a varying proportion of fat cells normally occupy the marrow space at the transilial biopsy site. If these normal marrow elements have been displaced by fibrous tissue (osteitis fibrosa), clumps of tumor cells, or sheets of abnormal hematopoietic cells, this change will be obvious to the histomorphometrist. The biopsy preparations described here preserve cellular detail, spatial relationships, and architectural features. However, this approach is unsuitable for hematologic diagnosis because of the time that histomorphometry laboratories require to generate a report (typically, at least 4 weeks).

Cortical bone deficit

Both the angle of the biopsy and site-to-site variation in cortical thickness at the biopsy site influence Ct.Wi. Nevertheless, low bone density at the lumbar spine and/or proximal femur is often reflected in low values for Ct.Wi [24]. Evidence of trabeculation of the cortex (i.e., formation of a transitional zone with characteristic coarse trabeculae) indicates that cortical bone once present in the area adjacent to the marrow space, has been lost [25].

Cancellous bone deficit

Low BV/TV indicates a cancellous bone deficit. Generalized trabecular thinning (decreased Tb.Th) and/or complete loss of trabecular elements (poor trabecular connectivity) may contribute to this deficit. The latter finding (e.g., low Tb.N with high Tb.Sp) characterizes bone that is more fragile than its overall mass would suggest.

Altered bone remodeling

Ac.f is an indicator of the overall level of remodeling activity in cancellous bone. Values for Ac.f correlate with excretion of bone resorption markers ($r = 0.71$) (Recker, unpublished observations). In biopsy specimens from ostensibly healthy women, we have yet to see a case in which the subject had followed the fluorochrome labeling protocol but that label could not be found in cancellous areas. However, a recent paper from our laboratory, cited earlier, reports three cases of no label (i.e., zero Ac.f) among women with untreated postmenopausal osteoporosis [19]. Further, extensive attention has been directed at osteoporosis drugs that suppress remodeling, and whether they might sometimes suppress remodeling to the extent that microdamage repair is not adequate. This has led to questions concerning a histomorphometric definition of abnormally low remodeling rates and has been thoroughly discussed in a recent publication [26]. These authors concluded that absence of fluorochrome label in a human transiliac biopsy is evidence of abnormal reduction in remodeling.

Abnormal osteoid morphology

The characteristic arrangement of osteoid (collagen) fibers in lamellar and woven bone is readily apparent. Lamellar bone contains collagen fibers arranged in layers, and woven bone contains collagen fibers arranged in a random fashion. Woven bone in transilial specimens is generally associated with an intense stimulus to rapid bone formation, as in Paget's disease or renal osteodystrophy. It can also occur in osteitis fibrosa. In osteogenesis imperfecta, collagen abnormalities result in production of variable amounts of woven bone, but may be subtle enough to escape detection. The presence of woven bone can be suspected in stained sections by the presence of increased numbers of osteocytes, and by the hint of randomly arranged collagen. However, the best way to identify woven bone is by using polarizing lenses and light microscopy of unstained sections. One polarizing lens is placed under the substage of the microscope above the light source, and the other is placed in the light path above the section. When the polarizing lenses are rotated so that the polarity of one is arranged 90° relative to the polarity of the other (the views in the eyepieces are very dark) the differences between areas of woven and lamellar bone are readily apparent due to refraction of light in random directions by woven bone.

Accumulation of unmineralized osteoid

Parfitt has described the complex relationships between dynamic indices of bone formation and static indices of osteoid accumulation [14]. Increases in OS/BS, O.Th, and Mlt indicate failure of osteoid to mineralize normally. If mineralization is arrested completely, no double-label will be seen, and Mlt is unmeasurable [27].

FINDINGS IN METABOLIC BONE DISEASE

In Table 36.1, we identify key histomorphometric findings that characterize representative types of metabolic bone disease. For further information, we encourage the reader to consult disease-specific chapters in this volume and the current literature.

Table 36.1. Patterns of Key Histomorphometric Findings That Characterize Several Types of Metabolic Bone Disease

	Marrow Spaces	Cortical Bone	Cancellous Bone	Bone Remodeling	Osteoid Morphology	Osteoid Mineralization
Postmenopausal osteoporosis	–	Cortical bone deficit with endocortical trabeculation	Cancellous bone deficit with poor trabecular connectivity	Ac.f generally increased, but values vary widely	–	–
Glucocorticoid-induced osteoporosis	–	Cortical bone deficit	Cancellous bone deficit	Early, increased Ac.f; later, decreased Ac.f	–	–
Primary hyperparathyroidism	Peritrabecular fibrosis may be seen	Cortical bone deficit, incr. Ct.Po, endocortical trabeculation	Typically unremarkable	Increased Ac.f	Woven bone may be seen	–
Hypogonadism (males and females)	–	Cortical bone deficit	Cancellous bone deficit, sometimes with poor trabecular connectivity	Increased Ac.f	–	–
Hypovitaminosis D osteopathy	Fibrous tissue may be seen	–	–	Early, increased Ac.f	–	Early, increased OS/BS; later, increased MLT and O.Th. double-label may be absent
Hypophosphatemic osteopathy	Fibrous tissue may be seen	–	–	–	–	Increased MLT and O.Th; double label may be absent
Renal osteodystrophy (high turnover type)	Fibrous tissue may be seen	Endocortical trabeculation	Osteoblast, osteocyte, and trabecular abnormalities	Markedly increased remodeling activity	Woven bone may be seen	Increased OS/BS
Renal osteodystrophy (low turnover type)	–	–	–	Markedly decreased remodeling activity	–	Increased OS/BS (osteomalacic type); decreased OS/BS (adynamic type)
Renal osteodystrophy (mixed type)	Fibrous tissue may be seen	–	Variable BV/TV	Patchy remodeling activity	Irregular, woven bone and osteoid may be seen	Increased OS/BS and O.Th

Postmenopausal osteoporosis

Osteoporosis in postmenopausal women is characterized by a cortical bone deficit with trabeculation of endocortical bone and a cancellous bone deficit with poor trabecular connectivity. Decreases in Tb.Th are modest, and dynamic measures vary widely [28, 29]. Median Ac.f. remains high in specimens from women with postmenopausal osteoporosis, but values vary widely [19].

Glucocorticoid-induced osteoporosis

Early in treatment, Ac.f is increased; later, Ac.f, MAR, and MS/BS are all decreased. In femoral specimens from patients with glucocorticoid-induced osteonecrosis, abundant apoptotic osteocytes and lining cells have been reported [30]. This has led to questions as to how viable osteocytes function to maintain bone mechanical integrity independent of bone mass and/or bone remodeling. (See the chapter on glucocorticoid-induced osteoporosis and detection of apoptotic osteocytes.)

Primary hyperparathyroidism

Primary hyperparathyroidism leads to a cortical bone deficit, with increased Ct.Po and trabeculation of endocortical bone [31]. Ct.Po correlates positively with fasting serum PTH [32]. BV/TV is generally preserved, and normal cancellous bone architecture is maintained [33, 34]. Osteoid with a woven appearance and peritrabecular fibrosis is also seen [35].

Hypogonadism

Hypogonadism in both women and men increases Ac.f and leads to deficits of both cortical bone and trabecular bone. At low levels of BV/TV and/or Tb.Th, loss of trabecular connectivity occurs [36].

Hypovitaminosis D osteopathy

Vitamin D depletion of any etiology leads to hypovitaminosis D osteopathy (HVO). Parfitt [27] describes three stages. In HVOi ("pre-osteomalacia"), Ac.f and OS/BS are increased, but O.Th is not. Accumulation of unmineralized osteoid characterizes both HVOii and HVOiii (osteomalacia), with Mlt and O.Th clearly increased (i.e., Mlt >100 days and O.Th >12.5 μm after correction for obliquity) [27]. Some double-label can be seen in HVOii, but not in HVOiii. A cortical bone deficit also characterizes advanced HVO; secondary hyperparathyroidism in response to reduced serum ionized calcium is usual, and fibrous tissue in the marrow spaces is frequently seen. Lifelong subclinical vitamin D insufficiency may contribute to the development of osteoporosis later in life in both men and women.

Low bone mass and bone disease with osteomalacic features occurs among patients treated with antiepileptic drugs (AEDs) [37]. Hepatic enzyme-inducing AEDs have been most clearly associated with these problems, but the newer AEDs cannot be exonerated at this time [38].

Hypophosphatemic osteopathy

Phosphate depletion of any etiology also leads to osteomalacia, with histomorphometric findings similar to those of advanced HVO [27]. These cases involve defects in phosphorus metabolism that manifest as defects in renal tubular reabsorption of phosphorus. However, most cases are not due to a primary renal tubular abnormality, but instead, are due to an abnormality in plasma phosphorus homeostasis [39]. Secondary hyperparathyroidism occurs variably. Transilial biopsy can be quite useful to assess the efficacy of treatment.

Gastrointestinal bone disease

Evidence of HVO has been reported in a variety of absorptive and digestive disorders [40]. However, these conditions also may promote deficiency of calcium and other nutrients. Malabsorption is not the only issue. For example, a calcium balance study of asymptomatic patients with celiac disease showed increased endogenous fecal calcium; the gut appeared to "weep" calcium into its lumen [41]. Bone histomorphometry may also reflect the results of treatment (i.e., corticosteroids or surgery). Parfitt describes a histomorphometric profile of low bone turnover, often with evidence of HVO and secondary hyperparathyroidism, that represents the result of multiple insults to bone health in these patients [27].

Renal osteodystrophy

At least three patterns of histomorphometric findings have been described among patients with end-stage renal disease (ESRD): high bone turnover with osteitis fibrosa (hyperparathyroid bone disease); low bone turnover (including osteomalacic and adynamic subtypes); and mixed osteodystrophy with high bone turnover, altered bone formation, and accumulation of unmineralized osteoid [42–45]. (See the chapter on chronic kidney disease mineral bone disorder.)

Transilial bone biopsy remains a useful "gold standard" on which to base decisions about treatment of bone disease in ESRD [42]. A dramatic example is the evaluation of bone pain and fractures in a chronic dialysis patient with hypercalcemia. If the biopsy shows high bone turnover and osteitis fibrosa, partial parathyroidectomy may be indicated. However, if the biopsy shows little turnover (little or no fluorochrome label), with or without extensive aluminum deposits, then parathyroidectomy is contraindicated, and treatment with a chelat-

ing agent may be indicated. The same biopsy can also help determine the extent of vitamin D deprivation and indicate the adequacy of vitamin D treatment.

OBTAINING THE SPECIMEN

In this section, we outline the procedures for obtaining bone biopsy specimens, processing them, and carrying out histomorphometric analysis. For greater detail, we recommend another recent publication [46].

Fluorochrome labeling

In clinical settings, tetracycline antibiotics are the only suitable fluorochrome labeling agents [12]. Demeclocycline (150 mg, four times daily) or tetracycline hydrochloride (250 mg, four times daily) are commonly used. The double-labeling process involves two dosing periods, and close adherence to the dosing schedule is crucial. A schedule of 3 days on, 14 days off, 3 days on, and 5–14 days off before biopsy (abbreviated as 3–14-3–5) produces good results, with a marker interval of 17 days [13]. Tetracyclines must be taken on an empty stomach; Thus, oral intake must be avoided for at least 1 hour before and after each dose.

Biopsy procedure

Specimens for histomorphometric examination require use of a trephine with an inner diameter of 7.5 mm or less. The teeth should be sharpened (and reconditioned, if necessary) after every two to three procedures. Transilial bone biopsy is performed in outpatient minor surgery facilities, with the usual procedures (e.g., the surgeon scrubs and uses a cap, mask, gown, and gloves, and the site is prepared and draped) and precautions (e.g., pulse oximetry and blood pressure monitoring). Before the procedure, the patient should be off aspirin for at least 3 days and have nothing orally for 4 hours. If a second biopsy is done on another occasion, it should always be on the side opposite the first; there is thus a practical limit of two transilial biopsy specimens per patient. The gowned patient lies in the supine position on the surgical table, and midazolam (2.5–5 mg) is given through a forearm intravenous catheter.

The biopsy site is approximately 2 cm posterior to the anterior–superior spine, which is approximately 2 cm inferior to the iliac crest. The skin, subcutaneous tissues, and periostium on both sides of the ilium are infiltrated with local anesthetic. The periosteum is accessed by a 2-cm skin incision and blunt dissection. The trephine is inserted and advanced with steady, gentle pressure and a deliberate pace. The specimen—an intact, unfractured core with both cortices and the intervening cancellous bone—is transferred into a 20-ml screw-cap vial containing 70% ethanol. (Note that certain special procedures, presently used in research settings, require unfixed specimens.)

The bony defect is then packed with Surgicel. After local pressure to facilitate hemostasis, the wound is closed with three to five stitches and covered by a pressure dressing. Follow-up care is specified clearly (i.e., dressing in place and absolutely dry for 48 hours; then a daily shower is allowed; no bathing or strenuous physical activity until suture removal, 1 week after the procedure). The procedure produces localized aching for about 2 days and a small scar at the site.

Patients typically describe feeling something "like a cramp" as the trephine advances, and the bone biopsy procedure described here rarely evokes more than mild discomfort. Although bleeding during the procedure is typically minimal, there is risk of bleeding in some situations (e.g., liver disease, hemodialysis, or medications that compromise hemostasis). Local bruising sometimes occurs, but hematoma is uncommon. In an early survey, physicians who were doing transilial biopsy specimens reported adverse events in 0.7% of 9,131 biopsy specimens, that is, 22 with hematomas, 17 with pain for more than 7 days, 11 with transient neuropathy, 6 with wound infection, 2 with fracture, and 1 with osteomyelitis. No cases of death or permanent disability were reported [47].

SPECIMEN PROCESSING AND ANALYSIS

Specimen handling and processing

For routine histomorphometry, the bone biopsy specimen should remain in 70% ethanol for at least 48 hours for proper fixation. This solution is suitable for shipping and long-term storage at room temperature. The specimen vials should be filled to capacity with 70% ethanol for shipping, handling, and storage.

Steps in laboratory processing include dehydrating, defatting, embedding, sectioning, mounting, deplasticizing, staining, and microscopic examination.

After proper trimming, the tissue block is sectioned parallel to the long axis of the biopsy core. Two or more sets of sections are obtained at an intervals of 400 µm, beginning 35–40% into the embedded specimen. Unstained sections 8–10-µm thick are used to examine osteoid morphology and to measure fluorochrome-labeled surfaces. Sections 5–7-µm thick stained with toluidine blue are used to measure wall thickness. Sections 5-µm thick with Goldner's stain [48] are used for other histomorphometric measurements.

Microscopy

The histomorphometric variables described earlier are derived from data gathered at the microscope. These data include the width of both cortices and—in defined sectors

of cancellous bone—volumes of bone, osteoid, and marrow; total trabecular perimeter; perimeters with features of formation (see Fig. 36.1) or resorption (see Fig. 36.2); thickness of osteoid and osteon walls; and interlabel width. Methods have been described for unbiased sampling of microscopic features [49].

Our histomorphometry laboratory uses an interactive image analysis system (BIOQUANT OSTEO 2011 v11.2 Bone Biology Research System; BIOQUANT Image Analysis Corporation, Nashville, TN, USA). A digital camera mounted on the microscope presents the microscopic images on screen, and measurements are made using a mouse. Fluorescent light at a wavelength of 350 nm is used to examine fluorochrome labels (see Fig. 36.3).

INDICATIONS FOR BONE BIOPSY AND HISTOMORPHOMETRY

The purpose of bone histomorphometry in the clinical setting is to gather information (i.e., to establish a diagnosis, clarify a prognosis, or evaluate adherence or response to treatment) on which to base informed clinical decisions. As is the case for every invasive procedure, the risk, discomfort, and expense should be proportionate to the importance of the information to be gained. Given these caveats, the number of clinical indications for this procedure is limited. Clinicians can manage most metabolic bone diseases, including osteoporosis, without the aid of a bone biopsy. However, there are some situations in which bone biopsy after fluorochrome labeling is appropriate, as outlined in Table 36.2.

Bone histomorphometry has been, and remains, crucial for assessing the mechanism of action, safety, and efficacy of new bone-active agents. Preclinical animal work includes serial biopsy specimens at multiple skeletal sites, using different colored fluorochrome labels (e.g., calcein or xylenol orange). Testing of every new bone-active treatment should include bone biopsy in at least a subset of subjects.

Table 36.2. Examples of Clinical Situations in Which Bone Histomorphometry Can Provide Useful Information*

1. When there is excessive skeletal fragility in unusual circumstances
2. When a mineralizing defect is suspected
3. To evaluate adherence to treatment in a malabsorption syndrome
4. To characterize the bone lesion in renal osteodystrophy
5. To diagnose and assess response to treatment in vitamin D-resistant osteomalacia and similar disorders
6. When a rare metabolic bone disease is suspected

*Adapted with permission (Ref. 50).

Trabecular bone histomorphometry provides a method for examining both bone properties and bone physiology. Cortical bone histomorphometry is seldom used because it requires obtaining a rib biopsy, a procedure more risky, expensive, and painful than transilial biopsy. Because of the random orientation of the transilial specimen with regard to the long axis of haversian systems, minimal information on cortical bone remodeling can be obtained from transilial specimens.

ACKNOWLEDGMENTS

The author thanks Susan Bare, Kathy McCon, and Toni Howard for assistance in describing technical methods and preparing digital photomicrographs.

SIGNIFICANCE OF VERTEBRAL FRACTURE

Vertebral fracture is usually the first osteoporotic fracture to occur and is also the most common osteoporotic fracture, being present in 15% of women aged 50–59 years and in 50% of women aged more than 85 years [1, 2]. Accurate recognition of vertebral fracture is essential to comprehensive clinical evaluation, determination of population prevalence, fracture risk, and evaluating treatment efficacy [3–5]. Almost half of all vertebral fractures occur in patients with low bone mineral density (BMD) (T-score at or below –1.0; osteopenia) rather than osteoporosis (T-score at or below –2.5) as defined by dual energy X-ray absorptiometry (DXA), as low BMD is much more common than osteoporosis [6, 7]. The presence of a nontraumatic vertebral fracture in older subjects provides such indisputable evidence of reduced bone strength that these patients should be considered as having osteoporosis. For this reason the National Osteoporosis Foundation has recommended that patients aged over 50 years with nontraumatic new vertebral fracture receive appropriate bone protective/bone enhancing therapy, irrespective of DXA T-score [8].

The presence, severity, and number of osteoporotic vertebral fractures are important predictors of further vertebral fracture risk [9]. Over an 8-year period, subjects with prevalent (i.e., preexisting) vertebral fractures had a fivefold increased risk of further vertebral fracture and a threefold increased risk of proximal femoral fracture than those without an incident vertebral fracture [10]. Vertebral fracture risk is 20% in the year following the incident (i.e., new) vertebral fracture. However, this relative risk is fourfold greater in those with a severe, rather than a mild, fracture and threefold greater in those with multiple, rather than a single, vertebral fracture [11]. In addition to being an indicator of increased fracture risk, vertebral fracture is also associated with reduced quality of life and increased mortality, particularly from pulmonary disease and cancer [12]. If vertebral fractures are recognized early and treated with appropriate antifracture medication, there is a significant reduction in the occurrence of new vertebral and nonvertebral fractures [13].

Despite the clear clinical importance of vertebral fractures, they remain underdiagnosed in clinical practice [14, 15]. There are two main reasons for this underdiagnosis: firstly, the typical clinical symptoms of back pain and restricted movement are usually attributed to spondylosis rather than vertebral fracture so that most patients with vertebral fracture do not seek medical attention [15]. However, improving patient awareness may not improve diagnosis, as only about one-third of vertebral fractures diagnosed retrospectively have a symptomatic period [16]. Secondly, many vertebral fractures evident on imaging are not reported. For example, 17% of elderly subjects attending an accident and emergency center had a moderate or severe vertebral fracture on lateral chest

radiographs, but only 50% of these fractures were included in the radiology reports, and even fewer affected patients received appropriate medical intervention [7]. Even this study underestimated the true fracture prevalence as mild fractures were not included and lumbar radiographs were not available [17].

As many vertebral fractures are clinically asymptomatic, radiologists and clinicians who review imaging studies are urged to look specifically for the presence of vertebral fractures [4, 5]. If a vertebral fracture is present, then it is imperative that the report states this clearly as a "vertebral fracture" and that ambiguous terminology (e.g., "vertebral collapse," "compressed vertebral body," "loss of vertebral height," "wedging of vertebral body," "wedge deformity," "biconcavity," or "codfish deformity") is avoided. The presence, location, and severity of a vertebral fracture should also be clearly stated.

The World Health Organization's 10-year fracture risk assessment tool (FRAX®) was released in 2008 to help individualize osteoporotic fracture risk. While DXA-measured BMD is predictive of overall relative vertebral fracture risk, this risk is difficult to apply to an individual patient in clinical practice. The FRAX Web-based prediction model integrates easily assessed clinical risk factors such as age, sex, ethnicity, weight, height, fracture history, smoking, alcohol, steroid use, and rheumatoid arthritis, and has been adapted for different populations worldwide (http://www.shef.ac.uk/FRAX). FRAX is an important initiative in allowing clinicians to individualize fracture risk. It helps identify patients who are at fracture risk and can also be applied without BMD measurements in patients with limited access to densitometry. FRAX is mainly applicable to osteopenic patients as the results do not influence clinical management in patients with normal BMD or those known to have osteoporosis [18, 19]. FRAX is being incorporated into national guidelines on the management and treatment of osteoporosis, though intervention algorithms vary between nations. In the U.S., the National Osteoporosis Foundation (NOF) has added FRAX to the criteria for treating patients with a threshold of 3% for hip fracture and 20% for a major osteoporotic fracture [20]. In the U.K., a different treatment algorithm was issued by the National Osteoporosis Guidelines Group (NOGG), which recommended that FRAX be used in a triage scheme to select patients who would benefit from having a DXA examination [20, 21].

PATHOPHYSIOLOGY OF VERTEBRAL FRACTURE

The vertebral body has a relatively large trabecular bone component and relies more on trabecular bone than cortical bone for its strength. As trabecular bone is thin with a large surface area, it is particularly responsive to changes in the microenvironment and is affected before cortical bone in the development of osteoporosis. As a result, the vertebral body is particularly prone to osteoporotic fracture. The weakest parts of the vertebral body are the central component of the endplates and anterosuperiorly where lower BMD is not compensated for by a higher trabecular strength [22]. As opposed to appendicular skeletal fractures, which occur as a definitive event, vertebral body fractures often progress incrementally over many months or years. This incremental progression of osteoporotic vertebral fracture is evident histologically with features of both recent fracture and bone repair occurring together [23, 24] (Fig 37.1).

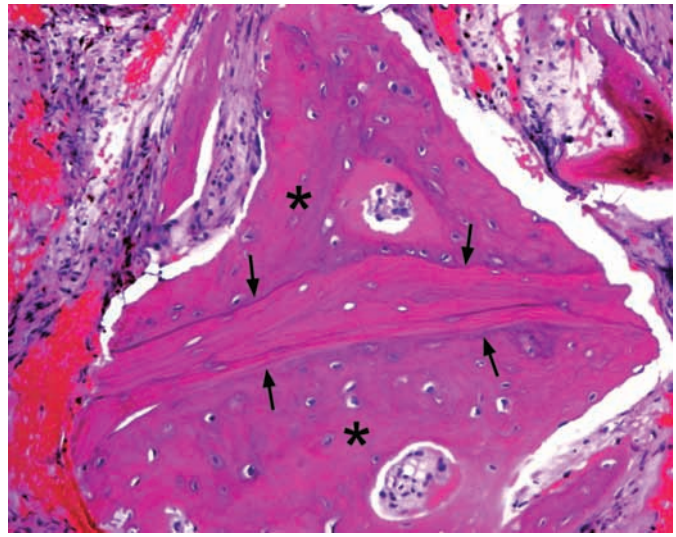

Fig. 37.1. Histological section from fractured human vertebral body showing a band of dead bone (arrows) containing osteocytes reduced to lacunae without viable nuclei. This band of dead bone is juxtaposed against less mature reparative new bone (*). Hematoxylin & Eosin x 180.

Bone is architecturally an adaptive tissue that responds to mechanical load and use. Increase in vertebral body cross-sectional area will increase vertebral body strength. Males have larger bones than females, which are also substantially more heavily loaded. Periosteal bone apposition, particularly in males, may potentially compensate for the increased fragility caused by reduction in BMD, through an increase in vertebral cross-sectional area. A longitudinal volumetric quantitative CT (vQCT)-based study confirmed that females, in addition to having smaller vertebral bodies and losing BMD more rapidly, increase vertebral cross-sectional area more slowly than males, predisposing females to higher vertebral fracture risk [25].

A vertebral fracture occurs when the forces applied to a vertebral body exceed its strength. Functional loading of the spine is primarily compressive in nature. Micro-computed tomography, combined with finite element analysis (FEA), have shown that major load pathways through the vertebral body seem to be parallel to the columns of vertical trabeculae. The cortical shell and the horizontal trabeculae, although considered important in

bracing vertical trabeculae against bending and buckling, appear to have a relatively modest role in resisting compressive forces [26]. While both horizontal and vertical trabeculae reduce in number with aging, only horizontal trabeculae reduce in thickness [27]. FEA suggests that this may be due to horizontal trabeculae being reabsorbed preferentially as the result of "adaptive strain resorption," while vertical trabeculae are reabsorbed as a result of microdamage [28]. This results in prominent vertical striated appearances of the vertebral bodies on imaging, which may be evident before vertebral fractures occur. When radiographic osteopenia is evident, osteoporosis should be suspected and DXA scanning would be appropriate. In addition to trabecular orientation being relevant to strength of the vertebral body, trabecular shape is also important with osteoporosis associated with a transition from plate-like to a more rod-like trabecular morphology [29].

Depending on the force applied and inherent vertebral body strength, fracture severity varies from a small peripheral fracture to a complete vertebral body fracture. Most vertebral fractures occur in the mid-thoracic and thoracolumbar regions [30]. Forces applied to the spine in these sites may exceed the inherent vertebral body strength. Compressive loading is accentuated in the mid-thoracic spine during flexion when there is a kyphosis present and also in the thoracolumbar region, which is the transition zone between the relatively fixed thoracic and more mobile lumbar segments. Osteoporotic vertebral fractures are very uncommon above the T4 level [31]. Loading on the spine is determined by gravitational forces and muscle contracture, which in turn are influenced by body weight, height, muscle action, coordination, and strength, as well as spinal curvature and intervertebral disks characteristics [32]. Fracture of a single vertebral body, particularly if of an anterior wedge type, shifts compressive forces toward the anterior aspects of the vertebral bodies to the extent that a "vertebral fracture cascade" may ensue, with fractures in adjacent vertebrae occurring in quite rapid succession [32].

DETECTION OF VERTEBRAL FRACTURE

Clinical detection

Increasing age, previous nonvertebral fracture, low BMD, low body mass index, current smoking, low milk consumption during pregnancy, low physical activity, having a fall, and regular use of aluminum-containing antacids all increase the likelihood of a first vertebral fracture [33]. Only about one in four vertebral fractures are recognized as a distinct clinical event as symptoms are nonspecific [4]. Probably the most effective clinical discriminator of incident vertebral fracture is a measured height loss of greater than 2 cm or a recalled height loss of greater than 4 cm. A measured height loss of greater than 2 cm had a 35% sensitivity and 94% specificity for incident vertebral fractures [34], while a recalled height loss of greater than 4 cm is associated with a threefold increased likelihood of identifying a vertebral fracture [35].

Spinal radiography

Radiography, as the most widely available and least expensive bone imaging modality, can reveal grades of bone density with normal bone being appreciably more dense than osteoporotic bone. On radiography, one can accurately distinguish between unequivocally normal bone and unequivocally osteoporotic bone. However, bone in most subjects is neither unequivocally normal nor unequivocally osteoporotic. In these subjects, the use of radiography to separate patients with mildly reduced bone density from those with osteoporosis is not very accurate. Osteoporotic vertebral fractures will only occur in the presence of reduced bone density. Radiographic detection of reduced bone density and osteoporosis is subjective and also dependent on radiographic technique, radiographic equipment, and patient body habitus. Additional radiographic signs of osteoporosis such as cortical thinning, trabecular rarefaction, cortical endosteal scalloping and intracortical tunneling can also be used to help recognize osteoporosis though appreciation of these radiographic signs is, similar to bone density, heavily dependent on the experience of the observer.

The majority of vertebral fractures are diagnosed using radiography of the thoracic and lumbar spine. Radiography is a good method for the diagnosis of vertebral fractures because it is easy and quick to perform, widely available, and of relatively low cost. For optimal radiographic assessment, a standardized high-quality image is essential. A radiographic protocol should visualize the C7-S1 vertebrae. Time and effort should be spent on obtaining finely collimated properly positioned anteroposterior (AP) and lateral views of the spine with the X-ray beam centered at T7 and L3 for the thoracic and lumbar spines respectively and a focus–film distance of 100 cm [Fig. 37.2(a), (b)]. The C7-T3 vertebral bodies are often not clearly seen on lateral thoracic spine radiographs due to superimposition of the scapulae and shoulder regions, but fortunately, isolated osteoporotic fractures are uncommon in this region. On the lateral projection, the spine must be parallel to the film so that the vertebral endplates at the level of the central X-ray beam are superimposed and seen as a single dense, well-defined cortical line. As a result of the divergent X-ray beam the endplates distant from the centering point will appear concave ("bean can" effect) and must not be mistaken for vertebral fractures. Usually a lateral spinal projection will suffice, although an AP projection is occasionally useful to (i) determine if scoliosis is present and (ii) determine the anatomical level of a vertebral fracture. The anteroposterior projection is particularly useful in assessment of the thoracic spine since the vertebral body outline is not so consistently seen as in the lumbar region. One should be aware, however, that mild

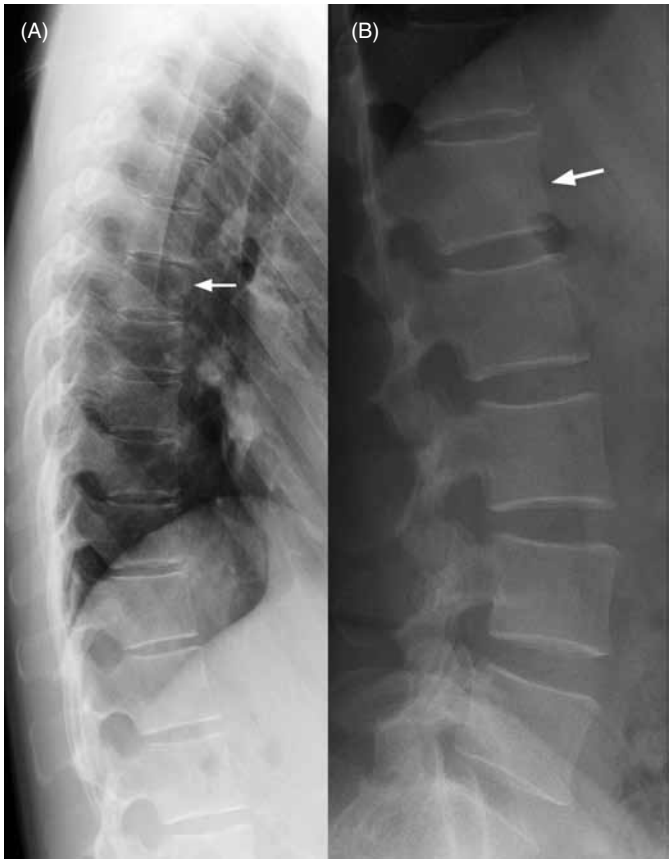

Fig. 37.2. (A) Lateral radiograph of normal thoracic spine in subject with low BMD. There is minor physiological anterior wedging of the T6 vertebral body (arrow). (B) Lateral radiograph of normal lumbar spine. There is slight physiological wedging of the L1 vertebral body (arrow).

vertebral fractures may be overlooked on a frontal (antero-posterior) projection of the thoracic spine. The typical effective dose of ionizing radiation from a single lateral and AP projection of the thoracic spine are 0.3 mSv and 0.4 mSv, respectively, while for the lumbar spine they are 0.3 mSv and 0.7 mSv, respectively. For comparison, a 16-hour return transatlantic flight would amount to 0.07 mSv background radiation [36].

Problems in the diagnosis of vertebral fracture on radiographs

Although there is good agreement in the radiological diagnosis of moderate and severe vertebral fractures, there is considerable contention in the diagnosis of mild vertebral fractures. The difficulty in defining a mild vertebral fracture is a reflection of six pitfalls when assessing spinal radiographs for vertebral fracture:

(1) Mild physiological anterior or posterior wedging may be misinterpreted as a mild fracture but is a normal and entirely necessary feature of the thoracic and lumbar vertebral bodies as the spine changes from a thoracic kyphosis to a lumbar lordosis. Normal spinal curvature dictates that vertebral bodies are slightly anteriorly wedge shaped in the thoracic and upper lumbar spine, not wedged in the mid-lumbar region and slightly posteriorly wedge shaped in the lower lumbar region [Fig. 37.3(a), (b)] [37]. The degree of wedging is dependent on inherent sagittal spinal curvature, which varies between subjects.

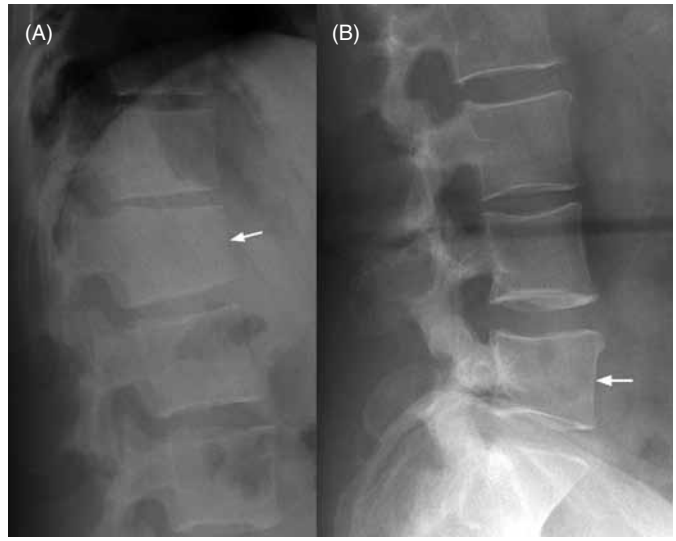

Fig. 37.3. (A) Anterior physiological wedging of the L1 vertebral body (arrow). (B) Posterior physiological wedging of the L5 vertebral body (arrow).

(2) Short vertebral body height (SVH) is a common feature of this physiological wedging as well as increasing age and spondylosis in the absence of osteoporosis (Fig 37.4). In women, between about 30 and 70 years of age, the combined height of the anterior aspects of the vertebral bodies from T4-L5 decreases by about 1.5 mm per year while the combined middle and posterior heights decline by about 1.2 mm per year [38, 39]. Since true reduction in vertebral body height can only be ascertained on serial imaging studies, one cannot always be certain that a mild reduction in vertebral height evident on a baseline image is necessarily the result of a vertebral fracture. While SVH refers to reduction in vertebral height of up to about 20% expected height. Differentiating SVH from a mild vertebral fracture is probably the most contentious and difficult area in vertebral fracture diagnosis. The majority of evidence suggests that isolated SVH is not associated with low BMD or vertebral fracture [40]. In a DXA vertebral fracture assessment (VFA) study in which comparison was made between 250 premenopausal and 1,350 postmenopausal women, the prevalence of SVH was approximately 35%. The prevalence was similar in pre- and postmenopausal women and was not associated with low lumbar spine BMD. Premenopausal women with SVH tended to be older and heavier than those without SVH, while postmenopausal women with SVH tended to have higher spine BMD than those without SVH [41]. SVH, when isolated and in the absence of endplate changes, is most likely the result of physiological wedging exacerbated by

Fig. 37.4. Lateral radiograph of lumbar spine. There is "short vertebral height" with all of the lumbar vertebrae reduced in height by 15–20% compared to expected vertebral body height. Note associated spondylosis with marginal osteophytosis.

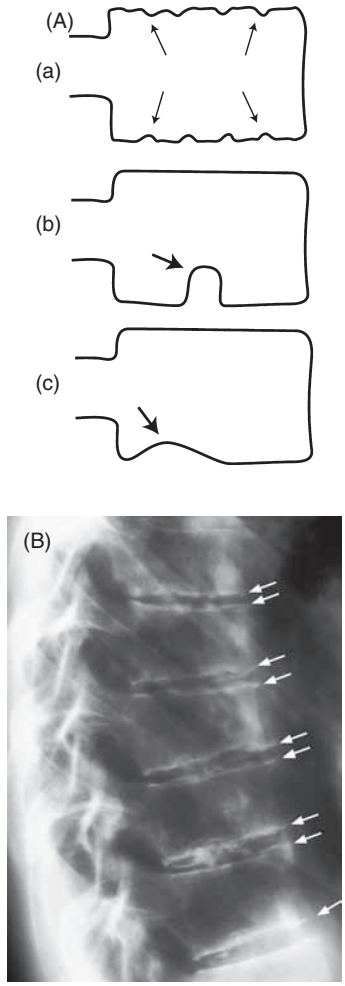

Fig. 37.5. (A) Schematic diagram showing endplate impressions caused by (a) Scheuermann's disease (b) Schmorl's node, and (c) Cupid's bow deformity. (B) Lateral radiograph mid-thoracic region showing diffuse endplate irregularity (arrows), narrowing of the intervertebral discs and elongated anteroposterior diameter of the vertebral bodies all consistent with Scheurmann's disease.

vertebral body remodeling due to increasing age or spondylosis.

(3) Vertebral deformity is a feature of an uncommon spinal disorder known as Scheuermann's disease [40]. Scheuermann's disease generally occurs during the teenage years and is characterized by endplate irregularity/indentation of the thoracic or lumbar vertebrae [Figs. 37.5A, 37.5B]. The disorder may involve only one or two vertebrae or longer segments of the spine. It is typically associated with reduced vertebral height, often in conjunction with an increased anteroposterior vertebral body diameter and usually associated with small discs and premature disc degeneration.

(4) Developmental, or more commonly degenerative, scoliosis may lead to obliquity of vertebral bodies and side-to side discrepancy in vertebral body height. On the lateral projection, this obliquity produces a spurious biconcave outline to the vertebral endplates that may be misinterpreted as a vertebral fracture. On the AP projection, the vertebral bodies, particularly at the apex of the curve, will be shortened on the concave side and of normal height or even elongated on the convex side. This scoliotic wedging, providing it is predominantly one-sided and commensurate with the severity of scoliosis, should not be misinterpreted as a vertebral fracture. Difficulty with interpretation of vertebral body height in moderate to severe scoliosis often leads to such patients being excluded from clinical trials, in part also due to the confounding effects on DXA BMD.

(5) Schmorl's nodes are discrete indentations of the endplates related to degenerative disc disease. Small Schmorl's nodes are a common finding, being present in 40–75% of imaging studies, particularly in degenerative disease of the lumbar spine. Medium-sized or large Schmorl's nodes occur much less frequently and may be misinterpreted as an endplate

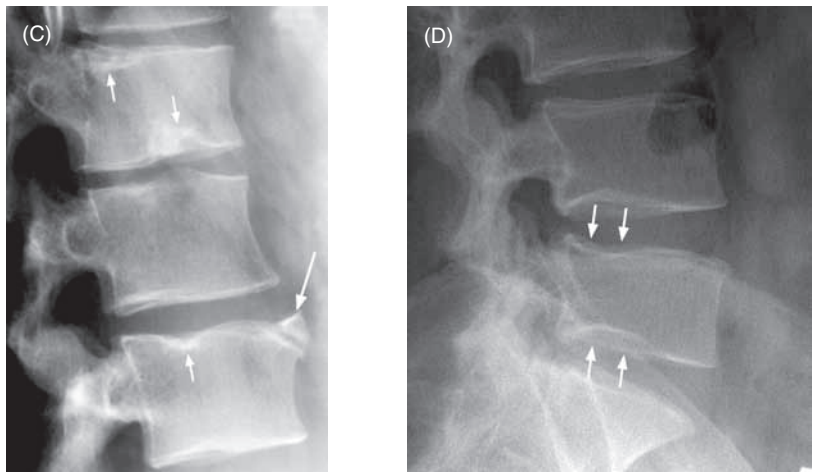

Fig. 37.5. (*Continued*) (C) Lateral radiograph of lumbar spine showing medium-sized Schmorl's nodes of the superior and inferior endplates (small arrows). This is also a limbus vertebra present (long arrow). (D) Lateral radiograph lower lumbar region showing smooth indentation of inferior and superior endplates of L5 (arrows) due to Cupid's bow deformity.

fracture. However, they can usually be readily distinguished from fractures by their well-defined rounded contour, intact sclerotic margin, and only focal involvement of the endplate [Figs. 37.5A, 37.5C].

(6) Cupid's bow deformity is a reasonably common developmental endplate contour abnormality most frequently affecting the inferior, and less frequently the superior, endplates of the fourth and fifth lumbar vertebral bodies [42] [Figs. 37.5A, 37.5D]. This contour deformity may also involve the endplates of the more cephalad lumbar vertebrae and those of the thoracolumbar vertebrae. Cupid's bow deformity most likely results from focal deficiency of the cartilage component of the endplate in the parasagittal regions of the vertebral body [42]. This absence of the cartilage component focally impairs endochondral growth of the vertebral body leading to the characteristic concave endplate depressions seen radiographically. The shape of the resulting deformity on the anteroposterior projection resembles "Cupid's bow." On the lateral projection, the posterior two-thirds of the inferior endplate are indented, simulating endplate fracture depression.

One can therefore appreciate that while all vertebral fractures result in vertebral deformity, not all vertebral deformities represent a vertebral fracture [31]. Vertebral fracture must be differentiated from these other etiologies , which may also change vertebral shape. The term "deformity" is appropriate when reporting such etiologies [43]. With careful scrutiny of imaging features, these various vertebral deformities can be differentiated from vertebral fractures.

Defining a vertebral fracture

Although there is no universally accepted definition of what constitutes a vertebral fracture, there is wide agreement that a vertebral fracture involves decrease in anterior, middle, or posterior vertebral height. Accurate identification of vertebral fracture on imaging studies is critically important not just for clinical management but also in research studies assessing the prevalence of vertebral fracture or efficacy of anti-fracture therapies. The over- or underreporting of vertebral fracture by an inexperienced reader can significantly skew research findings [44].

The approach to vertebral fracture diagnosis can vary considerably between a clinical setting and a research setting. In a clinical setting there is a specific clinical indication, only a single examination is being evaluated, previous radiographs or other imaging studies may be available for review, and a more experienced opinion or additional imaging can be sought to aid diagnosis if indicated. In the research setting, imaging is often performed without specific clinical need, evaluation is generally limited to lateral radiographs, a large number of subjects are involved requiring that high efficiency and assessment be performed by various readers with different levels of experience [31].

In an effort to produce definable, reproducible, and objective methods of detecting vertebral fracture, several methods have been developed and refined to diagnose and grade the severity of vertebral fracture on radiographs. These methods, which have also been applied to DXA VFA and computed tomography (CT) images, can be broadly considered as either qualitative, semi-quantitative (SQ), or quantitative morphometic (QM) in approach.

Semi-quantitative assessment

Semi-quantitative (SQ) analysis may involve either (a) measurement of vertebral height followed by evaluation of vertebrae reduced in height by an expert reader to determine the cause, or, more commonly, (b) evaluation

of spinal radiographs by an experienced reader without prior measurement of vertebral heights. The most widely used SQ approach is that of Genant et a1. [30, 45] (Fig. 37.6). Vertebral fractures are graded from 1 (mild) to 3 (severe), and incident fractures are defined as an increase of one grade or more on follow-up radiographs (Fig. 37.7). Grade 1 (mild) vertebral fracture corresponds to a ~20–25% reduction in anterior, middle, and/or posterior height compared to normal adjacent vertebrae or compared to expected height of the vertebral body based on experience (Fig. 37.6). Grade 2 (moderate) vertebral fracture is a ~25–40% reduction in vertebral height (Fig. 37.6), while grade 3 (severe) vertebral fracture is a ~>40% reduction in vertebral height (Fig. 37.6). The approximation symbol (~) is applied because the height reductions are generally visually estimated rather than measured directly. Additionally, other morphologic changes of endplate buckling or bowing and interruption of cortical margins are factored into the diagnosis of vertebral fracture. Applying these grades in research studies enables a spinal deformity index (SDI) to be assigned to each patient by summating the semi-quantitative scores for the T4 to L4 vertebrae [46].

Grading the severity of vertebral fracture recognizes the incremental nature of vertebral fracture and enables fracture progression from mild to moderate or moderate to severe to be meaningfully described on follow-up radiographs (Fig 37.7). The more severe the vertebral fracture, the greater the deterioration in bone architectural parameters as assessed by two-dimensional (2D) histomorphometry and three-dimensional (3D) microcomputed tomography [47], and this increases the risk of future fracture. It is therefore clearly important in both clinical practice and in a research setting to report and grade the severity of vertebral fracture in addition to simply recording the presence of a fracture.

The SQ method is a standardized method with excellent interreader reliability. For prevalent fractures, the agreement between each of three readers and a consensus reading yielded a kappa score of 0.84–0.87 for incident fractures and 0.86–0.96 for prevalent fractures [47, 48]. SQ analysis of spinal radiographs for vertebral fracture is quicker to perform than other methods of vertebral fracture assessment, is easy to implement in clinical practice, and suited to both epidemiological research studies and clinical therapeutic efficacy trials. Vertebral fractures detected by SQ analysis are associated with low BMD and are predictive of future fracture, independent of BMD [9, 14, 49, 50]. For follow-up studies, serial radiographs should be viewed together in a temporal order to fully appreciate changing vertebral morphology. Although visual assessment methods of vertebral fracture detection are more subjective than morphometric analysis, they do allow the experienced reader to address issues such as nonosteoporotic deformity. SQ analysis is also better suited to deal with errors introduced by radiographic technique such as varying magnification effect, which clearly would influence serial vertebral body measurements. The SQ method is a practical and reproducible method of vertebral fracture assessment when performed by trained and experienced readers [41, 51].

Vertebral quantitative morphometry

Vertebral quantitative morphometry (QM) is used in a research, but not in a clinical, setting [52]. The two main advantages of vertebral morphometry over other methods is that (i) it can be undertaken by relatively inexperienced or nonmedical research staff, and (ii) it provides an objective measure of loss of vertebral height on serial images. While the description and definition of the methodology is straightforward, the application in practice is often rather subjective.

The margins of each vertebral body from T4 to L4 are identified by six points on the upper and lower endplates—one for each corner and one for each of the endplate midpoints (Fig. 37.8). Marginal osteophytes, uncinate processes, and Schmorl's nodes are not included. For vertebrae off center from the central X-ray beam causing an oval shape to the endplates, the midpoint of the ovoid upper and lower endplate contour is chosen (Fig. 37.8).

Placement of the six points can be manual or automated. The automated method comprises computerized vertebral boundary recognition of a digitalized spinal radiograph. Automated point placement is checked and adjusted, if necessary, by a trained reader. The anterior (A_H), middle (M_H), and posterior (P_H) vertebral heights are immediately available for analysis and archiving.

Vertebral height ratios are used to define vertebral shape with A_H/P_H reflecting anterior wedging, M_H/P_H reflecting endplate concavity, and $P_H/P_{H'}$ of the adjacent normal vertebrae reflecting posterior compression [53]. Prevalent vertebral fracture is defined as a reduction in one or more of the three vertebral height ratios (A_H/P_H, M_H/P_H, or $P_H/P_{H'}$) of greater than 20% or 3 SD (standard deviations) from the mean of a reference population. Incident vertebral fracture is defined as a reduction in one of the three height ratios (A_H/P_H, M_H/P_H, or $P_H/P_{H'}$) greater than 15% or 3–4 mm compared to the baseline [1, 54]. While the reproducibility of QM is good in normal subjects (interobserver coefficient of variation less than 2%), it is lower in those with osteoporotic fractures [(interobserver and intraobserver coefficient of variation of 5% and 6.3% for M_H, respectively] [55].

Positioning QM reference points is partly subjective, especially for the vertebral midpoints where obliquity of the radiographic beam often produces a double endplate contour. Even with good radiographic technique, a mild degree of scoliosis will invariably lead to the endplate being visualized slightly en face. In such situations, observer experience will influence reference point placement for baseline and sequential imaging examinations. Small differences in reference point placement on follow-up radiographs can result in misdiagnosis of incident vertebral fracture by QM, though readily interpreted by the expert reader as simply due to a slight alteration in projection. QM also does not distinguish between

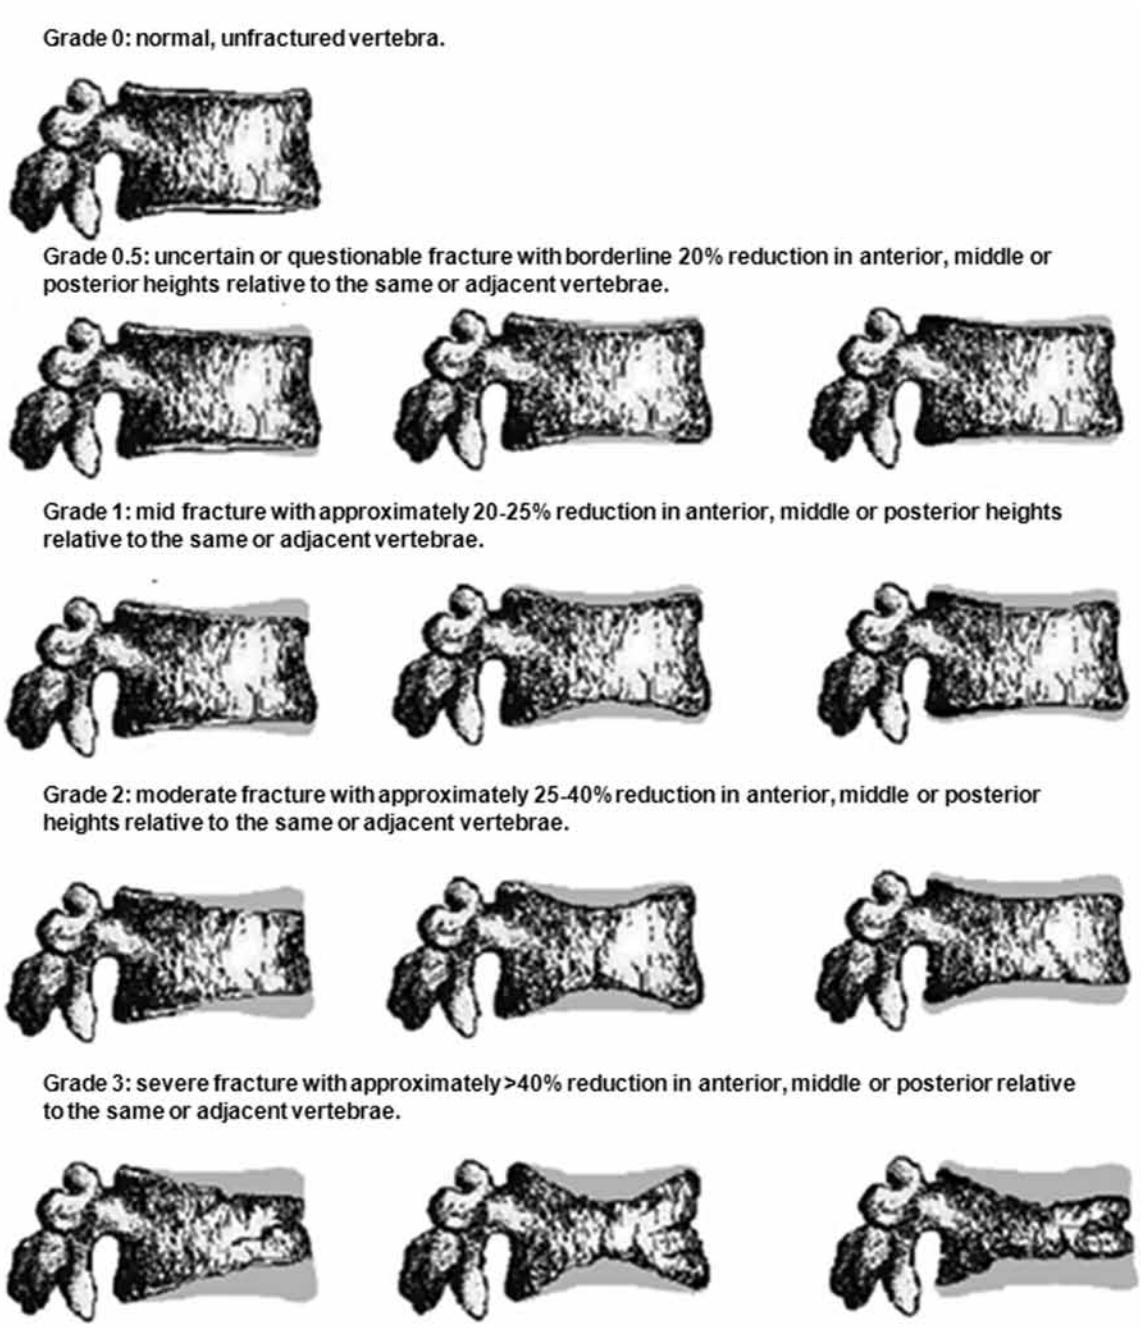

Fig. 37.6. Schematic diagram of Genant semi-quantitative analysis of vertebral fracture severity (adapted from Ref. 26).

vertebral fracture and non-fracture vertebral deformity (such as SVH or physiological wedging). While there is good concordance between QM and SQ methods in the detection of moderate or severe vertebral fractures, the concordance between both methods for detection of mild vertebral fractures is poor. In most instances, this is due to a false positive diagnosis of mild fractures by quantitative morphometry [15, 55]. Therefore, all fractures identified by vertebral morphometry should be confirmed by an expert reader before diagnosis of a vertebral fracture is made [55].

Defining normative databases for QM is fraught with difficulty, as is defining the threshold used for vertebral fracture diagnosis, as the quality of reference data, and, more particularly, the thresholds chosen will greatly influence fracture detection rate [2]. Vertebral morphometry is probably most suited to evaluating (a) large longitudinal studies and (b) individual vertebra in DXA VFA

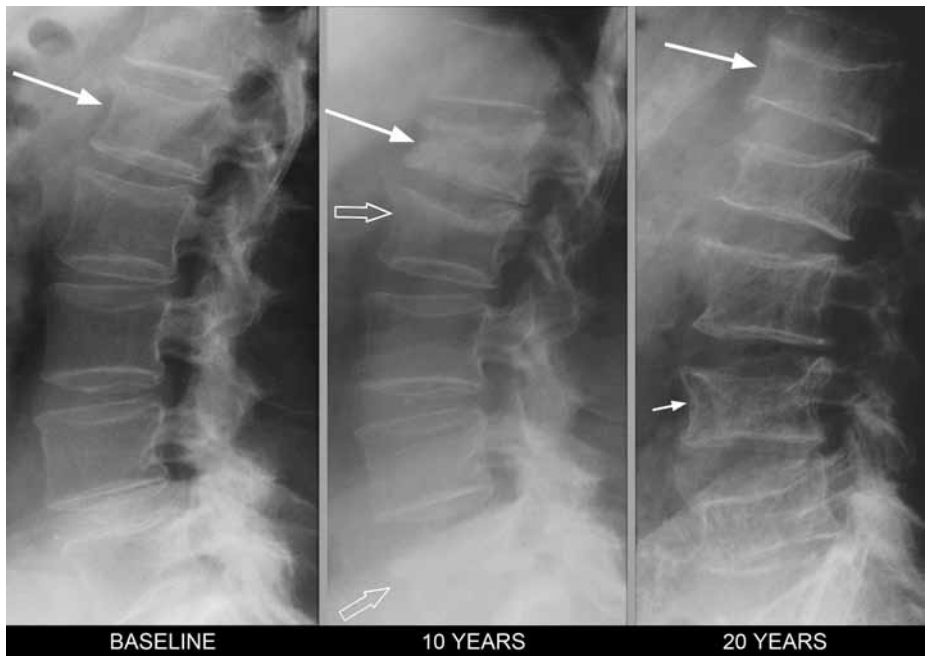

Fig. 37.7. Lateral radiographs of lumbar spine in same patient showing progression of vertebral fractures akin to "vertebral cascade." At baseline, there is a mild vertebral fracture of L1 (long arrow). Ten years later, this L1 vertebral fracture is now moderate in severity (long arrow) and there are new fractures of L2 and L3 (open arrows). Twenty years later, there is a new fracture of L4 (short arrow).

where large normative databases are available. Computerized vertebral morphometry is suited to analysis of a large number of spine radiographs and particularly for single center analysis in multicenter trials. More sophisticated automated models for vertebral morphometry have recently been developed using statistical-model-based and other approaches [2, 56].

Algorithm-based qualitative assessment

The algorithm-based qualitative (ABQ) method, as the name implies, emphasizes a qualitative assessment of vertebral fracture and relies more on detection of vertebral endplate abnormalities related to fracture than loss of vertebral body height. The ABQ method categories vertebrae as either (i) normal, (ii) osteoporotic fracture, or (iii) non-osteoporotic deformity or short vertebral height (SVH). The diagnosis of an osteoporotic vertebral fracture requires evidence of vertebral endplate fracture with loss of expected vertebral height but with no minimum threshold for apparent reduction in vertebral height [57]. If a fracture of the cortical margin in also visible radiographically, this provides clear-cut evidence that there is a fracture present and it is likely to be of recent origin. When one of more vertebral height (anterior, middle, or posterior) is shorter than expected but without specific endplate abnormalities of fracture (altered texture below endplate due to microfractures), this is designated as nonosteoporotic deformity.

Dual energy X-ray absorptiometry

Imaging vertebral fractures using dual energy X-ray absorptiometry (DXA) is known as vertebral fracture assessment (VFA) (Fig 37.9). VFA has several advantages over radiography, including greater convenience, as it can be performed at the same time as DXA and on the same equipment; lower radiation dose (less than 5% of spine radiography); and low cost [36, 58]. VFA allows a more ready detection of prevalent vertebral fractures [58]. Combining prevalent vertebral fracture status with BMD enhances fracture risk prediction of both vertebral and nonvertebral fractures [5, 9, 59].

VFA requires a fan-beam DXA scanner with appropriate software and can be performed either with the patient lying supine on a scanner with rotating "C" arm gantry or with the patient in a lateral decubitus position when performed in a scanner with a fixed gantry. Modern fan-beam DXA scanners can obtain single energy images of the spine from T4 to L4 in less than 10 seconds during suspended respiration. These low dose images can be used to assess for vertebral fracture at the time patients are undergoing DXA bone densitometry. The T4-T6 vertebral bodies can be adequately visualized in 40–70% of patients while vertebrae from T7 and below can be adequately identified in nearly all patients [60].

As VFA is a digital technique, it lends itself to computational analysis. Following image acquisition, manual or automated vertebral morphometry known as MXA is available [2]. The vertebral body is demarcated by four or

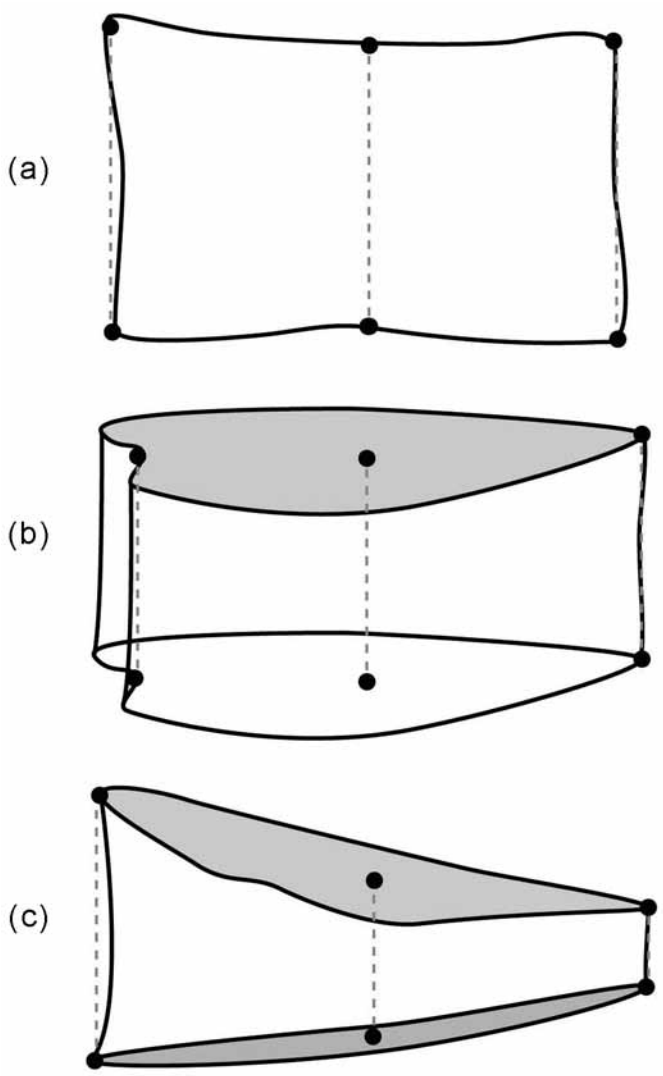

Fig. 37.8. Schematic diagram showing reference point placement for (a) normal vertebral body, (b) obliquely depicted vertebral body, and (c) anterior wedge fracture.

Fig. 37.9. Vertebral fracture assessment (VFA) by DXA showing moderate fracture of L1 vertebral body (arrow).

six reference points and vertebral body height, height ratios and average height calculated automatically (Fig. 37.10). An automated assessment of fracture status based on comparison with normative data is also available [2]. Superimposition of these baseline reference points on follow-up VFA spine images is also possible to allow more ready comparison of baseline and follow-up VFA [2]. VFA in children may be problematic as current software cannot consistently detect the vertebral outline in most children [61].

Although morphometic analysis is routinely undertaken on VFA, this alone is not recommended for fracture diagnosis. Visual inspection using the Genant semi-quantitative method is the International Society of Clinical Densitometry (ISCD) recommendation for diagnosing and grading severity of vertebral fracture on VFA. (http://www.iscd.org/Visitors/positions/OfficialPositionsText.cfm). Semi-quantitative analysis of vertebral fracture on VFA compares well with radiography [45, 62], but as the images are of lower spatial resolution than radiography, VFA visualization of the upper thoracic spine is limited (although this is an uncommon site for fracture) but superior, and VFA has only moderate sensitivity for the diagnosis of mild grade 1 vertebral fracture (20–25% reduction in expected vertebral body height). However, the sensitivity/specificity for detecting moderate (more than 25–40% reduction in expected vertebral body height) or severe (greater than 40%) vertebral fractures is greater than 90% [63]. More sophisticated MXA analytical models, such as the active appearance model (AAS), may potentially help overcome this problem with mild vertebral fracture detection. AAS is a computational technique that analyzes statistical differences in vertebral morphometry and bone texture adjacent to the endplate,

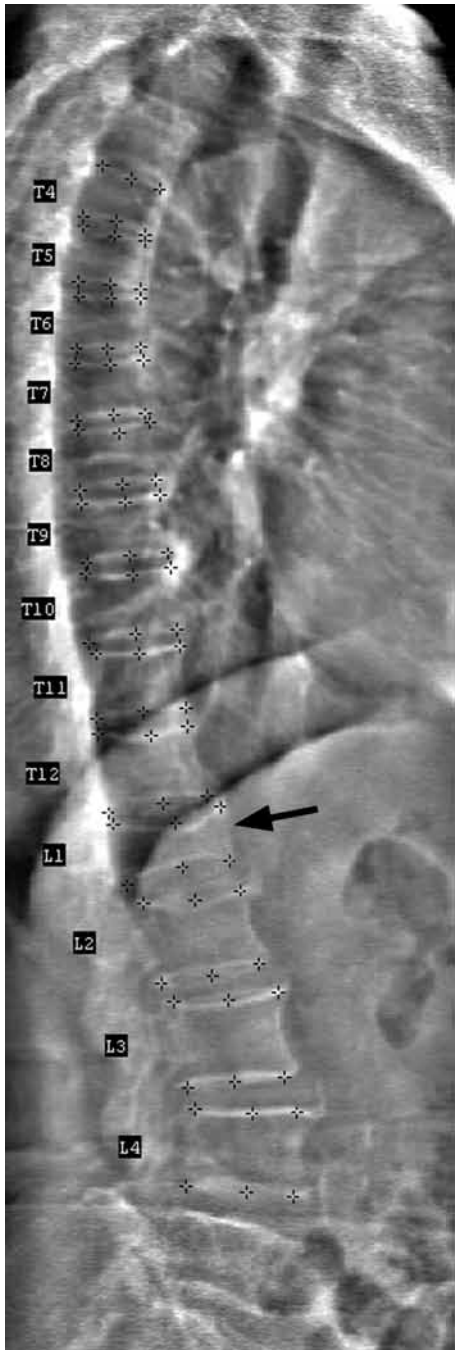

Fig. 37.10. Vertebral fracture assessment (VFA) by DXA with margins of vertebral bodies from T4 to L4 outlined by six reference points. There is a mild fracture of the L1 vertebral body (arrow).

which may improve discrimination of mild vertebral fractures from other non-fracture vertebral deformities [64].

One other advantage of VFA over radiography is that image distortion ("bean can" effect) is less as the scanning technique ensures that the X-ray beam is orthogonal, rather than divergent, to the spine, reducing the parallax effect on the endplates. However, VFA will have the same difficulties as radiography in assessment of vertebral fracture when scoliosis is present. Other advantages of VFA include convenience as both densitometry and vertebral fracture assessment can be performed at the same visit and on the same equipment, a low radiation dose [36], and relatively low cost. VFA will have an increasing important role in the diagnosis of vertebral fractures and in estimating fracture risk. In a DXA-based study of almost 1,000 patients (64% female, mean age 53 years), adding VFA to BMD analysis detected a high number of undiagnosed vertebral fractures and altered Canadian fracture risk classification in 20% of patients [65]. The added information provided by vertebral fracture by DXA assessment can be incorporated into the fracture risk assessment (FRAX) model along with DXA BMD of the femoral neck and clinical risk factors to improve individual prediction of 10-year probability (%) of developing a hip fracture or major osteoporotic fracture (distal radius, proximal femur, proximal humerus, or clinical vertebral fracture) [19] .

OTHER IMAGING METHODS

Computed tomography

The widespread availability of multidetector computed tomography (MDCT) and ease of midline sagittal reconstructions allows the thoracic or lumbar spine to be evaluated on all CT studies of the thorax or abdomen being performed for various clinical indications (Fig. 37.11). As with other image studies that may incidentally include the spine, CT enables fortuitous identification of vertebral fractures. It is important that such factures are always sought and, if present, clearly reported [4]. In a study of patients older than 55 years who had thoracic CT, one-fifth had a moderate or severe thoracic vertebral fracture but fewer than one-fifth of these fractures were reported [66]. The CT scout views should also be scrutinized routinely for vertebral fractures since these usually will include a greater length of the spine than that covered by axial sections [67, 68].

Although MDCT enables submillimeter imaging of vertebral structure (with a minimal slice thickness of 0.6 mm and minimal pixel size of 0.25 mm), this is still insufficient to image individual trabeculae. Nevertheless, textural analysis methods, rather than true structural analysis, can be applied to study vertebral architecture. Volumetric MDCT-derived structural parameters separated patients with and without vertebral fracture better than DXA-derived BMD [69], while the treatment effect of teriparatide was better evaluated by MDCT vertebral structural parameters than DXA-derived BMD [70].

Finite element analysis (FEA) is a well-established engineering computational technique that is used in virtual strength analysis of complex structures. FEA and

Fig. 37.11. Sagittal reconstruction of abdominal CT dataset (bone window) showing moderate generalized osteopenia and severe fracture of L1 (arrow) vertebral body with intravertebral gas.

other structural analytic methods can be applied to volumetric quantitative CT (vQCT) data to noninvasively estimate bone strength better than quantitative CT densitometry alone, with the potential to provide a more vigorous tailoring and monitoring of treatment protocols to prevent vertebral and other osteoporotic fractures [71]. FEA of microCT data from cadaveric vertebral bodies indicates how the integrated effects of trabecular and cortical bone on bone strength in different areas of the vertebral body can be assessed [72].

The major limitation to the more widespread primary, rather than fortuitous, use and evaluation of CT in vertebral fracture diagnosis is the cost and radiation dose involved. While the effective dose for DXA examination is 0.01–0.05 mSv, the dose for 2D QCT of the lumbar spine is 0.06–0.3 mSv, and the dose for examining vertebral microarchitecture by volumetric CT is 3 mSv (equivalent to 1.5 years of background radiation) [73].

Magnetic resonance imaging

Although spatial resolution issues currently limit the use of magnetic resonance imaging (MRI) in structurally evaluating the microarchitecture of vertebral bodies compared to CT, MRI does have distinct advantage as it does not use ionizing radiation, can measure physiological function such as molecular diffusion and perfusion, and can assess marrow changes better than any other imaging modality.

Because vertebral fractures are typically incremental in development, with occasional mild stepwise progression in severity, high sensitivity and specificity with radiographic assessment may not be achievable. Hence, a vertebral fracture is only diagnosed on radiography when there is more than 20% loss of vertebral height. This approach clearly overlooks a significant number of mild vertebral fractures that may not cause much vertebral deformity but can cause significant pain. MRI offers a solution to this problem by demonstrating marrow edema in even mild acute vertebral fractures. Marrow edema, in the absence of marrow infiltration, is a sensitive sign of acute or subacute vertebral fracture even when no fracture is visible radiographically. As MR scanners become more widely available, the use of MRI in the assessment of acute vertebral fractures may increase.

Determining the age of a vertebral fracture is usually difficult on radiographs in the absence of previous imaging to assess changes in appearance. Lack of cortical disruption, the presence of reparative sclerosis, and marginal hyperostosis or osteophytosis can help make the diagnosis of an old fracture. However, often these features may not be present. The best guide to the age of a fracture is the presence of marrow edema on fat-suppressed MR imaging. The presence and degree of edema on sagittal T2-weighted fat-suppressed MR images is a reliable guide as to the age and severity of a vertebral fracture. Conversely, vertebral fractures that lack marrow edema are not recent fractures, are not likely to respond to percutaneous vertebroplasty or balloon kyphoplasty and are less likely to be the cause of symptoms.

MRI studies have shown how perfusion is reduced in non-fractured osteoporotic vertebrae bodies compared to those of normal BMD [74, 75]. This reduced perfusion is most likely to be due to atherosclerosis, impaired endothelial function, or reduced demand for tissue oxygenation due to a relative decrease in the amount of hemopoetic marrow within osteoporotic vertebral bodies [76, 77]. MR-based perfusion parameters are reduced in osteoporotic vertebral fractures compared to adjacent non-fractured vertebrae [78]. Good perfusion is clearly a prerequisite for normal bone metabolism and fracture healing, including microdamage repair. The smaller the area of enhancing tissue within an acutely fractured vertebral body, the more likely that fractured vertebral body will reduce in height on subsequent follow up [79].

Nonunion affects about 10% of acute osteoporotic vertebral fractures. Nonunion is particularly prevalent in the T12 and L1 vertebrae and is evident radiographically

as a vacuum cleft extending horizontally across the vertebral body. These nonunited vertebral fractures are associated with more severe back pain than united fractures [80]. Risk of nonunion is increased significantly if there is retropulsion of the posterior vertebral cortex with areas of localized high intensity on T2-weighted images or diffuse low intensity within the vertebral body on T2-weighted images [80]. MRI may therefore have the potential to distinguish those acute vertebral fractures particularly susceptible to progression or nonunion and consequently more likely to benefit from more aggressive fracture treatment such as vertebroplasty.

Differentiating osteoporotic fracture from neoplastic fracture

The spine is the most common site for skeletal metastases and osteoporotic fracture, with both being features of middle-aged and elderly subjects. Almost one-third of vertebral fractures in patients with known primary malignancy are due to osteoporosis and not neoplasia [81]. In the acute stage, the marrow cavity of the vertebral body in osteoporotic fracture is filled with blood and fluid. This is gradually reabsorbed and replaced by a variable amount of granulation and fibroblastic tissue. This reparative tissue is reabsorbed over time with restoration of normal fatty marrow. It is thus not difficult to differentiate a chronic osteoporotic vertebral fracture in which the marrow is filled with fat from a pathological fracture due to neoplasia (Fig. 37.12). Difficultly arises when differentiating acute/subacute osteoporotic fracture from neoplastic fracture.

Table 37.1 outlines the most helpful imaging signs used to discriminate between acute/subacute osteoporotic fracture and neoplastic fracture [82]. A combination of these signs should be applied when making the distinction, with suitable weighting being given to their relative discriminatory power. Residual marrow fat within the fractured vertebral body is a very helpful sign of osteoporotic fracture. Fluid in a cavity within the vertebral body is another helpful sign of osteoporotic fracture on MRI, being present in more (about 40%) osteoporotic fractures when compared to neoplastic fractures (about 6%) [83] (Fig. 37.12). Fluid accumulates in a fracture cavity adjacent to the endplates of a severely fractured vertebral body and is accounted for by the vacuum cleft on radiographs or CT. Gas within a vacuum cleft arises from compression/decompression forces leading to the release of nitrogen [84]. Intravertebral gas is thus generated by flexing or extending the spine, which will be replaced by fluid on resting supine for about 15 minutes (as is applicable to MRI scans) [84]. Hence, in the vertebral body fluid on MRI and gas on radiographs reflect similar pathology. Both indicate a medium to large cavity within the vertebral body and provide good evidence that a vertebral body is not filled with neoplastic or other soft tissue. Intravenous contrast medium enhancement is not a useful discriminatory criterion as acute/subacute vertebral fractures will enhance, as will most neoplastic related fractures [82]. However, occasionally postcontrast enhancement along fracture lines may be evident in osteoporotic vertebral fracture. This would not be an expected feature of neoplastic vertebral fracture.

Fig. 37.12. T2-weighted sagittal MR image showing typical osteoporotic-type fracture of T12 vertebral body with preservation of some marrow fat and fluid- filled cavity within vertebral body (closed arrow). There is a chronic fracture of the L3 vertebral body with fat occupying the marrow cavity (open arrow).

The standard MR protocol for vertebral fracture should include (a) a T1-weighted sagittal sequence, mainly to assess fracture morphology and the presence of marrow fat; (b) a T2-weighted fat-suppressed sagittal sequence, mainly to assess marrow edema and fluid; and (c) a T2-weighed axial image to assess vertebral and paravertebral soft tissues. If doubt still exists as to the likely fracture etiology, standard MRI can be supplemented with functional imaging techniques such as diffusion

Table 37.1. Useful Imaging Signs That Help Distinguish Osteoporotic From Neoplastic Vertebral Fracture

1.	Preservation of some marrow fat signal within marrow ***
2.	No involvement of pedicles or posterior elements ***
3.	Fluid or gas within vertebral body **
4.	T1-hypointense fracture line within vertebral body (often near fractured endplate) **
5.	Lack of discrete soft tissue mass ***
6.	Only minimal or mild paravertebral soft tissue swelling **
7.	Absence of epidural mass **
8.	Fracture not occurring above T4 level ***
9.	Posterior located triangular fracture fragment *
10.	Non-convex posterior cortical margin *
11.	Evidence of metastases elsewhere in spine *
12.	Near complete fatty marrow of adjacent vertebrae *
13.	Radiographic evidence of osteopenia *
14.	Preservation of trabeculae within fractured vertebral body on CT *** (Fig 37.13)

The relative usefulness of these signs is indicated with *** = most useful, ** = less useful, and * = least useful signs. A known history of malignancy is moderately helpful. If doubt still exists after standard MR imaging, one can proceed to diffusion-weighted imaging or chemical shift imaging (Ref. 82).

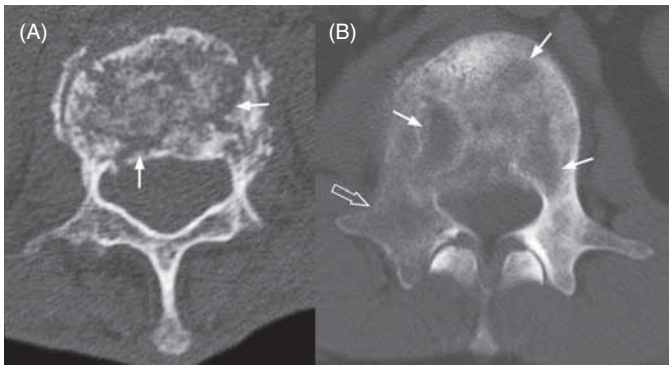

Fig. 37.13. Axial CT images of (A) osteoporotic fracture showing preservation of vertebral trabeculae with intervening fracture lines (arrows), (B) neoplastic fracture showing quite discrete lytic areas (arrows) due to metastatic infiltration and also expansion of right pedicle and adjacent neural arch (open arrow).

weighted imaging [85] or chemical shift imaging [86]. If doubt exists after MR imaging, CT is a useful additional investigation. In practice, one can usually distinguish accurately between osteoporotic and neoplastic vertebral fractures on imaging (radiography, CT, MRI) features alone, without the need for percutaneous vertebral biopsy.

Patients may, in certain circumstances, undergo FDG-PET (flurodeoxyglucose positron emission tomography) imaging as part of clinical investigation, and this too can be helpful in differentiating osteoporotic from neoplastic vertebral fracture. As expected, a higher radioactive uptake is present in neoplastic vertebral fractures [standardized uptake value 2.2–7.1, mean 3.99±1.52 (SD)] than in osteoporotic fractures [standardized uptake value 0.7–4.9, mean 1.94±0.97]. A preliminary study indicates that the positive predictive value of FDG-PET for detecting malignant vertebral fracture is 71% while the negative predictive value is 91% [87].

CLINICAL RECOMMENDATIONS FOR SPINE IMAGING TO DETECT VERTEBRAL FRACTURE

In general, the indications for spine imaging for vertebral fracture detection are similar, irrespective of whether radiography or VFA is used. The current recommendations for using VFA by the ISCD are summarized in Table 37.2 [12]. Ultimately, the decision on whether to undertake spinal radiography or VFA by DXA depends on availability and local expertise.

If a patient has normal BMD, most clinicians would not undertake spine imaging unless there has been significant loss of height or back pain.

If the patient has osteoporosis on DXA examination, most clinicians would start treatment, and, in this instance, it can be argued that there is no added benefit from identifying a vertebral fracture [13] though the recognition of a vertebral fracture would influence the 10-year fracture prediction by FRAX [19]. Similarly, if moderate, severe, or multiple vertebral fractures are identified on imaging, this may alter the choice of treatment. For example, an anabolic drug (e.g., parathyroid hormone [PTH]) may be appropriate before considering long-term therapy with bone protective therapy (e.g., bisphosphonate).

If a patient has low BMD and an insufficiency fracture at any site (the most common of which is vertebral fracture), most clinicians would intervene with therapy. If a patient has low BMD and no previous history of insufficiency fractures, spinal radiographs or VFA are indicated as the presence of a vertebral fracture would influence management. Patients with low BMD and vertebral fracture do benefit from a range of antiresoptive therapies that reduce future fracture risk [12]. If a patient is taking long-term oral glucocorticoids and has a history of osteoporotic fracture at any site, most clinicians would consider antiosteoporotic therapy, irrespective of whether spine imaging shows a vertebral fracture. Therefore, additional imaging is probably not warranted unless a comprehensive fracture risk assessment by FRAX is required. Patients on long-term oral glucocorticoids with no history of osteoporotic fracture warrant spine imaging, particularly if there is a history of back pain, height loss, or they are over 65 years old.

Table 37.2. ISCD Recommendations for Screening for Vertebral Fractures Using VFA*

- Consider VFA when the results may influence clinical management
- Postmenopausal women with low bone mass (osteopenia) by BMD criteria, PLUS any one of the following:
  - Age greater than or equal to 70 years
  - Historical height loss greater than 4 cm (1.6 in)
  - Prospective height loss greater than 2 cm (0.8 in)
  - Self-reported vertebral fracture (not previously documented)
  - Two or more of the following:
    - Age 60 to 69 years
    - Self-reported prior nonvertebral fracture
    - Historical height loss of 2 to 4 cm
    - Chronic systemic diseases associated with increased risk of vertebral fractures (for example, moderate to severe COPD, seropositive rheumatoid arthritis, Crohn's disease)
- Men with low bone mass (osteopenia) by BMD criteria, PLUS any one of the following:
  - Age 80 years or older
  - Historical height loss greater than 6 cm (2.4 in)
  - Prospective height loss greater than 3 cm (1.2 in)
  - Self-reported vertebral fracture (not previously documented)
  - Two or more of the following:
    - Age 70 to 79 years
    - Self-reported prior nonvertebral fracture
    - Historical height loss of 3 to 6 cm
    - On pharmacologic androgen deprivation therapy or following orchiectomy
    - Chronic systemic diseases associated with increased risk of vertebral fractures (for example, moderate to severe COPD or COAD, seropositive rheumatoid arthritis, Crohn's disease)
  - Women or men on chronic glucocorticoid therapy (equivalent to 5 mg or more of prednisone daily for 3 months or longer)
- Postmenopausal women or men with osteoporosis by BMD criteria, if documentation of one or more vertebral fractures will alter clinical management

*http://www.iscd.org/visitors/positions/OfficialPositionsText.cfm. (Ref. 48).

CONCLUSION

Vertebral fractures occurring in the presence of minor or no trauma provide evidence of reduced bone strength, irrespective of BMD. They are usually the first insufficiency fracture to occur. Recognition and appropriate treatment of vertebral fracture at this relatively early stage can reduce future fracture risk, patient pain, deformity, and suffering. Radiographic evaluation with qualitative, semi-quantitative, or quantitative assessment is the standard for detecting vertebral fracture. Good technique in performing spinal radiographs and a high level of observer experience in image interpretation are key to the reliable diagnosis of vertebral fractures. VFA is being utilized increasingly for vertebral fracture identification. Vertebral fracture diagnosis may be made fortuitously from any imaging method on which the spine is included. Density and structural parameters obtained by volumetric QCT can predict vertebral compressive strength *ex vivo*, and these parameters, together with nonlinear FEA, can also be applicable *in vivo*. In the future, virtual measurement of vertebral body strength with high-resolution imaging techniques may enable patients who are at risk of vertebral fracture to be identified more efficiently. MRI can detect minor acute or subacute vertebral fracture or re-fracture, determine fracture age, and distinguish between osteoporotic and neoplastic fracture with greater sensitivity than other imaging techniques.

Introduction 336
Overview of the Types of Genetic Testing Available 336
Genetic Tests Available for Skeletal Disorders 338
When to Order Genetic Testing 340
References 341

INTRODUCTION

Genetic testing is the analysis of human DNA, RNA, chromosomes, proteins, and certain metabolites in order to detect heritable disease-related genotypes, mutations, phenotypes, or karyotypes for clinical purposes [1, 2]. In practice, genetic testing mainly involves looking at an individual's DNA (genes and genome) for variants that may be the underlying cause of a clinical condition, and this chapter will focus on genetic testing of DNA. As knowledge about genetic disorders of bone has expanded greatly over the past few years, the number of disorders for which genetic testing is commercially available has increased. In this chapter we will discuss the types of genetic testing available, what testing is available for disorders of bone, and suggest an approach to genetic testing in individuals with a disorder of bone.

OVERVIEW OF THE TYPES OF GENETIC TESTING AVAILABLE

There are many ways in which an individual's genome can vary from "normal." Based on the impact on genome structure, variants can be classified as either small or large scale, and each category consists of different types of variants. Laboratory molecular techniques have been developed to specifically test the different types of variants. Here we briefly discuss the types of genetic testing available in molecular diagnostic laboratories to detect different types of variants associated with a variety of genetic disorders.

Types of variants

Small-scale variants

Base-pair substitutions

The replacement of one nucleotide base by another is the most abundant variant type in the human genome. The vast majority of single nucleotide variants are located in intergenic regions (stretches of DNA that contain few or no genes) and intronic regions (stretches of DNA within a gene that is removed by RNA splicing). Those located in the coding regions (exons) can be further classified based on the effect on the amino acid sequence of the protein.

Synonymous variants are also called "silent variants" and cause no change in the final protein product as they do not change the amino acid due to redundancy of the genetic code. In most cases, they are thought not to have clinical consequences, although theoretically a synonymous variant could be clinically significant if it affects coding usage. The consequences of synonymous variants can be hard to predict.

Non-synonymous variants are those that result in changes in the amino acid sequence. When the nucleotide change results in the replacement of one amino acid for another it is called a *missense variant*; when the

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

nucleotide change results in the gain of a stop codon it is called a *nonsense mutation*. Sometimes a nucleotide change results in the loss of a stop codon (i.e., a stop codon changes to a codon that inserts an amino acid). A non-synonymous variant that causes a significant impact on protein structure may have clinical consequences.

Splicing variants are variants at the splicing junctions (the first two or last two nucleotides at the beginning or end of the exon, respectively), which results in an alteration in exon splicing. This can lead to exon skipping and the loss of an exon in the mRNA. If the number of nucleotides in the skipped (deleted) exon is not a multiple of 3, it results in a frameshift and a downstream change in the amino acid sequence usually leading to a new stop codon downstream, resulting in a truncated protein. This type of variant often has significant clinical consequences.

Indels

Indels are the insertion or deletion of one or several nucleotides. When the number of nucleotides is a multiple of 3, it usually results in an in-frame deletion or insertion of one amino acid. When the number of nucleotides is not a multiple of 3, it results in out-of-frame deletion or duplication, a frameshift, and an in the amino acid sequence and a new stop codon. Out-of-frame indels usually have larger impact on protein structure and function than in-frame indels and often have clinical consequences.

Repeat expansions

There are areas within the genome that contain repeating sequences, and an increase in the number of simple repeating sequences can occur in both coding and non-coding regions. This type of variant is known to be associated with a limited number of disease-causing genes, but constitutes an important category of mutation and disease mechanism.

Epigenetic variants

Some disorders are caused by changes in the epigenetic modification pattern such as methylation. Changes in the methylation pattern can affect gene expression and cause disease.

Methods to detect small scale changes in the DNA

Sanger sequencing using PCR (polymerase chain reaction) amplified product has been the most effective method for detecting most small scale variants. Genotyping methods are also useful in detecting targeted mutations but are less often used. For repeat expansions, PCR-based assays, and occasionally Southern-blot based assays, are necessary to assess the number of the repeats. Methylation specific PCR or MLPA (multiplex ligation dependent probe amplification) methods are often used to detect the methylation status of disease-related genes for epigenetic mutations. MPLA is a form of multiplex PCR commonly used not only to detect methylation status but also to detect mutations and gene deletions/duplications. Multiple genomic targets are amplified using a common primer pair located at the outside ends of the multiple oligonucleotide probe pairs specific to the genomic targets. Since PCR amplification of the genomic targets only occurs when the two probes hybridize to their target, probes that are unbound will not be amplified. Thus, the strength of amplification signal reflects the amount of genomic target (inferred as copy number) available for hybridization and ligation. MLPA is used to detect methylation status by using probes at the methylation loci and treating the genomic DNA with methylation sensitive restriction enzymes that disrupt the methylated DNA preventing the ligation, hence reducing the amplification signal. The strength of the amplification signal at the methylated sites compared to the signal generated from DNA that has not been treated with enzyme reflects the methylation level. MLPA is also used to complement Sanger sequencing, in which case Sanger sequencing is performed first, and if the result is normal, MLPA is then performed to detect possible exonic deletions; sometimes, the two tests are performed simultaneously. For disorders in which deletions or duplications are common, MLPA is performed first as it is much easier and fast than sequencing.

Large-scale variants

This type of variant affects at least one exon of a gene or a larger genomic segment. Large-scale variants cannot be reliably detected by conventional PCR and Sanger sequencing based assays. Large scale variants can be categorized into the following types.

Copy number variants (CNVs)

Copy number variants (CNVs) are imbalanced structure variants. Genomic DNA copy number gain or loss has been known for many years, but a renewed interest in CNVs is due to the finding that not only are CNVs much more abundant in the human genome than previously appreciated, they are now known to have a large impact on genome structure and function. Many CNVs, especially large ones, have significant clinical relevance. CNVs constitute the second most frequent mutation type associated with genetic disorders. Recently, microarray-based genomic profiling technologies have enabled the effective analysis of genomic imbalances in a genome-wide manner with much improved sensitivity, resolution, and reproducibility. The microarray-based genomic profiling techniques have been recommended as the first tier genetic test in many clinical scenarios.

There are two basic microarray-based genomic profiling types. One originated from comparative genomic hybridization (CGH) technology and is currently represented by the oligo-based CGH array. Recent addition of single nucleotide polymorphism (SNP) probes onto the CGH array has enabled detection of both CNV and LOH

(loss of heterozygosity) by CGH array. Another array platform is derived from SNP genotyping arrays. The addition of CNV probes onto genotyping arrays significantly enhances the sensitivity of detecting CNVs by genotyping array. The two array types show a functional convergence. Next generation sequencing (NGS) may eventually replace array-based technologies for interrogating CNV, as well as for many other types of large-scale variants discussed below. Detecting CNV by NGS is an area of great bioinformatic research interest at this moment.

Balanced structure variants

Translocations and inversions represent another type of large-scale variant. Until very recently, balanced genomic variants could only be detected by conventional cytogenetic approaches. Microarray techniques are not able to detect balanced variants. Due to the limited resolution of cytogenetic approaches, the balanced genomic variants are believed to be underdetected. On the other hand, many apparently balanced rearrangements ascertained by cytogenetic approaches are later found to harbor cryptic imbalances when high-resolution microarray-based genomic profiling techniques are used. NGS-based approaches are poised to effectively solve the technical difficulty of detecting balanced rearrangements; it will become the method of choice for genome-wide detections of both balanced and imbalanced genomic variants when the informatic challenges are solved.

Loss of heterozygosity (LOH)

Loss of heterozygosity (LOH) results from deletion of one allele or from uniparental origin of both alleles, which results in copy neutral LOH (cn-LOH) and is often referred to as uniparental disomy (UPD). Within a family cn-LOH can be due to identity-by-descent (IBD), which indicates distant relatedness between two individuals, or to consanguinity, indicating recent relatedness. Traditionally, microsatellite marker-based genotyping methods have been used to detect UPD. Recent microarray platforms are able to detect large segments of LOH and UPD in a genome-wide manner. NGS data can also easily provide detailed genotyping information for the whole genome at base pair resolution, thus eventually providing a much more complete picture of cn-LOH in the whole genome.

Evolving approaches of DNA-based genetic testing

The nature of the variant dictates what method should be used for genetic testing. Technical innovations have been changing the way we perform genetic testing on patients. As described below, genetic testing is undergoing a significant paradigm shift with the advent of microarray-based and NGS-based technologies.

Conventional approaches deal with one mutation or one gene and one patient a time. Clinicians make a preliminary diagnosis and order the gene test that is most likely to explain a patient's clinical condition. Depending on the known mutation spectrum of the disease gene, a molecular diagnostic laboratory will either use Sanger sequencing to test for small-scale variants or targeted methods for CNV such as quantitative PCR or MLPA.

Whole-gene- or gene-panel-based tests are currently the most commonly used approaches in genetic testing. Since sequencing can only detect small-scale variants, it is often complemented by CNV testing using MLPA or quantitative PCR to detect potential exonic deletion or duplication.

Whole-genome chromosomal microarray (CMA) analysis for CNV and LOH has much enhanced clinical utility over conventional cytogenetic techniques, which justifies its use as the first tier test for patients with complex or unknown genetic conditions. CMA is a useful scanning tool for genome-wide detection of possible genomic defects associated with many genetic conditions.

NSG-based whole-exome or whole-genome testing generates sequence data by massive parallel sequencing of clonally amplified or single DNA molecules. Recent advances in NGS technologies are making the NGS-based diagnostic approach more cost-effective with a reasonable turnaround time. NGS is poised to bring a paradigm shift in genetic testing. The premise for using whole-exome, instead of whole-genome, sequencing for Mendalian disorders, both in research as well as in genetic testing, is that protein coding sequences constitute about 1% of the human genome but harbor about 85% of the known mutations that cause human diseases. However, given the fact that large-scale variants can be simultaneously detected by a whole-genome-based test, but not easily by whole-exome sequencing, it is predicted that when the cost for whole-genome sequencing becomes acceptable for routine testing, it will become the method of choice for both research and clinical diagnostics. Many challenges lie ahead, particularly in the area of data interpretation, which often involves database searching, segregation analysis, bioinformatic prediction, and functional demonstration. Even though NGS will eventually replace many current genetic testing methods, conventional sequencing, genotyping, and CNV detecting technologies are still useful for validating and confirming variants detected by NGS.

GENETIC TESTS AVAILABLE FOR SKELETAL DISORDERS

As knowledge about the genetic disorders of bone has expanded greatly over the past few years, the number of disorders for which genetic testing is commercially available has also increased. Unfortunately, there has been a lag between the discovery of causative genes on a research basis and the availability of commercial diagnostic testing [3]. However, genetic testing is available for a large number of skeletal diseases commonly seen in the

clinic, both metabolic bone disorders and skeletal dysplasias.

Metabolic bone disease

Genetic testing for metabolic disorders of bone can be useful in the clinical setting for diagnostic purposes. There are a number of genetic causes of metabolic bone disease for which there is genetic testing available.

Familial hypophosphatemic rickets

Familial hypophosphatemic rickets (FHR) is the most common form of heritable rickets. Clinically, FHR presents in childhood with the typical signs of rickets, including bowing of the legs and growth delay as the child starts walking, and in the absence of a family history, FHR can be misidentified as nutritional rickets. The biochemical findings that distinguish FHR from other forms of rickets include a normal 25-hydroxyvitamin D, hypophosphatemia, and a low-normal 1,25-dihydroxyvitamin D level; in addition, calcium levels are normal and the PTH is normal or slightly elevated. Classic findings of rickets on radiographs exclude other possible diagnoses including physiologic bowing and a skeletal dysplasia. X-linked hypophosphatemic rickets (XLH) is by far the most common form of FHR and is due to mutations in the phosphate-regulating gene with homology to endopeptidases located on the X-chromosome (PHEX). XHR is inherited in an X-linked dominant manner and thus there are more affected females than males (2:1 ratio) and no male-to-male transmission. Other forms of hypophosphatemic rickets including autosomal dominant hypophosphatemic rickets (ADHR) and autosomal recessive hypophosphatemic rickets (ARHR). While XLH is by far the most common, genetic testing for all forms is available and can be used to differentiate between the forms when it is not clear from an inheritance pattern [4].

Vitamin D-related disorders

There are two genetic defects in the vitamin D pathway that lead to rickets. Vitamin D-dependent rickets type I (VDDR-I), also known as 1-alpha-hydroxylase deficiency. This disorder is characterized by low 1,25-dihydroxyvitamin D levels in the face of normal 25-hydroxyvitamin D levels, an elevated parathyroid hormone (PTH), and hypocalcemia. On the other hand, in vitamin D-dependent rickets type II (VDDR-II), also called vitamin D-resistant rickets, 1,25-dihydroxyvitamin D levels are markedly elevated due to the receptor resistance. VDDR-I is due to mutations in the 1-alpha-hydroxylase gene CYP27B, and VDDR-II is due to mutations in the vitamin D receptor, VDR; both genetic tests are available clinically.

Hypophosphatasia

Hypophosphatasia is an inherited bone disorder characterized by rickets in childhood and osteomalacia in adulthood due to a defect in mineralization of bone and teeth, and low serum and bone alkaline phosphatase activity. There are six clinical forms that span a wide spectrum of disease, from severe demineralization that leads to stillbirth, to rickets in childhood, to pathologic fractures in later adulthood, to odontohypophosphatasia (severe dental caries and/or premature exfoliation of primary teeth). Hypophosphatasia is due to mutations in ALPL, the gene encoding the alkaline phosphatase, tissue-nonspecific isozyme (TNSALP).

Skeletal dysplasias

Genetic testing for skeletal dysplasias can be used to confirm a clinical diagnosis, as well as for cases where a clinical diagnosis is not immediately clear but several different disorders are under consideration. All patients with a suspected skeletal dysplasia should have a through physical exam documenting any dysmorphic features, as well as a full radiographic skeletal survey in cases where the diagnosis is not suggested by history and physical exam alone. There are hundreds of skeletal dysplasias and many genes that are affected. Here we highlight some of the more common skeletal dysplasias for which there is genetic testing available.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is characterized by low bone mass and increased fracture risk. Most patients with OI have mutations in the type I collagen genes, COL1A1 and COL1A2, or in genes encoding proteins that participate in the assembly, modification, and secretion of type I collagen. Dominant mutations in the COL1A1 and COL1A2 genes are responsible for OI types I through IV. Phenotypes range from the very severe type II form (perinatal lethal) to a "mild" type I form; type III OI is the most severe form that is not lethal, and type IV is moderate OI. The recessive forms of OI are much rarer in the general population (although they are more common in certain ethnic subgroups) and typically cause a severe phenotype.

Genetic testing in OI generally serves two purposes. In children with multiple fractures but who are otherwise normal without significant short stature or deformities, genetic testing can be used to make the diagnosis of type I OI. In children with the more severe forms of OI that are diagnosed on clinical exam, genetic testing can confirm the diagnosis of OI. In addition, genetic testing can be useful for prenatal counseling for patients and family members and help distinguish the more common COL1A1 and COL1A2 mutations in the dominant OI types I through IV from the recessive forms of OI. Genetic testing for recessive forms should be considered in patients with a severe OI phenotype who test negative for a COL1A1 and COL1A2 mutation. In addition, confirming the diagnosis of OI is helpful as there is available pharmacologic treatment of OI with bisphosphonates (typically pamidronate) in the pediatric population [5],

although other treatments are being studied in the adult population. Bisphosphonates are used in many children with OI and are thought to act by preventing the high bone turnover seen in patients with OI due to their abnormal collagen [6]. Although bisphosphonate therapy does not correct the underlying genetic defect in patients with OI, the therapy has been reported to increase bone density and reduce fracture rates in treated patients [7].

Achondroplasia and other FGFR3-related disorders

Achondroplasia is a relatively common skeletal dysplasia. Affected patients have severe short stature, rhizomelic shortening of the limbs, and a relatively large head with frontal bossing. Although the diagnosis of achondroplasia is typically made based on the physical examination and radiographs, genetic testing for the disorder is useful to confirm the diagnosis, especially if the diagnosis is unclear. Nearly all cases of achondroplasia are caused by one of two mutations in the same nucleotide of the fibroblast growth factor receptor 3 (FGFR3) gene. Achondroplasia is inherited in an autosomal dominant manner, and approximately 80% of cases are new mutations [8, 9].

Mutations in FGFR3 are responsible for several other conditions, including hypochondroplasia, thanatophoric dysplasia types I and II, and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN). Of these, hypochondroplasia is the most common and presents as a milder form of achondroplasia, without the large head, and with milder short stature.

Multiple epiphyseal dysplasia

Multiple epiphyseal dysplasia (MED) is a skeletal dysplasia characterized by abnormal epiphyses of the long bones. Patients typically develop symptoms of joint pain in the hips and knees in childhood, leading to the development of early onset osteoarthritis. Mildly shortened stature is also common. There are two forms of MED: a dominantly inherited form as well as a recessive form. Although the symptoms of the two forms are similar, patients with the recessively inherited form may also have congenital defects such as cleft palate or clubfeet. While a clinical diagnosis of MED is typically made based on symptoms and abnormal epiphyses seen on radiographs, genetic testing can be very useful in confirming the diagnosis and differentiating between the dominant and recessive forms when the family history is not a suggestive. Dominant MED is a disorder with genetic heterogeneity, i.e., mutations in several different genes can cause the disorder. Mutations in five different genes—COMP, COL9A1, COL9A2, COL9A3, and MATN3—have all been shown to cause dominant MED. Given this scenario, a staged approach to genetic testing is recommended, where testing begins with the most commonly affected gene and proceeds sequentially through the next most affected until the gene defect is found [10, 11].

WHEN TO ORDER GENETIC TESTING

A metabolic bone disease may be suspected if there is bowing of the lower extremities, multiple fractures, a laboratory finding suggestive of metabolic bone disease (e.g., an elevated alkaline phosphatase, hypocalcemia, a low vitamin D level, or hypophosphatemia), or radiographs that suggest changes consistent with rickets. The initial evaluation of a suspected metabolic bone disorders should include X-rays and laboratory tests including: serum creatinine, calcium, magnesium, phosphorus, alkaline phosphatase, 1,25-dihydroxyvitamin D, 25-hydroxyvitamin D, PTH, and urine calcium, phosphorus, and creatinine. In addition, studies looking for systemic causes of metabolic bone disease, such as renal dysfunction, inflammatory bowel disease, and Celiac disease, should also be considered. In the case of a suspected skeletal dysplasia, the evaluation starts with a comprehensive physical examination and a skeletal radiographic series to characterize the skeletal findings.

The evaluation of a suspected metabolic bone disease may suggest a genetic condition. Examples include hypophosphatemic rickets (low phosphate, normal 1,25-dihydroxyvitamin D and 25-hydroxyvitamin D, and normal calcium) and pseudohypoparathyroidsim (low calcium, high PTH). Radiographs may confirm the clinical suspicion of skeletal dysplasia and often narrow the differential diagnosis to a limited group of disorders. Once a preliminary diagnosis of a genetic condition is made, the decision to order genetic testing is influenced by several factors, including the diagnostic and treatment necessity, the need for reproductive counseling, patient and family desire for testing, and cost and payment issues. Prior to ordering any genetic test, the provider needs to determine if the desired test is clinically available. In the United States, all genetic testing must be performed in a CLIA-certified clinical laboratory for both legal and reimbursement reasons [12]. The website www.genetests.org is an excellent source for determining which CLIA-certified clinical laboratories offer the desired testing. Any testing sent on a research basis must be done under the supervision of an institutional review board, and often the results cannot be legally revealed to the patient until the testing is repeated and the results verified in a CLIA-certified lab [13]. Fortunately, genetic testing tends to move rather quickly in most cases from the research setting to clinical testing.

The most common clinical situation where genetic testing is ordered is when the genetic testing is required to make a diagnosis or to confirm the diagnosis. Genetic testing is especially useful if a course of treatment is available and dependent on the diagnosis. In these cases, genetic testing will provide a clear benefit for the care of the affected patient. A clear example of this is OI, in which bisphosphonates may be beneficial.

Often if the diagnosis is unclear, a staged approach to testing, while perhaps prolonging the time to final diagnosis, can potentially conserve resources. This involves

requesting one genetic test at a time and moving on to other genetic testing only if the initial tests are negative. Frequently, one blood sample can almost always provide enough DNA for a laboratory to carry out multiple sequencing analyses, thus preventing repetitive blood draws. This staged testing approach is also useful for disorders with genetic heterogeneity. Testing can begin with the most commonly affected gene and then proceed to subsequent genes only if the first test is negative. However, in cases where diagnosis will affect treatment and delaying therapy is not optimal, ordering multiple tests at once may benefit the patient.

Reproductive counseling is another reason that genetic testing may be useful in a clinical setting. It is not uncommon for skeletal disorders to be diagnosed clinically based on family history, physical exam, and radiographic evidence. While the diagnosis may not be in question, knowledge of the specific mutation causing the phenotype may be useful for future reproductive decisions. In the pediatric setting, parents of an affected child may desire prenatal testing with future pregnancies. In this situation, the patient's exact mutation needs to be known to determine if the parents are carriers (or affected themselves if the mutation is dominant) and to allow for prenatal testing with future pregnancies. In the case of recessive disorders, carrier testing is appropriate for adult family members but should not be performed on minor children until they reach maturity and can consent to their own testing [14].

Patients or family members may request or refuse genetic testing for various reasons. In cases where genetic testing is needed for initial diagnosis or to confirm a clinical diagnosis, a full discussion of the risks and benefits should be undertaken with the patient (or parents if the patient is a minor). This discussion should include the reasons why genetic testing is needed, how the results (whether a mutation is found or not) will affect the patient's immediate treatment, and how the results may affect the patient's care in the future. Discussion of these issues can help alleviate many misunderstandings and anxieties around genetic testing [15]. In the U.S., the 2008 Genetic Information Nondiscrimination Act (GINA) bars discrimination by health insurance providers and employers due to genetic testing results, although GINA does not protect from genetic discrimination in other areas such as long-term care or life insurance [16]. Finally, the discussion should include the limits of genetic testing, particularly when a negative test will not exclude a clinical diagnosis, which is often the case. Available genetic tests may only detect mutations in a small number of clinically diagnosed patients depending on the disorder. Patients and families may consider a negative test result "the final answer" and need to understand that a negative genetic test does not always exclude a given clinical diagnosis.

The cost of genetic testing can affect the ability to order genetic tests in different settings. Genetic tests can be among the most expensive laboratory-based tests available, ranging from hundreds to tens of thousands of dollars. Third-party payers are becoming increasingly reluctant to pay for the costs of genetic testing, particularly in the absence of documented clinical necessity. In the pediatric population, genetic testing for diagnostic purposes is typically covered by private insurance companies as long as the patient's pertinent history and physical findings are well documented. However, families with high-deductible plans should be warned that the cost of one genetic test may be greater than the entire deductible, requiring a single large payment. Carrier testing may not be covered, except when done for prenatal testing purposes. As genetic tests are ordered more frequently, institutions such as hospitals may limit the number of tests that can be ordered or require that tests be ordered only from laboratories that bill the patient's insurance company directly. This can effectively put testing for some disorders out of the reach of patients and providers. These increasing costs place a responsibility on providers to ensure that genetic tests are only ordered under appropriate circumstances where there is a clear benefit for the patient.

The increasing availability of genetic testing for all types of skeletal disorders can be of great benefit to patients and providers. Genetic testing can be useful for diagnosis and subsequent treatment as well as for reproductive counseling for patients and families. However, as with all medical testing, genetic testing has risks and benefits and may not be appropriate for every clinical situation.

Osteoporosis Overview

Michael Kleerekoper

In March 2000, a National Institutes Consensus Development Conference redefined osteoporosis as "a skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fracture. Bone strength reflects the integration of two main features: bone density and bone quality. Bone density is expressed as grams of mineral per area or volume and in any given individual is determined by peak bone mass and amount of bone loss. Bone quality refers to architecture, turnover, damage accumulation (e.g., microfractures), and mineralization. A fracture occurs when a failure-inducing force (e.g., trauma) is applied to osteoporotic bone. Thus, osteoporosis is a significant risk factor for fracture, and a distinction between risk factors that affect bone metabolism and risk factors for fracture must be made."

In the intervening decade much has been learned about this very common disease, and the next 27 chapters provide details of all aspects of osteoporosis—etiology, diagnosis, management. A synopsis of those chapters is provided here.

Understanding of the epidemiology and pathogenesis of osteoporosis as detailed in Chapters 40 and 41 have advanced beyond the age-related decline in bone mass assessed by dual energy X-ray densitometry (DXA) and an assessment of fracture risk determined by the WHO-developed FRAX model to include invasive (bone biopsy) and noninvasive (high-resolution computed tomography and magnetic resonance imaging) documentation of bone microarchitecture. It is now more clear that risk of fracture is heavily dependent on bone quality, possibly even more so than bone mass. Not to be forgotten in this emerging science is the contribution of falls to the likelihood of fracture occurrence. An osteoporosis-related fragility fracture is best defined as a fracture resulting from a fall from a standing height or less. The less bone mass, the more disrupted the bone microarchitecture, the greater the likelihood of sustaining a fracture (Chapter 40).

Not all fall-related fractures reflect osteoporosis, particularly in children. Figure 39.1 is a schematic of gain and loss of bone throughout life. Bone mass is low at birth and increases for the next 2 or 3 decades (it varies with the skeletal site being evaluated) before peak bone mass is acquired. Both bone formation and bone resorption are highest at birth, declining rapidly over the first few years of life. This is an age group where falls are not uncommon, either as the toddler is learning to stand and walk or as they grow and become involved in sporting activities. Advancing from a tricycle to a bicycle is a common cause of falls and fracture, but the high bone remodeling rate promotes rapid and complete healing in most children. The pubertal growth spurt results from a second surge of remodeling activity, but fractures are less common until engagement in more rigorous contact sports. In healthy people, peak bone mass and bone remodeling are stable unless a secondary cause of bone loss is present. In women, the decline in estrogen and/or the increase in gonadotropins at menopause (Chapters 43) result in a reversal of bone remodeling such that resorption now exceeds formation and bone mass decreases. Coincident with this is remodeling induced disruption of bone microarchitecture and most likely other as yet incompletely identified disturbances in skeletal integrity.

While osteoporosis is more prevalent after menopause, there are many factors that contribute to bone loss and osteoporosis with increased fracture risk in premenopausal women. In particular, anorexia, bulimia, and athletic amenorrhea interfere with the cyclical production of estrogen and progesterone (Chapter 43). Paradoxically, the alterations in menstrual function in patients with polycystic ovarian syndrome (PCOS) do not have an adverse effect on bone mass. Bone mass may even be higher in patients with PCOS than in age-matched controls with normal menses—presumably related to the increased levels of androgens.

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

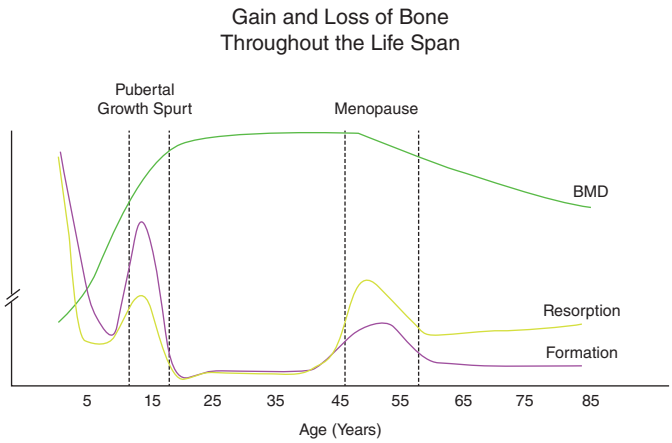

Fig. 39.1. Schematic representation of gain and loss of bone and changes in bone remodeling throughout life in women.

Age-related bone loss occurs in men but the mechanisms are not as well documented as they are in women. Age-related decline in testosterone and likely the change in diurnal excursion of testosterone as men age are important determinants of bone loss in men. There is also increasing data that links changes in fat mass (increase) and muscle mass (decrease) as major contributors to bone loss in women and men. The contributions of the sex hormones, sex-hormone binding proteins, gonadotrophins, and growth factors to gain and loss of bone in both men are elegantly described and detailed in Chapter 43.

Nutrition and lifestyle are critical factors in the development and maintenance of bone health (Chapters 42 and 47). Key nutritional factors are adequate intake of calcium and vitamin D. Guidelines for the optimal amount of calcium and vitamin D intake have recently been published by several major organizations but there is limited consistency in these guidelines. At issue is just "how much" or "how little" is regarded as adequate intake of calcium and vitamin D at different stages of life. It is possible to have inadequate intake of calcium, but dietary calcium overload is much less likely. Patients with calcium-containing kidney stones are often ill-advised to lower their calcium intake or do so of their own volition. Lowering dietary calcium is more likely to increase kidney stone risk as well as jeopardize skeletal health. Most recently, controversy has arisen about a possible link between excess calcium intake and the risk of coronary artery disease, but this issue remains unresolved. The issues regarding vitamin D are more complex. In particular there is a trend, at least in the United States, to measure 25- hydroxyvitamin D (25OHD) at annual physical examinations. Compared to the cost of the laboratory procedure, the cost of taking 1,000–2,000 units of vitamin D daily is substantially lower, with very limited likelihood of developing vitamin D toxicity. Patients with a history of malabsorption or overt malnutrition will benefit from regular monitoring of 25OHD, but this is a small fraction of the general population. As calcium intake has been linked to cardiovascular disease, there is a burgeoning literature linking 25OHD levels to diseases in seemingly every organ system and disease state. Hypothetically, this makes sense since the vitamin D receptor is present in many, perhaps most, tissues. However, to date the published data are inconsistent and inconclusive. In the 90 days before this chapter was written, there were 129 peer-reviewed publications listed in PubMed on the topic "diseases associated with vitamin D." The chapters "Premenopausal Osteoporosis" (Chapter 63) and "Prevention of Falls" (Chapter 45) provide additional critical information about maintenance of skeletal health and integrity throughout life.

The bulk of the synopsis presented above relates to "primary" osteoporosis in which bone loss can be attributed to aging *per se* or the known hormonal consequences of aging such as the decline in estrogen and testosterone. "Secondary" osteoporosis refers to those conditions that do not start as a skeletal issue but reflect adverse consequences of the primary disease itself (e.g., celiac disease with associated malabsorption) and/or as a result of therapy (e.g., glucocorticoid) for many diseases. Diseases and therapies that adversely affect bone remodeling and bone mass or are associated with an increased risk of falling are detailed in Chapter 45.

Much has already been learned about the cellular and molecular mechanisms underlying both primary and secondary osteoporosis and exciting new science is unraveling potential new factors in this scenario. This has resulted in the development of pharmacologic approaches to minimize further bone loss and to a great extent reverse the bone loss and decrease the likelihood of fracture. Chapters 48–53 describe the mechanism of action and the clinical use of therapies that have been documented to improve bone mineral density and reduce fracture risk and provide guidance into the appropriate use of these therapies for the several clinical scenarios described above. Each of these has demonstrated antifracture effectiveness for the clinical scenario for which a specific drug has received regulatory approval. Chapter 53 explores the potential use of combination or sequential antiresorptive and formation stimulation therapies. Since gain and loss of bone throughout the life span depends on the interaction between formation and resorption, it makes sense to determine the optimal combined use of drugs with different effects on bone remodeling. Bringing these forward into the clinical arena will take some time but must be pursued.

Chapter 56 describes future therapies for osteoporosis prevention and treatment that are founded on the rapidly increasing knowledge and pre-clinical studies of more intricate metabolic pathways affecting skeletal health. Denosumab (Chapter 50) is already approved as an effective therapy to reduce fracture risk with seemingly fewer adverse events than have been reported for other monoclonal antibodies used to treated diseases or conditions other than osteoporosis. Understanding of the mecha-

nisms by which the Wnt signaling and LRP5, and molecules such as cathepsin K expressed in osteoclasts are linked will undoubtedly lead to development and marketing of other therapies.

While this is a very exciting step forward in understanding and maintaining skeletal health, it remains to be seen whether this will lead to medications more effective in reducing fracture risk than those drugs currently available—existing approved therapies all reduce fracture risk. Marketed therapies are not without potential adverse effects in a small number of patients, and the hope is that newer potential therapies under investigation will be associated with even fewer side effects. Some of these adverse effects (e.g., atypical femoral shaft fractures, osteonecrosis of the jaw) have a marked impact on the patient's well-being, and it is imperative that prescribing clinicians familiarize themselves with the potential side effects—as should be the case for any therapy for any disease. Guidelines for monitoring the effectiveness of therapy and minimizing the risk of an adverse event have been published, but there remain many unanswered questions. Pivotal clinical trials in osteoporosis leading to approval for marketing and dispensing have not resulted in any pre-marketing warning label with the exception of the formation stimulation agent teriparatide. The labeling was not based on any adverse events in patients, only on the occurrence of osteosarcoma in weanling rats. This has resulted in the duration of clinical use for teriparatide being limited to 2 years. The occurrence of osteosarcoma in patients with osteoporosis treated with teriparatide is rare! However, it is becoming apparent that overuse of some of the approved osteoporosis therapies does result in significant harm to some patients, but these occurrences cannot yet be predicted in individual patients. Carefully developed guidelines have provided directions by which clinicians can monitor the patient for adverse events and some less certain guidance about possible temporary interruption of therapy.

In sum, since the first edition of the *Primer* was published in 1990, our understanding of the pathogenesis of osteoporosis, both primary and secondary, has increased exponentially, as has the technology for assessing fracture risk and the availability of current therapies. The chapters in this section highlight our existing knowledge base and give insight into future therapeutic options.

INTRODUCTION

Osteoporosis is a skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture [1]. The term "osteoporosis" was first introduced in France and Germany during the last century. It means "porous bone" and initially implied a histological diagnosis, but it was later refined to mean bone that was normally mineralized, but reduced in quantity. Clinically, osteoporosis has been difficult to define: A focus on bone mineral density (BMD) may not encompass all the risk factors for fracture, whereas a fracture-based definition will not enable identification of at risk populations. In 1994, the World Health Organization (WHO) [2] convened to resolve this issue, defining osteoporosis in terms of bone mineral density, and previous fracture. Thus the WHO definition does not take into account microarchitectural changes that may weaken bone independently of any effect on BMD. More recently, there has been a move toward assessment of individualized risk [3], with the development of the FRAX algorithm [4], a Web-based tool that uses clinical risk factors plus or minus BMD to calculate an individual's absolute risk of major osteoporotic or hip fracture over the next 10 years. This has the advantage of incorporating risk factors that are partly independent of BMD, such as age and previous fracture, and thus allows decisions regarding commencement of therapy to be made more readily. Osteoporosis-related fractures have a huge impact economically, in addition to their effect on health: The cost to the U.S. economy is around $17.9 billion per annum, with the burden in the U.K. being £1.7 billion (Table 40.1 summarizes fracture impact for a Western population) [5]. Hip fractures contribute most to these figures.

FRACTURE EPIDEMIOLOGY

Incidence and prevalence

Figure 40.1 shows the radiographic vertebral, hip and wrist fracture incidence by age and gender [6, 7].

The 2004 report from the U.S. Surgeon General highlighted the enormous burden of osteoporosis-related fractures [8]. An estimated 10 million Americans over 50 years old have osteoporosis, and there are about 1.5 million fragility fractures each year. Another 34 million Americans are at risk of the disease. A study of British fracture occurrence indicates that population risk is similar in the U.K. [6]. Thus, 1 in 2 women aged 50 years will have an osteoporosis-related fracture in their remaining lifetime; the figure for men is 1 in 5.

Fracture incidence in the community is bimodal, showing peaks in youth and in the very elderly. In young people, fractures of long bones predominate, usually after substantial trauma and are more frequent in males than females. In this group the question of bone strength rarely arises, although there are now data suggesting that this may not be entirely irrelevant as a risk factor [9]. Over

the age of 35 years, fracture incidence in women climbs steeply, so that rates become twice those in men. Before studies that ascertained vertebral deformities radiographically, rather than by clinical presentation, this peak was thought to be mainly due to hip and distal forearm fracture, but as Fig. 40.1 shows, vertebral fracture can now be shown to make a significant contribution.

Hip fracture

In most populations hip fracture incidence increases exponentially with age (Fig. 40.1). Above 50 years of age, there is a female-to-male incidence ratio of around 2 to 1 [10]. Overall, about 98% of hip fractures occur among people aged 35 years and over, and 80% occur in women (because there are more elderly women than men). Worldwide there were an estimated 1.66 million hip fracture in 1990 [11]; about 1.19 million in women and 463,000 in men. The majority occur after a fall from standing height or less, and 90% occur in people over 50 years old [12]. Recent work has characterized the age and gender specific incidence in the U.K. population, using the General Practice Research Database (GPRD), which includes 6% of the U.K. population). Thus, the lifetime risk of hip fracture for 50-year-olds in the U.K. is 11.4% and 3.1% for women and men, respectively [6]. Most of this increased risk is accrued in old age, such that a 50-year-old woman's 10-year risk of hip fracture is 0.3%, rising to 8.7% when she is 80 years old [6]. The corresponding figures for men are 0.2% and 2.9%, respectively. Hip fractures are seasonal, with an increase in winter in temperate countries, but their occurrence mainly indoors would imply that this increase is not simply due to slipping on icy pavements: other possible causes may include slowed neuromuscular reflexes and lower light in winter weather. The direction of falling is important, and a fall directly onto the hip (sideways) is more likely to cause a fracture than falling forward [13].

Incidence rates vary substantially from one population to another, and incidence is usually greater in whites than nonwhites, although there are differences within populations of a given gender or race. In Europe, hip fracture rates vary sevenfold between countries [14]. These findings suggest an important role for environmental factors in the aetiology of hip fracture, but factors studied thus far, such as smoking, alcohol consumption, activity levels, obesity, and migration status, have not explained these trends.

Table 40.1. Impact of Osteoporosis-Related Fractures (5)

	Hip	Spine	Wrist
Lifetime risk (%)			
Women	23	29	21
Men	11	14	5
Cases/year	620,000	810,000	574,000
Hospitalization (%)	100	2–10	5
Relative survival	0.83	0.82	1.00

Costs: All sites combined ~39 billion Euros.

Vertebral fracture

Recent data from the European Vertebral Osteoporosis Study (EVOS) have shown that the age-standardized population prevalence across Europe was 12.2% for men and 12.0% for women aged 50–79 years [15]. Historically, it

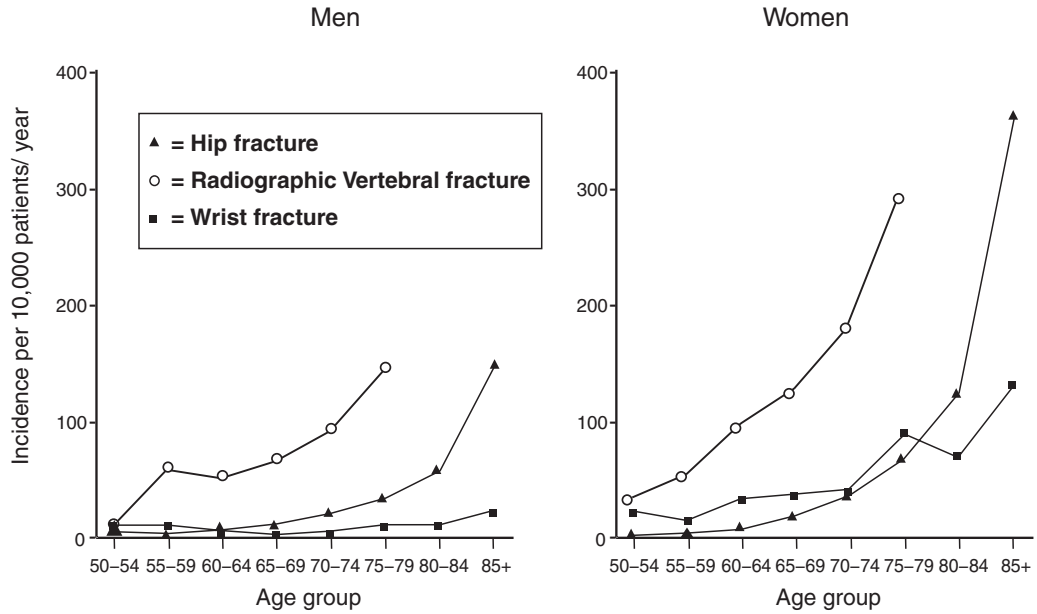

Fig. 40.1. Radiographic vertebral, hip, and wrist fracture incidence by age and gender (Refs. 6, 7).

was believed that vertebral fractures were more common in women than men, but the EVOS data suggest that this is not the case at younger ages: The prevalence of deformities in 50- to 60-year-olds is similar, if not higher in men, possibly because of a greater incidence of trauma [15]. The majority of vertebral fractures in elderly women occur through normal activities such as lifting, rather than through falling.

Many vertebral fractures are asymptomatic, and there is disagreement about the radiographic definition of deformities in those patients who do present. Thus, in studies using radiographic screening of populations, the incidence of all vertebral deformities has been estimated to be three times that of hip fracture, with only one-third of these coming to medical attention [16]. Data from EVOS have allowed accurate assessment of radiographically determined vertebral fractures in a large population. At age 75–79 years, the incidence of vertebral fractures so-defined was 13.6 per 1,000 person-years for men and 29.3 per 1,000 person-years for women [7]. This compares with 0.2 per 1,000 person-years for men and 9.8 per 1,000 person-years in 75–84 year olds where the fractures were defined by clinical presentation in an earlier study from Rochester, Minnesota [17]. The overall age-standardized incidence in EVOS was 10.7 per 1,000 person-years in women and 5.7 per 1,000 person-years in men.

Figure 40.2 shows the incidence rates of morphometrically (by radiograph) defined vertebral fracture in EVOS compared with rates derived from other population-based radiographic studies. It shows that the heterogeneity in vertebral fracture incidence is markedly lower than the geographic variation in age and gender-adjusted rates of hip fracture. The figure contrasts incidence rates for vertebral fractures defined radiographically with those identified by clinical diagnosis or hospitalization for the fracture. It clearly demonstrates the enormous shortfall in clinical recognition and hospital identification of this important osteoporotic fracture.

Distal forearm fracture

Wrist fractures show a different pattern of occurrence to hip and vertebral fractures. There is an increase in incidence in white women between the ages of 45 and 60 years, followed by a plateau [16]. This may relate to altered neuromuscular reflexes with aging, and as a result, a tendency to fall sideways or backward, and thus not to break the fall with an outstretched arm. Most wrist fractures occur in women, and 50% occur in women over 65 years old. Data from the GPRD show that a woman's lifetime risk of wrist fracture at 50 years old is 16.6%, falling to 10.4% at 70 years. The incidence in men is low and does not rise much with aging (lifetime risk 2.9% at age 50 years and 1.4% at age 70 years) [6].

Clustering of fractures in individuals

Epidemiological studies suggest that patients with different types of fragility fractures are at increased risk of developing other types of fracture. For example, the presence of a previous vertebral deformity leads to a seven- to tenfold increase in the risk of subsequent vertebral deformities [18]. This is a comparable level of increased risk to that seen for individuals who have sustained one hip fracture to then sustain a second. Furthermore, data from Rochester, Minnesota, suggest that the risk of a hip fracture is increased 1.4-fold in women and 2.7-fold in men after the occurrence of a distal forearm fracture [19]. The corresponding figures for subsequent vertebral fracture are 5.2 and 10.7. Data from EVOS demonstrate that prevalent vertebral deformity predicts incident hip fracture with a rate ratio of 2.8 to 4.5, and this increases with the number of vertebral deformities [20]. The number and morphometry of base line vertebral deformities also predict incident vertebral fractures [21]. The incidence of new vertebral fracture within a year of an index vertebral fracture is 19.2% [22], and in Rochester the cumulative incidence of any fracture 10 years after the baseline event was 70%. These data emphasize the importance of prompt therapeutic action upon discovering vertebral deformities. A recent study from the Netherlands, in which 4,140 postmenopausal women were followed, provides further support for this notion [23]. Within this cohort, 54% had re-fractured within 5 years, and 23% had re-fractured within 1 year of an initial fracture. The relative risk of subsequent fracture declined with time from initial fracture: Thus, the relative risk of subsequent fracture in the first year after the initial fracture was 5.3; within 2–5 years it was 2.8; within 6–10 years it was 1.4; and then it dropped to 0.41 for greater than 10 years post initial fracture. Finally, the Dubbo Osteoporosis Epidemiology Study demonstrated similar rates of re-fracture in men and women over a 10-year period; increased fracture rates were seen after most different types of baseline fractures, excluding rib (men) and ankle (women) [24].

Time trends and future projections

Life expectancy is increasing around the globe, and the number of elderly individuals is rising in every geographic region. The world population is expected to rise from the current 323 million individuals aged 65 years or over to 1.555 billion by the year 2050. These demographic changes alone can be expected to increase the number of hip fractures occurring among people aged 35 years and over worldwide: The incidence is estimated to rise from 1.66 million in 1990 to 6.26 million in 2050. Assuming a constant age-specific rate of fracture, as the number of over 65-year-olds increases from 32 million in 1990 to 69 million in 2050, the number of hip fractures in the U.S. will increase threefold [25]. In the U.K., the number of hip fractures may increase from 46,000 in 1985 to 117,000 in 2016 [26]. However, in the developed world, studies from Switzerland and Finland suggest that the age-adjusted incidence of hip fracture has declined over the past decade [2, 3, 27, 28]. The reason for these changes

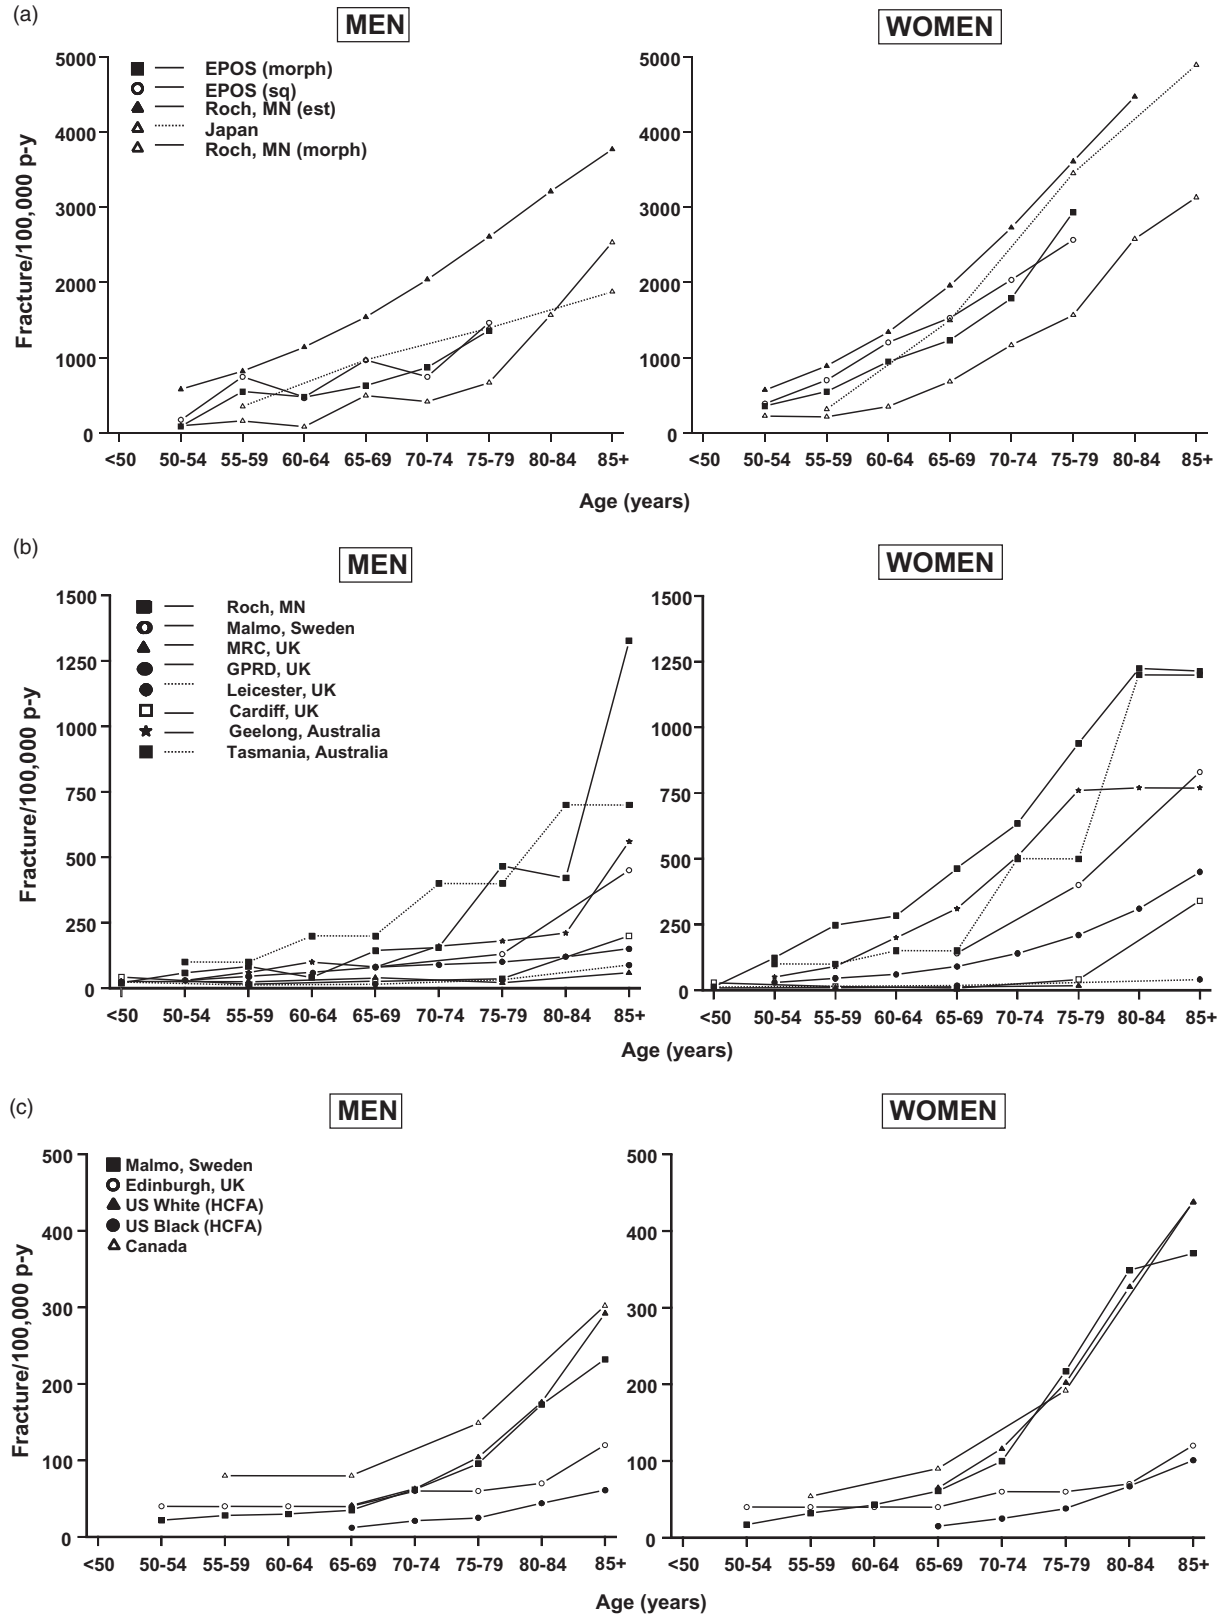

Fig. 40.2. Incidence for vertebral fracture in several populations, defined (a) morphometrically, (b) clinically, and (c) by hospitalization for fracture.

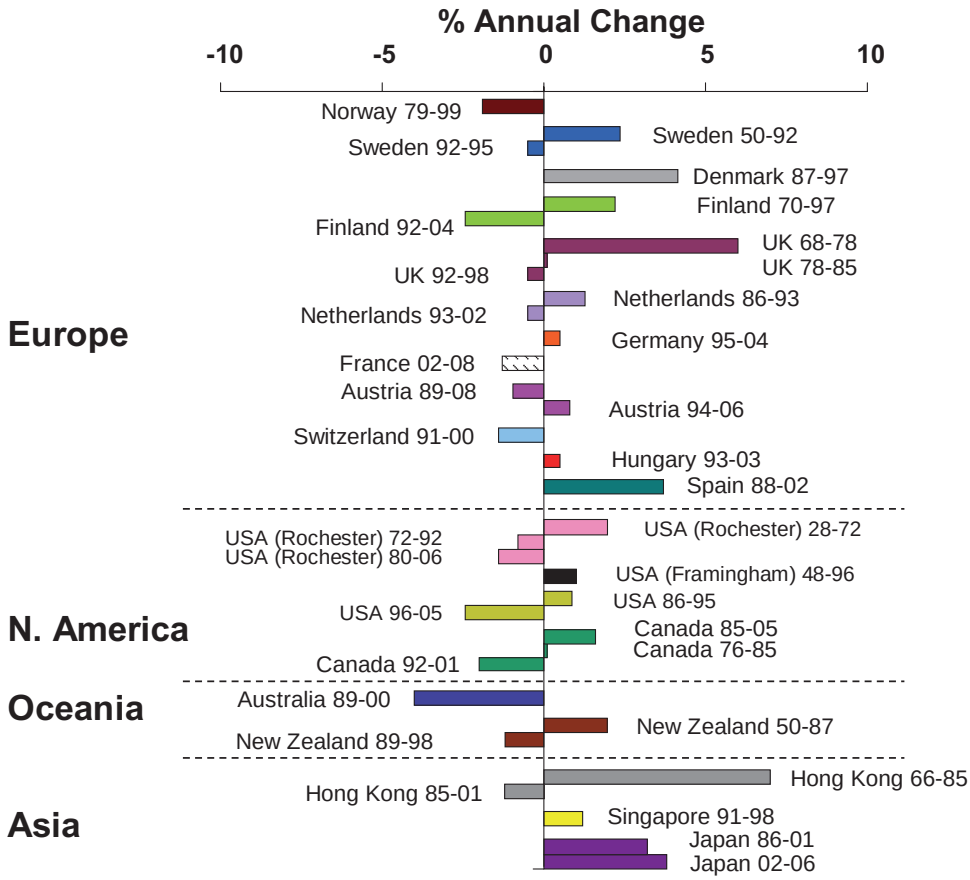

Fig. 40.3. Secular trends in hip fracture incidence. Reproduced with permission from Cooper et al. (Ref. 29).

may be a birth cohort effect, an increase in obesity or better screening and treatment for osteoporosis, and might potentially partly offset the impact of the projected increase in the elderly population. This pattern of declining age-adjusted incidence is supported by further studies reported in a recent systematic review [29]: Thus, in Western populations, whether in North America, Europe, or Oceania, while increases in age-adjusted hip fracture incidence have been reported through the second half of the past century, those studies that continue to follow trends over the past two decades have found that rates stabilize, with age-adjusted decreases being observed in some centers. In contrast, this decrease in age-adjusted incidence has not been recorded in the Third World, and thus the increase in the elderly population, together with the adoption of Westernized lifestyles, is likely to ensure an increase in the worldwide burden of osteoporotic fractures in future generations. Figure 40.3 summarizes these secular changes.

Thus the increase in fracture numbers is likely to be uneven across the globe, with the increase in the elderly population in Latin America and Asia potentially leading to a shift in the geographical distribution of hip fractures, with only a quarter occurring in Europe and North America [25].

Geography

There is variation in the incidence of hip fracture within populations of a given race and gender [14, 30]. Thus, age-adjusted hip fracture incidence rates are higher among white residents of Scandinavia than comparable subjects in the USA or Oceania. Within Europe the range of variation was approximately 11-fold [14, 30]. These differences were not explained by variation in activity levels, smoking, obesity, alcohol consumption, or migration status [14]. The EVOS study demonstrated a threefold difference in the prevalence of vertebral deformities between countries, with the highest rates in Scandinavia. The prevalence range between centers was 7.5–19.8% for men and 6.2–20.7% for women. The differences were not as great as those seen for hip fracture in Europe, and some of the differences could be explained by levels of physical activity and body mass index [15].

MORTALITY AND MORBIDITY

Mortality

Mortality patterns have been studied for the three most frequent osteoporotic fractures. In Rochester, Minnesota, survival rates 5 years after hip and vertebral fractures were found to be around 80% of those expected for men and women of similar age without fractures [31].

Hip fracture

Hip fracture mortality is higher in men than women, increases with age [31], and is greater for those with coexisting illnesses and poor pre-fracture functional status. There are around 31,000 excess deaths within 6 months of the approximately 300,000 hip fractures that occur annually in the U.S. About 8% of men and 3% of women older than 50 years die while hospitalized their fracture. In the U.K., the 12-month survival post hip fracture for men is 63.3% vs 90.0% expected, and for women, 74.9% vs 91.1% expected [6]. The risk of death is greatest immediately after the fracture and decreases gradually over time. The cause of death is not usually directly attributable to the fracture itself, but to other chronic diseases, which lead both to the fracture and to the reduced life expectancy.

However, recent data suggest that elevated mortality persists for up 10 years after hip fracture. In the Dubbo Epidemiology Study of community-dwelling women and men aged 60 years and older, risk of death was further elevated over another 5 years by a subsequent fracture [32]. Reduced survival was observed following all types of fracture except for minor fractures where mortality was increased only for those of 75 years old or greater. Only 25% of deaths from hip fracture are estimated to be directly due to the fracture or resulting complications such as infection, thrombo-embolism and subsequent surgery [33]. In the Dubbo study the main predictors of higher mortality were gender (male), increasing age, quadriceps weakness and subsequent fracture, but not comorbidities. Smoking, low BMD, and body sway were also predictors in women, as was a lower level of physical activity in men [32]. A recent Australian nested case-control study suggested that the pattern and causes of death may differ somewhat for those in institutional care. Thus, in 2,005 elderly people in residential care, survival rates for hip fracture and control patients became equal within a year post fracture repair [34]: After adjusting for age, gender, institution type, weight, immobility, cognitive function, comorbidities and number of medications, there was a threefold increased risk of death for cases compared with controls in the first three months following surgery for hip fracture; the hazard ratios decreased subsequently (1.99 for 3 to 9 months post fracture and 0.88 for greater than 9 months post fracture). Infections in females and cardiac disease in both genders were the main causes of death in the first 9 months, and bisphosphonate use was associated with a reduction in mortality post hip fracture repair. It seems likely that the swift equalization of mortality rates between cases and controls in this population reflects the high risk of death of institutionalized populations compared with those free-living individuals in the GPRD and Dubbo studies.

Vertebral fracture

Vertebral fractures are associated with increased mortality well beyond a year post fracture [31], with comorbid conditions contributing significantly to the decreased relative survival.

The impairment of survival following vertebral fracture also markedly worsens as time from diagnosis of the fracture increases. This is in contrast to the pattern of survival for hip fractures. In the U.K. GPRD study, the observed survival in women 12 months after vertebral fracture was 86.5% vs 93.6% expected. At 5 years, survival was 56.5% observed and 69.9% expected [6].

Morbidity

In the U.S., 7% of survivors of all types of fracture have some degree of permanent disability, and 8% require long-term nursing home care. Overall, a 50-year-old white American woman has a 13% chance of experiencing functional decline after any fracture [35].

Hip fracture

As with mortality, hip fractures contribute most to osteoporosis-associated disability. Patients are prone to developing acute complications such as pressure sores, bronchopneumonia, and urinary tract infections. Perhaps the most important long-term outcome is impairment of the ability to walk. Fifty percent of those ambulatory before the fracture are unable to walk independently afterwards. Age is an important determinant of outcome, with 14% of 50–55-year-old hip fracture victims being discharged to nursing homes, versus 55% of those older than 90 years [35].

Vertebral fracture

Despite only a minority of vertebral fractures coming to clinical attention, they account for 52,000 hospital admissions in the USA and 2,188 in England and Wales each year in patients aged 45 years and older. The major clinical consequences of vertebral fracture are back pain, kyphosis, and height loss. Quality of life (QUALEFFO) scores decrease as the number of vertebral fractures increases [36].

Distal forearm fracture

Wrist fractures do not appear to increase mortality [6]. Although wrist fractures may impact on some activities such as writing or meal preparation, overall few patients are severely disabled, although over half report only fair to poor function at 6 months post fracture [35].

Low bone mass in children

There has been considerably less investigation of the role of bone fragility in childhood fractures, probably because of the perception that the primary determinant of fracture in this age group is trauma. There are also considerable difficulties in reaching a definition of "osteoporosis" in a growing skeleton, when there is no straightforward relationship between BMD and fracture risk. Thus the consensus view is that the phrase "low bone mass for age (with or without fractures)" is used rather than "osteoporosis." Most evidence comes from two large European studies that describe the epidemiology of fractures in childhood [37–39]. In Malmo, Sweden, the overall incidence of fracture was 212 per 10,000 girls and 257 per 10,000 boys, with 27% of girls and 42% of boys sustaining a fracture between birth and 16 years of age. Fractures of the distal radius occurred most commonly, followed by fractures of the phalanges of the hand [38, 39]. A follow-up study in Malmo a decade later found the incidence of fracture had decreased by almost 10% since the original study [40].

A similar pattern was found in the U.K. GPRD [37]. The overall incidence of fracture was 133.1 per 10,000 children, with fractures being more common in boys than girls, with an incidence of 161.6 per 10,000 and 102.9 per 10,000, respectively. Again, the most common fracture site in both sexes was the radius/ulna with a total of 39.3 per 10,000 per year. Historically, most work has focused on the impact of trauma in the aetiology of childhood fractures, contrasting with the role of bone fragility in the elderly. However, several recent studies have documented lower areal and volumetric BMD in children with distal forearm fractures than age- and sex-matched controls [41, 42]. Consistent with these observations is the finding from GPRD that peak fracture incidence corresponds to age of entry to puberty, when the discordance between height gain and accrual of volumetric bone density is greatest [37]. Other studies have suggested that risk factors for childhood fracture include obesity and high levels of vigorous activity [42, 43]. As increased physical activity has been associated with increased bone mass in childhood [43, 44], this raises the possibility of there being different routes to increased fracture risk, relating separately to bone mass and risk of trauma.

Early life influences on adult fragility fracture

The importance of bone mineral accrual in childhood and achievement of adequate peak bone mass (PBM) in early adulthood has been emphasized in recent work, demonstrating that PBM is a major determinant of osteoporosis risk in later life [45]. Over the past twenty years, evidence has accrued that the early environment may have long-term influences on future bone health. This phenomenon of "developmental plasticity," whereby a single genotype may lead to different phenotypes, dependent upon the prevailing environmental milieu, is well established in the natural world. There is a growing body of epidemiological evidence that a poor intrauterine environment leads to lower bone mass in adult life, both in third and sixth/seventh decades [46–48]. Additionally work in Finland has demonstrated an association between poor infant and childhood growth and increased risk of hip fracture 7 decades later [49, 50]. Physiological studies have implicated the parathyroid hormone/vitamin D axis in mechanisms that underly this phenomenon, such that mothers who are deficient in vitamin D in late pregnancy have children with decreased bone mass in childhood [51–53]. This novel area of research may lead ultimately to innovative strategies to improve bone health in children, with a subsequent reduction in the burden of osteoporotic fracture in future generations.

CONCLUSION

Osteoporosis is a disease that has a huge effect on public health. The impact of osteoporotic fracture is massive, not just for individuals, but for the health service, economy, and population as a whole. Many risk factors for inadequate peak bone mass, excessive involutional loss and fracture have been characterized, and coupled with new pharmacologic therapies, we are now in a position to develop novel preventative and therapeutic strategies, both for the entire population and those at highest risk.

Overview of Pathogenesis

Ian R. Reid

References 359

The pathogenesis of osteoporosis is as diverse as the influences that determine the strength of the skeleton and the trauma to which it is subjected. Skeletal trauma in the elderly is principally related to falls, and the propensity to fall is influenced by frailty, neuromuscular abnormalities, eyesight, sedative drugs, postural hypotension, and the safety of the home environment (presence of hazards such as loose carpets and electric cords, absence of safety devices such as handrails). Falls are dealt with elsewhere in this volume, so this chapter will focus on determinants of skeletal strength.

The elements that contribute to skeletal strength (and thus fragility) are listed in Table 41.1. In the past, the greatest emphasis has been on the mass of the skeleton, measured clinically as bone mineral density (BMD). Thus, factors that maximize bone mass during childhood and adolescence (e.g., global nutritional status, physical activity, genes) and delay or slow its loss during menopause and old age (fat mass, physical activity, calcium intake, vitamin D status) [1, 2] will reduce fracture risk. Throughout life, bone mass is influenced by intercurrent illnesses, body weight, lifestyle factors, and some medications, particularly glucocorticoids (Table 41.2). In women, bone mass is critically dependent on estrogen levels and can be maintained indefinitely with postmenopausal estrogen replacement [3].

One observation suggesting that bone mass is not the only determinant of fracture risk is the demonstration that age increases fracture risk independent of bone density. Thus, an 80-year-old woman with a femoral neck T-score of –3 is six times more likely to have a hip fracture than a 50-year-old woman with the same bone density [4]. A similar increase in fracture risk independent of bone density has been demonstrated in glucocorticoid users [5]. Accordingly, in recent years there has been an increasing focus on bone *quality*, as well as bone *quantity*. The components of bone quality are continuing to be defined, but include the material properties of both the proteinaceous matrix and the mineral phase of bone, as well as bone architecture (Table 41.1). Major perturbations of the matrix, as in osteogenesis imperfecta, clearly have a substantial effect on skeletal fragility, but it is now evident that collagen cross-linking, the state of cross-link isomerization, and levels of advanced glycation end products also have an impact on skeletal strength [6]. These aspects of bone matrix biology are thought to be influenced by rates of bone turnover, which is under the influence of sex hormones and cytokines, as well as genetic factors [7]. In addition, advanced glycation end products will be influenced by ambient glucose concentrations, and increased in the presence of diabetes mellitus. This probably contributes to the higher fracture risk of diabetics, independent of BMD [8]. Some studies have suggested that the presence of microcracks in bone might also compromise skeletal strength and that these are related to low turnover [9]. Adverse changes in these indices have been suggested to contribute to the deterioration in skeletal strength demonstrable in some animal studies of high-dose bisphosphonate use [6, 10]. Recent human studies, however, have suggested that these factors make only small contributions to bone strength, which is primarily determined by trabecular bone volume [11]. In pathological situations (e.g., Paget's disease) high turnover can result in disruption of the normal lamellar pattern of

collagen fibril assembly, leading to the deposition of woven bone, which has inferior mechanical properties. Hypocalcemia, hypophosphatemia, or the presence of interfering factors (such as fluoride or high-dose etidronate) can interfere with normal mineralization, with a resultant decrease in the compressive strength of bone.

The microarchitecture of bone impacts on its strength. As bone mass is lost, perforations occur in individual trabeculae, contributing to a much greater decrease in bone strength than the simple decrease in mass would predict (Fig. 41.1). Accordingly, loss of trabecular continuity is more frequently observed in patients with osteo-

porotic fractures than in controls [12]. High bone turnover contributes to trabecular perforation by increasing the likelihood of resorption lacunae coinciding on opposite sides of a trabecula. Even without leading to perforation, high turnover can increase trabecular fragility by causing critical trabecular narrowing where resorption lacunae are located close to one another on opposite sides of the trabeculae. This may explain the independent association of bone turnover with fracture risk [13], although this is probably also contributed to by the greater rate of bone loss observed in high turnover states [14]. In the cortex, increasing porosity resulting from increased osteoclast activity results in loss of strength and ultimately in the loss of cortical bone as a result of its "trabecularization" [15]. In the first 15 years after menopause, trabecular bone loss exceeds cortical, but subsequently this is reversed as the cortex becomes more porous and so has a greater area to be remodeled, whereas the loss of trabecular elements reduces the surface in that compartment [15].

Macroarchitecture also impacts on skeletal fragility. This has probably been most clearly demonstrated through the positive association between hip axis length and hip fracture risk [16]. Increases in hip axis length and height (also a risk factor for fracture) probably have contributed to the secular increases in hip fracture risk as global nutrition has improved over the past 60 years [17]. Macroarchitectural changes may counteract, to some extent, the loss of bone mass with age. Ahlborg [18] has elegantly demonstrated increasing medullary and periosteal diameters in the forearms of postmenopausal women, which substantially abrogate the loss of tissue-level strength caused by the sustained imbalance of osteoblast and osteoclast activity. The increase in diameter results in increased resistance to both bending and torsion.

The above paradigm dissects skeletal fragility in terms of the anatomical components that make up bone. Each of these components is under multiple influences including those of genes, nutrition (calcium, vitamin D, protein, fat mass, lean mass), and lifestyle (alcohol, smoking, physical activity) as well as the effects of pathologies and medications. It is equally valid to consider pathogenesis under these major headings, and that is the approach adopted in the following chapters. Thus, a matrix of multiple influences on multiple skeletal targets is established, and these interactions ultimately determine the fracture risk of a given individual. In the clinic, those elements of pathogenesis that are quantifiable can be combined to produce a numerical estimate of fracture risk, using one of the available indices [19, 20]. These analyses indicate that age, gender, body weight, bone density, and fracture history are the critical determinants of fracture risk, with further contributions from falls, smoking, alcohol intake, glucocorticoid use, height, family history of fracture, and the presence of other pathologies [21]. Again, this reflects the interaction of multiple factors on multiple end points in the determination of skeletal fragility.

INTRODUCTION

Nutrients are essential to the viability of all cells including those in bone. However, it is the whole diet rather than individual nutrients that determines many factors that influence bone, including nutrition adequacy of all essential nutrients, the presence or absence of inhibitors to absorption and utilization of individual nutrients, the energy available for growth and maintenance of bone and adiposity, and the acid–base balance. Diet and other lifestyle choices around the world lead to shortages of some nutrients that are particularly important to bone (i.e., calcium, protein, and vitamin D). Our ability to accurately link and quantify the role of individual nutrients or whole diet in building and maintaining bone is handicapped by methodological limitations in assessing dietary intakes and the time lag for seeing consequences of diet on bone. Nutrition is an important component for treating those with osteoporosis, as addressed in another chapter. Diet, including dietary supplements, may be the most important complement to drugs for combination therapy. However, the more important role of diet is preventive. The cumulative effect of diet over the life span influences development of peak bone mass and its subsequent maintenance. Osteoporosis has been called a pediatric disorder because adult peak bone mass is largely determined during childhood.

ROLE OF DIET IN BUILDING PEAK BONE MASS

Rapid skeletal growth occurs in infancy and adolescence. During growth, there is a high demand for nutrients. For bone mineral matrix formation, calcium, phosphorus, and magnesium are particularly important. Vitamin D status is essential for active calcium absorption across the gut, and many nutrients are vital for collagen synthesis, including protein, copper, zinc, and iron. Meeting nutrient needs is easier during infancy through breastfeeding or carefully developed infant formulas. With the exception of its vitamin D content, the nutrient profile of breast milk is relatively constant and nearly independent of the diet of mothers [1]. In contrast, the pubertal growth spurt occurs at a life stage where diet becomes increasingly influenced by peers. This is an extremely important period for development of peak bone mass. During the 4 years surrounding peak bone mass accretion, approximately 40% of peak bone mass is acquired. Peak bone mass velocity determined from a longitudinal study in white boys and girls was 409 g/day in boys and 325 g/day in girls [2]. During peak bone mass accrual, controlled feeding studies on a range of calcium intakes in black and white girls showed that calcium intake explained 12.3% of the variance in skeletal calcium retention compared with the 13.7% explained by race,

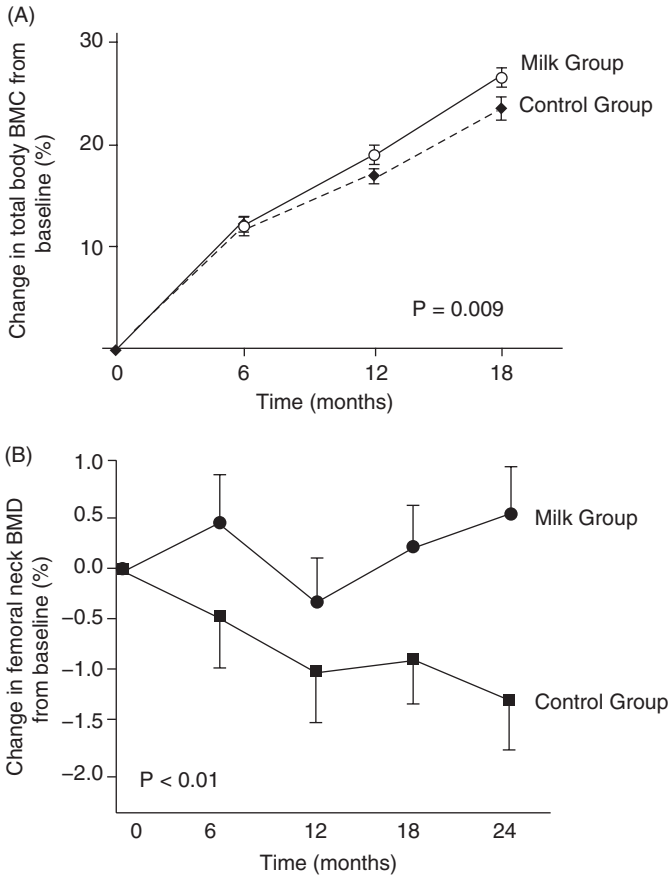

Fig. 42.1. (A) Milk supplementation in RCTs increases bone accrual in growing girls (Ref. 9), and (B) reduces bone loss in postmenopausal women (Ref. 25).

whereas a measure of sexual maturity explained an additional 4% [3]. The large contribution of just one nutrient [see Fig. 42.1(A)] emphasizes the importance of nutrition at this life stage. It also shows the large genetic influence on bone as race is a crude marker of genotype [4]. Interestingly, blacks do not require higher calcium intakes to achieve greater peak bone mass accrual than whites [3], and white boys do not need higher calcium intakes to achieve greater peak bone mass accrual than white girls [5], Chinese-American girls and boys have lower calcium requirements to maximize skeletal calcium accretion during puberty than do black and white adolescents [6]. Although, not many diet–gene interactions have been identified for bone accrual, calcium absorption efficiency has been associated with the Fok1 polymorphism of the Vitamin D receptor [7]. Genes associated with bone size are likely candidates for genetic differences in peak bone mass, as most racial variations in bone mineral content in early puberty disappear when adjusted for bone area [8]. Residual differences disappear when further adjusted for dairy calcium intake and physical activity [2].

In addition to providing raw materials for growth, diet can alter regulators of growth that affect bone accretion. In a randomized, controlled trial of a pint of milk a day in early pubertal girls, serum IGF-1 increased, which was thought to be partly causal for the increase in bone mineral density (BMD) in the intervention group relative to the control group [9]. Of the factors measured, serum IGF-1 was the greatest predictor of calcium retention after calcium intake in adolescent white boys; calcium intake predicted 21.7% and serum IGF-1 predicted 11.5% of calcium retention [10].

Diet can alter timing of menarche, perhaps through modulating growth hormones. This was shown in a study of girls 7.9 years of age who were randomized to products fortified with dairy minerals and followed for 16 years until approximate peak mass had been achieved [11]. Girls who had received the mineral complex, although only for 1 year, achieved menarche almost 5 months earlier on average than the control group. Earlier menarche with longer exposure to estrogen resulted in greater bone accretion at six skeletal sites.

The concern for low peak bone mass is risk of fracture, especially later in life. Fracture risk is also of concern in childhood, particularly during the period of relatively low BMD when bone consolidation lags behind growth [12]. Fracture incidence in childhood has dramatically increased over the past three decades [13], and the risk of fracture during childhood is compounded by the rapid increase in childhood obesity and suboptimal calcium intakes. In adolescence, as calcium intake increases, calcium retention increases to a plateau, but the plateau of calcium retention increases with increasing body mass index [14]. Thus, suboptimal calcium intakes may limit development of proportionally larger skeletons needed to reduce fracture risk in overweight and obese children.

The persistence of effects of short-term dietary interventions throughout life is controversial. The advantage in bone gain with supplementation of a calcium-rich source during randomized, controlled trials largely disappeared on follow-up after cessation of the intervention in some trials [15] but not others [16]. Additionally, the possibility of catch-up growth has been raised in a randomized controlled calcium supplementation trial from prepuberty to peak bone mass [17]. Although final BMD was not different on average for total body or radius, total hip BMD showed no catch-up growth, nor did taller women [18, 19]. Evidence of the lifelong consequences of diet early in life comes from those with eating disorders who fail to recover BMD [19].

ROLE OF NUTRITION IN MAINTAINING BONE MASS

Bone mass is ultimately determined by the genetic program as modified by current and past mechanical

loading and limited or permitted by nutrition. The genetic potential cannot be reached or maintained if intake and absorption of essential nutrients are insufficient.

Calcium is the principal cation of bone mineral. Bone constitutes a very large nutrient reserve for calcium, which, over the course of evolution, acquired a secondary, structural function that is responsible for its importance for osteoporosis. Bone strength varies as the approximate second power of bone structural density. Accordingly, any decrease in bone mass produces a corresponding decrease in bone strength. The aggregate total of bone resorptive activity is controlled systemically by parathyroid hormone (PTH), which in turn responds to the demands of extracellular fluid calcium ion homeostasis and not to the structural need for bone mass. Whenever absorbed calcium intake is insufficient to meet the demands of growth and/or the drain of cutaneous and excretory losses, resorption will be stimulated and bone mass will be reduced as the body scavenges the calcium released in bone resorption. Whereas reserves are designed to be used in times of need, such use would normally be temporary. Sustained, unbalanced withdrawals deplete the reserves and thereby reduce bone strength. The principal skeletal role of calcium once peak bone mass has been achieved is to offset obligatory losses of calcium through sweat, desquamated skin, and excreta.

In addition to depleting or limiting bone mass, low calcium intakes directly cause fragility through the PTH-stimulated increase in bone remodeling. Resorption pits on trabeculae cause applied loads to shift to adjacent bone, leading to increased strain locally. In this way excessive remodeling is itself a fragility factor, altogether apart from its effect on bone mass. When adequate calcium is absorbed, PTH-stimulated remodeling decreases immediately [20] and with it, fragility. Fracture rate responses in the major treatment trials show the predicted prompt reduction in fracture risk [21, 22].

DIETARY PATTERNS

Recommended food patterns around the world attempt to meet national nutrient requirements and to promote health and reduce risk of disease. The food group most associated with bone health is the dairy group. This food group provides between 20% and 75% of recommended calcium, protein, phosphorus, magnesium, and potassium. Recommended intakes of dairy products around the world are two to three servings per day. Intakes on average are much less than the recommended levels for most populations. Dairy intakes in much of the world have been low persistently, possibly related to the high incidence of lactose maldigestion. Milk consumption has declined over the past half century in the United States, concurrent with increased consumption of soft drinks [23]. Adequacy of milk intake has been associated with adequacy of a number of nutrients in children including calcium, potassium, magnesium, zinc, iron, riboflavin, vitamin A, folate, and vitamin D [24]. Alternative sources to replace this whole package of nutrients are not typically consumed in sufficient amounts to replace milk [25]. Milk consumption within various cultures has been positively associated with bone health. High dairy-consuming regions have better bone measures than low dairy-consuming regions in Yugoslavia [26] and China [27]. A two-year randomized controlled trial (RCT) of milk (1,200 mg Ca/day) in 173 postmenopausal Chinese women reduced loss of femoral neck BMD relative to a control group [28] [See Fig. 42.1(B)]. Milk avoiders have higher risk of fracture than milk-drinking counterparts in children [29] and adults [30]. Retrospective studies show that milk drinking in childhood is inversely associated with risk of hip fracture later in life [31]. A European panel concluded that most individuals can tolerate 12 g of lactose in a single dose [32]. A National Institute of Health Consensus Conference concluded that the majority of people who self-identify as lactose malabsorbers do not have clinical lactose intolerance [33]. Unnecessary avoidance of dairy due to perceived lactose intolerance can predispose individuals to decrease bone accrual [34].

Two other food groups have also been associated with bone health by affecting the acid–base balance: fruits and vegetables (positively), and meats, fish, and poultry (negatively). Sulfur-rich amino acids from the meat groups favor an acidic ash that increases calciuria, whereas fruits and vegetables favor an alkaline ash largely because of potassium content, which has a protective effect against calcium loss in the urine. However, recent studies have challenged this paradigm. A meta-analysis of balance studies found no evidence for the hypothesis that dietary protein leads to negative calcium balance despite increased hypercalciuria [35]. The hypercalciuria is offset by increased calcium absorption or decreased endogeneous secretion [36, 37]. Protein intake negatively predicts age-related bone loss, and protein supplements decrease fracture rates in the elderly [38]. A protein and calcium interaction has been identified [39] through retrospective analysis of an RCT. Subsequently, subjects in the Framingham Study with the highest tertile of animal protein intake who consumed less than 800 mg calcium/day had 2.8 times the risk of hip fracture as those in the lowest tertile of protein ($p = 0.02$), whereas higher protein intake was associated with decreased fracture incidence when calcium intakes were greater than 800 mg/day [40]. Similar to dietary proteins, potassium reduces calciuria, but it is offset by decreased calcium absorption so there is no change in calcium balance [41]. Some vegetables and herbs have the ability to decrease bone resorption, but the effect is independent of the alkaline load or potassium content [42].

Dietary salt is the largest predictor of urinary calcium excretion [43]. Sodium and calcium share transport proteins in the kidney. In adolescence, less sodium, and consequently less calcium, is excreted by black girls compared with white girls, presumably because of racial differences in renal transport [44].

DIETARY BIOACTIVE CONSTITUENTS

There is increasing interest in bioactive constituents that can replace or reduce the dose of drug therapies for ameliorating bone loss, or that can promote bone health in a preventative manner. Typically, these bioactive constituents must be added to the food supply or taken as dietary supplements, as effective doses may not be achievable in amounts naturally present in foods. There is much to learn about the nature and dose of bioactive constituents, their mechanisms of action, and under what conditions they may be effective.

One category of dietary bioactive constituents that has been studied more than other categories is the flavonoids that bind to estrogen receptors, notably soybean isoflavones [45]. Epidemiological evidence of soy isoflavone consumption in Asia is associated with reduced risk of hip fracture. But in Western countries, soy consumption is low so that the consumption of soy isoflavones is typically through dietary supplements. There is little support for soy isoflavone supplements as currently marketed to assess postmenopausal bone loss, although pure genistein aglycone [46] and higher doses have shown benefit [47].

Flavonoids from plant sources other than soy with promise in *in vitro* and in animal models are those in dried plums and blueberries. Osteoporosis and other chronic diseases are being considered as inflammatory disorders. To the extent that flavonoids can modify reactive oxygen species and redox status in bone cells involved in the regulation of bone turnover and survival of osteoblasts, osteoclasts, and osteocytes, they may have a protective role in the diet. Feeding blueberries activates the Wnt-β catenin signaling pathway to increase osteoblastogenesis and mineral apposition rate [48]. A mixture of phenolic acids could induce the same effects as whole blueberries [49]. Dried plums improved BMD of the ulna and spine more than dried apples at 100 g/day in a 1-year trial of postmenopausal women [50].

Certain carbohydrates and fibers that are fermented in the lower gut are of interest for their mineral-enhancing capacity with subsequent benefits to bone [51]. Upon fermentation of these prebiotics by gut microflora, short chain fatty acids are produced that may solubilize minerals and influence microbiota increasing the proportion of bifidobacteria.

CONCLUSIONS

Bone health rests on a combination of mechanical loading and adequate intakes of a broad array of macro- and micronutrients. Three important essential nutrients for bone health are calcium, vitamin D, and protein. Most diets that are inadequate in one key nutrient will be inadequate in several. Optimal protection of bone requires a diet rich in all the essential nutrients. Mononutrient supplementation regimens will often be inadequate to ensure optimal nutritional protection of bone health. Some bioactive ingredients may improve bone health by reducing chronic inflammation.

INTRODUCTION

Significant bone loss occurs with aging in both men and women, leading to alterations in skeletal microarchitecture and increased fracture incidence [1]. Much work has now significantly enhanced our understanding of the role that sex steroids (primarily estrogen and testosterone) play in the development and progression of osteoporosis in both men and women.

CHANGES IN BONE MASS AND STRUCTURE WITH AGING

The composite DXA data shown in Fig. 43.1 demonstrates that at the menopausal transition, women undergo rapid trabecular bone loss [2]. While somewhat variable in length, this period of accelerated bone loss extends for approximately 5–10 years, with loss of approximately 20–30% of trabecular bone, but only 5–10% of cortical bone. Following this initial phase of rapid bone loss, a second phase of slow and continuous bone loss becomes predominant. In this phase, which extends throughout the remaining female life span, cortical and trabecular bone loss occur at approximately equal rates. In comparison, men from middle life onward show slow progressive trabecular and cortical bone loss nearly equivalent to the latter phase seen in postmenopausal women. However, as men do not have a menopausal equivalent, the early accelerated phase of bone loss seen in women does not occur; thus overall loss of both trabecular and cortical bone is less in men compared to women.

Recent work has challenged the prevailing idea that there is relative preservation of skeletal integrity in both men and women from the end of puberty until middle age. Such work has been predicated upon studies performed using quantitative computed tomography (QCT), which permits measurement of volumetric bone mineral density (vBMD) and distinguishes trabecular and cortical components much more precisely than DXA imaging, which only provides areal BMD assessment. Thus, cross-sectional QCT studies show that in the spine (composed primarily of trabecular bone), large decreases (–55% in women and –45% in men) in vBMD occur beginning in the third decade (Fig. 43.2) [3]. In contrast, cortical vBMD (assessed at the distal radius) in the same cohort shows little change in either sex until midlife. Thereafter, roughly linear declines in cortical bone occur in both sexes, although cumulative decreases are greater in women than men (28% vs 18%,$p < 0.01$), reflecting the period of rapid bone loss seen in early menopausal women. Multivariate analysis in this same cohort showed that changes in trabecular microarchitecture at the wrist were most closely associated with reductions in sex steroid levels in subjects older than 60 years of age [4, 5]. Importantly, these cross-sectional findings have now been confirmed by longitudinal studies [6] in which vBMD was followed at both the distal radius and tibia,

Population based study of age and sex differences in bone volumetric density, size, geometry, and structure at different skeletal sites. *J Bone Miner Res* 19: 1945–1954.)

with substantial loss of trabecular bone found to start shortly after completion of puberty in both men and women, an age range during which sex steroid levels are considered to be normal. The relative contribution of bone loss during these years to future skeletal fragility remains to be determined.

In addition to changes in bone mass that occur with aging, changes in bone cross-sectional area also occur in both sexes across skeletal sites. Notably, despite a net decrease in cortical area and thickness resulting from endocortical resorption, concomitant outward cortical displacement due to ongoing periosteal apposition has been demonstrated to occur in both men and women. This net outward displacement increases bone strength for bending stresses, and partially offsets the decrease in bone strength due to cortical thinning [7].

When taken together, these changes in both bone quantity and structure in aging women and men lead to changes in the annual incidence of osteoporotic fractures (Fig. 43.3). Thus, distal forearm fractures rise markedly

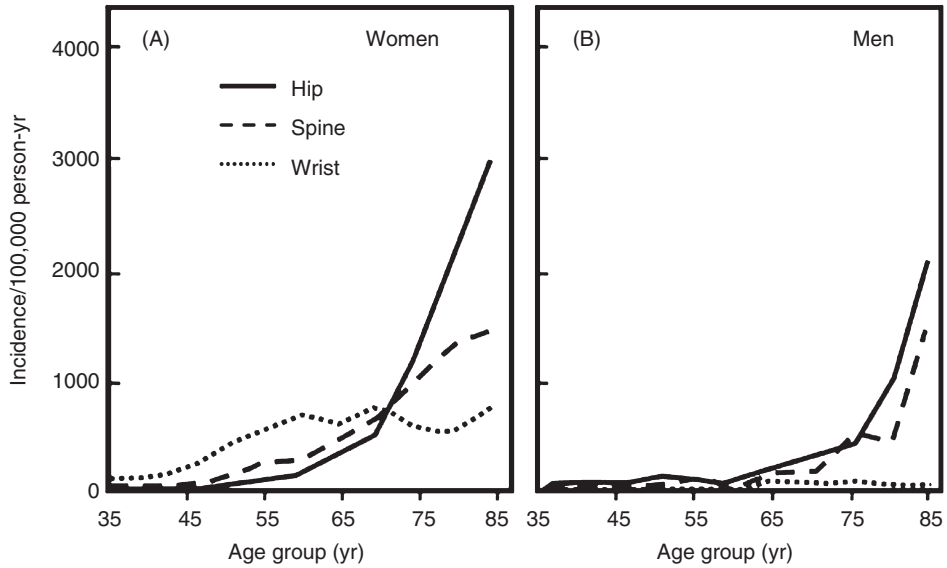

Fig. 43.3. Age specific incidence rates for proximal femur (hip), vertebral (spine), and distal forearm (wrist) fractures in Rochester, MN, women (A) and men (B). (Adapted with permission from Elsevier from Cooper C, Melton LJ. 1992. Epidemiology of osteoporosis. *Trends Endocrinol Metab* 3: 224–229. Copyright 1992.)

in women around the time of menopause and plateau approximately 15 years after menopause. Similarly, vertebral fracture incidence also begins to rise with the onset on menopause. In contrast to wrist fractures, however, vertebral fracture incidence continues to increase for the duration of the female life span. Hip fracture rates in women initially parallel those of vertebral fractures, but, as shown, rise markedly later in life.

In contrast, distal forearm fractures remain uncommon in men throughout life. Cross-sectional studies of the distal forearm in both sexes using peripheral quantitative computed tomography (pQCT)show that whereas women undergo both trabecular loss and increased trabecular spacing with aging, men begin young adult life with relatively thicker trabeculae and primarily sustain trabecular thinning rather than loss with aging [8]. Thus, in addition to having larger bones on average than women, elderly men also have comparatively more trabeculae at the distal forearm, likely contributing to the rarity of wrist fractures in aged men. Although delayed by about 1 decade relative to women, vertebral and hip fracture incidence in men is roughly equivalent to that in women, with the decade delay again likely reflecting the lack of a male menopause and the associated rapid skeletal loss seen during this period in women.

SEX STEROIDS AND BONE LOSS IN WOMEN

The relationship between diminishing estrogen levels in women caused by ovarian failure and the development of postmenopausal osteoporosis has been recognized for 7 decades [9]. Relative to premenopausal levels, serum estradiol (E2) levels decrease by 85–90%, and serum estrone (El; a fourfold weaker estrogen) decline by 65–75% during the menopausal transition [10]. Temporally associated with this decline are changes in both bone formation and resorption rates. Whereas bone formation and resorption rates are approximately equivalent due to coupled bone remodeling prior to menopause, the onset of menopause heralds an increase in the basic multicellular unit (BMU) activation frequency rate, extension of the resorption period [11], and shortening of the formation period [12]. Accordingly, as assessed by biochemical markers, bone resorption at the menopause increases by 90%, whereas bone formation increases by only 45% [13]. This net imbalance leads to the accelerated phase of bone loss detailed above, and a net efflux of skeletal-derived calcium to the extracellular fluid. As a result, compensatory mechanisms to limit the development of hypercalcemia are employed, including increased renal calcium clearance [14], decreased intestinal calcium absorption [15], and partial suppression of parathyroid hormone (PTH) secretion [16]. Together, however, these compensatory mechanisms contribute to a net negative total body calcium balance from skeletal losses. Importantly, these compensatory effects appear directly related to estrogen deficiency, as estrogen repletion, at least in early menopause, leads to preservation of both renal calcium reclamation and intestinal calcium absorption [17].

The effects of estrogen on modulating skeletal metabolism at the cellular and molecular level remain the subject of active study. Estrogen plays a central role

in osteoblast biology, where it promotes bone marrow stromal cell differentiation toward the osteoblast lineage, increases preosteoblast to osteoblast differentiation, and limits both osteoblast and osteocyte apoptosis [18–20]. In addition, estrogen increases the osteoblastic production of growth factors (IGF-1 and TGF-β) and procollagen synthesis [21, 22]. Recent work has also demonstrated that estrogen suppresses serum [23, 24] and bone marrow plasma [25] levels of the potent inhibitor of Wnt signaling, sclerostin, but further studies are needed to define the extent to which an estrogen-induced reduction in sclerostin production contributes to the effects of estrogen in maintaining bone formation. Impaired bone formation caused by estrogen deficiency becomes apparent soon after the onset of menopause. Direct evidence that pharmacologic dosages of estrogen have anabolic skeletal effects in postmenopausal women comes from histomorphometric studies of iliac crest bone biopsies from women given prolonged treatment with percutaneous estrogen, in whom a 61% increase in trabecular bone volume and a 12% increase in trabecular wall thickness relative to baseline was found following 6 years of continuous treatment [26].

In addition to its central role in regulating osteoblast biology, estrogen also plays a pivotal role in osteoclast biology. Both *in vitro* and *in vivo*, estrogen suppresses production of receptor activator of nuclear factor-κB ligand (RANKL), the central molecule in osteoclast development, from bone marrow stromal/osteoblast precursor cells, T cells, and B cells [27]. Furthermore, estrogen increases production of the soluble RANKL decoy receptor osteoprotegerin (OPG) by osteoblast lineage cells [28]. Thus, by modulating RANKL and OPG levels, estrogen limits exposure of osteoclast lineage cells (which express RANK) to RANKL, thereby effectively regulating osteoclast development. Declining estrogen levels as occur in menopausal women, however, alter the relative RANKL/OPG ratio, leading to increased osteoclast development and activity. Additional estrogen-suppressible cytokines produced by osteoblasts and bone marrow mononuclear cells, including interleukin-1 (IL-1), IL-6, tumor necrosis factor-α (TNF-α), macrophage colony stimulating factor (M-CSF), and prostaglandins also appear to play central roles in mediating bone resorption [29–32]. In support of this role for estrogen, a recent study showed that in early postmenopausal women induced to undergo acute estrogen withdrawal, pharmacologic blockade of either IL-1 or TNF-α activity was able to partially blunt a rise in bone resorption markers [33].

In addition to influencing osteoclast development, estrogen both directly and indirectly promotes the apoptosis of osteoclast lineage cells and mature osteoclasts. In osteoclast lineage cells, estrogen induces direct apoptosis through a decrease in c-jun activity, thereby limiting activator protein-1 (AP-1)-dependent transcription [34, 35]. In addition, estrogen can induce osteoblastic cell production of transforming growth factor-β (TGF-β), thereby indirectly leading to osteoclast apoptosis [11]. The importance of direct estrogen effects on osteoclast apoptosis was recently demonstrated in mice in which the estrogen receptor had been selectively deleted in osteoclasts so that the pro-apoptotic effects of estrogen deficiency on osteoclasts were lost [36, 37].

More recently, it has been noted that increases in bone resorption markers [38] and loss of spine and hip BMD [39] in perimenopausal women correlated more closely with the rise in follicle-stimulated hormone (FSH) levels than with E2 levels. Whether FSH has direct effects on bone has remained unclear, however, with evidence both for and against direct FSH effects in bone provided from rodent studies [40–42]. To address this issue directly in humans, Drake et al. recently performed a direct interventional study in women well past the menopausal transition, in whom hormonal levels other than FSH would be stable and low, to test whether FSH suppression in such postmenopausal women reduced bone resorption marker levels [43]. To suppress FSH levels, the experimental group received a gonadotropin releasing hormone (GnRH) agonist, while endogenous estrogen levels were controlled by aromatase inhibitor treatment of all subjects. In GnRH-treated subjects, FSH levels dropped rapidly into the premenopausal range, where they remained throughout the 4-month study period; as expected, FSH levels remained elevated in control subjects. Despite having markedly different circulating FSH levels, however, bone resorption [as assessed by serum C-terminal telopeptide of type I collagen (CTX) and tartrate-resistant acid phosphatase isoform type 5b (TRAP5b) levels] was not different between the groups when assessed at the study endpoint. In fact, both the control and GnRH-treated subjects had slightly increased bone resorption, likely due to the concomitant suppression of endogenous estrogen by aromatase inhibitor therapy in both groups. Together, these findings demonstrate that suppression of serum FSH levels in postmenopausal women into the premenopausal range does not reduce bone resorption.

Like estrogen, testosterone has a primary effect on bone to limit resorption, although at least part of this effect likely derives from aromatization of testosterone to estrogen [44]. *In vitro*, testosterone can both stimulate osteoblast proliferation [45], albeit weakly, and limit osteoblast apoptosis [12]. Whereas testosterone likely plays a role in increasing bone formation (and perhaps periosteal apposition) in women, there is at present little data suggesting a role of testosterone in maintaining postmenopausal skeletal integrity.

SEX STEROIDS AND BONE LOSS IN MEN

Relative to postmenopausal women, elderly men on average lose one-half as much bone and sustain one-third as many fragility fractures [16]. Although men do not undergo a hormonal menopausal equivalent, substantial changes in biologically available sex steroid levels occur over the male life span primarily as a result of the greater

than twofold age-related increase in sex hormone binding globulin (SHBG) levels [46]. Whereas SHBG-bound circulating sex steroids have limited capacity to reach target tissues, free (1–3% of total) and albumin-associated (35–55% of total) sex steroids are biologically available. As a result of this rise in SHBG levels, bioavailable estrogen and testosterone levels decline an average of 47% and 64%, respectively, over the male life span, as demonstrated in a cross-sectional study of 346 men between the ages of 23 and 90 in Rochester, MN [46].

Although testosterone is the predominant sex steroid in men, evidence from both cross-sectional [47–52] and longitudinal [53] studies shows that male BMD at various skeletal sites is better correlated with circulating levels of bioavailable E2 than with testosterone. In a longitudinal study, young men (age 22–39 years) were compared with older men (age 60–90 years) over a 4-year interval to evaluate the effects of sex steroid levels on the final stages of skeletal maturation (the younger cohort) versus age-related bone loss (the older cohort) [53]. Whereas BMD in the distal forearm (which primarily reflects cortical bone changes) in the younger men increased by 0.42–0.43%/year, distal forearm BMD in the older men decreased by 0.49–0.66%/year. As shown in Table 43.1, both the increase in BMD seen in younger men and the decrease in BMD found in older men were more closely associated with bioavailable E2 levels than with testosterone levels. Perhaps most intriguingly, in older men, there appeared to be a threshold level of bioavailable E2 of approximately 40 pM (11 pg/mL) below which the rate of bone loss was most clearly associated with E2 levels. Interestingly, vBMD analysis showed this threshold effect to be more pronounced at cortical sites as compared to trabecular sites [4]. Above this level, however, there was no firm relationship between the rate of bone loss and bioavailable E2 levels. Similar findings by other investigators have been supportive of this threshold effect [54].

Table 43.1. Spearman Correlation Coefficients Relating Rates of Change in BMD at the Radius and Ulna to Serum Sex Steroid Levels among a Sample of Rochester, MN, Men Stratified by Age

Although suggestive, the associations described above do not provide direct evidence for a causal role of estrogen in maintenance of the aging male skeleton. To address the relative roles of both estrogen and testosterone in skeletal maintenance in elderly men, Falahati-Nini et al. [44] used pharmacologic suppression of endogenous estrogen and testosterone production (through treatment with both a GnRH agonist and an aromatase inhibitor) in elderly men. Physiologic estrogen (E) and testosterone (T) levels were maintained by the placement of topical estrogen and testosterone patches, and baseline markers of bone resorption and formation were obtained. Subjects were then randomized to one of four groups: group A (–T, –E) discontinued both patches; group B (–T, +E) discontinued only the testosterone patch; group C (+T, –E) discontinued only the estrogen patch; and group D (+T, +E) continued both patches. As such, this direct human interventional study allowed for changes in bone metabolism resulting from either estrogen or testosterone to be determined, since suppression of endogenous sex steroid production was maintained for the entire intervention period.

As seen in Fig. 43.4(A), the significant increases in bone resorption seen in group A (–T, –E) were completely prevented by treatment with both testosterone and estrogen (group D). Whereas estrogen alone was almost completely able to prevent the rise in bone resorption (group B), however, testosterone alone was much less potent (group C). By comparison [Fig. 43.4(B)], the marked decreases in bone formation seen with dual sex steroid deficiency in group A were completely prevented by continuation of estrogen and testosterone (group D). Interestingly, serum osteocalcin levels were only slightly diminished with either estrogen or testosterone alone, whereas levels of serum amino-terminal propeptide of type I collagen (PlNP) were sustained with estrogen (group B) but not testosterone. In summary, these results are consistent with a dominant role for estrogen in maintenance of skeletal integrity in aging men.

As noted above, bioavailable testosterone levels decrease to an even greater extent than bioavailable estrogen levels in aging men. Despite this decline, however, the role of testosterone in age-related bone loss in men is less clear than that of estrogen. As seen in Fig. 43.4, testosterone does have modest antiresorptive effects and also plays a role in mediating bone formation. As shown by Nair et al. [55], a statistically significant increase in BMD at the femoral neck was seen in elderly males provided low-dose testosterone replacement for 2 years. Interestingly, however, no increase in BMD was seen at any other site (anterior–posterior lumbar spine, total hip, or ultradistal radius) examined. In addition, whether the noted effects of testosterone replacement on BMD in this study were direct effects of testosterone, or were mediated through testosterone aromatization to estrogen, is unclear. Finally, testosterone likely also

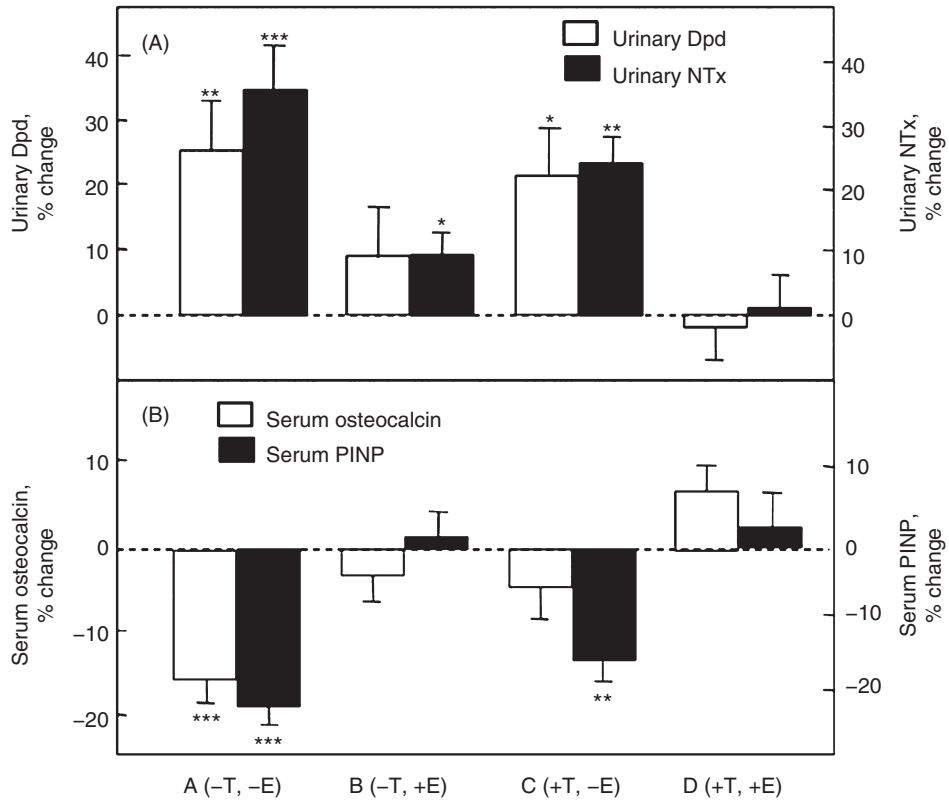

Fig. 43.4. Percent changes in (A) bone resorption markers (urinary deoxypyridinoline [Dpd] and N-telopeptide of type I collagen [NTX] and (B) bone formation markers (serum osteocalcin and N-terminal extension peptide of type I collagen [P1NP]) in a group of elderly men (mean age, 68 years) made acutely hypogonadal and treated with an aromatase inhibitor (group A), estrogen alone (group B), testosterone alone (group C), or both estrogen and testosterone (group D). Significance for change from baseline: *: $p < 0.05$; **: $p < 0.01$; ***: $p < 0.001$. plays a role in cortical appositional growth, although this has been most pronounced in studies of rodents [56] and may play a less important role in human biology.

OSTEOPOROSIS AND NON-SEX STEROID HORMONE CHANGES WITH AGING

Lastly, it is important to note that in addition to changes in sex steroid levels that occur with aging in both men and women, non-sex hormonal changes also occur. These include reductions in the production of growth factors important for osteoblast differentiation and function. Thus with aging, both the frequency and amplitude of growth hormone secretion is diminished [57], leading to decreased hepatic production of IGF-1 and IGF-2, an effect that may contribute to decreased bone formation with aging [58, 59]. Additionally, aging is associated with increased levels of the IGF inhibitory binding protein, IGFBP-2, which also correlates inversely with bone mass in the elderly [60]. Finally, it is likely that intrinsic changes occur in osteoblast and perhaps osteoclast lineage cells with aging [61]. These changes, which are likely independent of changes in sex steroids or other hormonal factors, are the focus of ongoing animal and human studies.

INTRODUCTION

Genetic factors have been found to play an important role in osteoporosis and fracture risk. Initial studies of monozygotic (identical) and dizygotic (nonidentical) twins and subsequently family studies demonstrated a high heritability, up to 60–80% of various measures of bone structure and a clear, albeit modest, heritability of fracture risk.

The demonstration of high heritability has led to a large body of studies aimed at identifying the genes responsible. The types of studies can be broadly divided into a candidate gene approach or genome-wide search strategy using either linkage or association studies. The candidate gene approach involves directly testing variation in genes known to be involved in bone biology for their role in osteoporosis and fracture risk. The **genome-wide search strategy** involves systematically screening all genes using DNA markers uniformly distributed throughout the entire genome. Localization is then progressively refined until a gene can be identified. **Association studies** are either population-based or case-control studies relating a polymorphism of a certain candidate gene to the desired phenotype. Association studies are also suitable for a genome-wide analysis where identified SNPs (single-nucleotide polymorphisms) are in linkage disequilibrium with the phenotype studied. **Linkage studies** relate the inheritance of genetic markers to the inheritance of phenotypes within families.

These studies have not always been very successful, for reasons related both to the complexity of the disease itself and methodological and statistical issues related to the types of studies. Osteoporosis is now widely accepted as being multifactorial with several genes involved, each having a small to moderate effect on various parameters affecting bone physiology and risk of fracture. Gene–gene interactions and gene–environment interactions potentially increase this complexity.

Linkage studies have been very successful in identifying rare monogenic diseases, and while they have been applied to complex diseases such as osteoporosis, they suffer from low statistical power when the gene effect is only modest and inherently are unable to determine the size of the genetic effect. In contrast, association studies are easier to perform, and the large numbers required for enough power to demonstrate a small effect may be easier to obtain; however, to date these studies in osteoporosis have often resulted in inconsistent results due to sample sizes that are too small, problems with population stratification, and variations in phenotype classification.

Nevertheless, the genetic studies performed over the past few decades have provided valuable insights into the

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

pathophysiology of osteoporosis. With the decreasing costs of genome-wide scanning, consortia have been able to pool much larger populations in genome-wide association studies for complex diseases that overcome some of the statistical problems that have plagued reproducibility from earlier studies in osteoporosis. The challenge facing the researcher is whether genetic information obtained can be utilized in a clinically relevant manner that will enhance either the prediction of fracture or response to treatment after readily measurable clinical and historical factors have been taken into account.

OSTEOPOROSIS AS A COMPLEX DISEASE

While bone mineral density (BMD) is one of the best predictors of fracture risk, there is no threshold of BMD that discriminates absolutely between those who will or will not have a clinical event. Hence, a nonosteoporotic BMD is no guarantee that fracture will not occur, only the risk is relatively low. Conversely, if BMD is in the osteoporotic range, then fractures are more likely, but still may not occur. It should be noted that up to 50% of women and 70% of men with a fracture do not have osteoporotic BMD [1]. This suggests that factors other than BMD play important role in the determination of fracture liability.

The remaining contributory factors are a combination of both familial and nonfamilial factors. Indeed, compelling evidence of genetic determination of fracture risk and BMD has accumulated over the past 30 years or so. Women whose mothers have experienced a hip fracture exhibit a twofold increase in risk of hip fracture compared with controls [2], but the penetrance is not complete. Although fracture risk segregates within families, the segregation does not follow the genetic laws seen in single-gene Mendelian disorders [3].

The involvement of multiple familial and nonfamilial factors suggests that osteoporosis is a complex disease. Like many other multifactorial diseases, osteoporosis is determined by environmental factors, by genetic susceptibility, and likely by the interaction between these factors. Genetic variations do not necessarily cause osteoporosis or fracture, but they can influence an individual's susceptibility to specific environmental factors and so modify the disease risk. The familial effect on fracture risk can be characterized by the heritability of fracture risk and its risk factors.

GENETICS OF BONE PHENOTYPES

The assessment of the genetic contribution to osteoporosis has largely been based on biometric methods (e.g., complex segregation analysis), family studies, and associations with candidate genes. At the population level, the key measure of the genetic influence on a trait is the index of heritability, which is defined as the extent to which genetic individual differences contribute to individual differences in the observed trait. Because the difference between individuals is often quantified in terms of variance, the index of heritability can be operationally interpreted as the proportion of phenotypic variance attributable to genetic factors.

Using the biometric approach, it has been shown consistently that the liability to fracture is partly determined by genetic factors. In a Finnish twin study, approximately 35% of the variance in the liability to fracture (in both males and females) was attributable to genetic factors [4]. In a recent family study, approximately 25% of the liability to one fracture type, i.e.. Colles' fracture of the wrist, was attributable to genetic factors [5]. Familial analysis within the Study of Osteoporotic Fracture [2] suggests that women whose mothers had had a hip fracture, had a twofold increase in the risk of hip fracture compared with controls. The risk of hip or other fractures was threefold higher with a paternal history of wrist fracture. In two small studies of osteoporotic women with vertebral or hip fractures, their daughters had bone density deficits intermediate between their mothers' and "expected" bone density at the site of their mothers' fracture, i.e., lumbar spine or proximal femur [6, 7]. Similar observations have been made in both elderly men and women [8].

Variation in BMD among individuals is also largely determined by genetic factors. It has been estimated from twin studies that 70% to 80% of variance of BMD measured at the lumbar spine and femoral neck is attributable to genetic factors [9–11]. The heritability of forearm BMD appears to be lower than that in either the femoral neck or lumbar spine [12, 13]. In these studies, there is evidence for pleiotropic effects, i.e., BMD in various skeletal sites being determined by both common and site-specific sets of genes [14, 15].

Change in BMD during adult life is the result of the net imbalance between bone formation and bone resorption. These are typically assessed by measurements (in blood or urinary excretion) of various products of osteoblast (bone formation) and osteoclasts (bone resorption) cell activity. Genetic factors have been shown to contribute significantly to the interindividual variance of bone formation markers (both osteocalcin and collagen C-terminal propeptide of type 1 collagen) in premenopausal twins [15–17].

Other markers of fracture risk have also been found to be heritable. For example, the genetic influence on different types of quantitative ultrasound (QUS) measurements, namely broadband ultrasound attenuation (BUA) and speed of sound (SOS), has been shown to be 0.53 to 0.82 [18]. BUA measurements have been reported to be more strongly correlated between mothers and their postmenopausal, rather than their premenopausal, daughters, i.e., the reverse of what has been reported for dual energy X-ray absorptiometry (DXA) measurements [19, 20]. These observations suggest that different genetic influences act on components of the bone phenotype as measured using

QUS and DXA. There are no data on heritability of SOS measures along cortical bone. Genetic correlations observed between transmission QUS and BMD measurements have been moderate, 0.32 to 0.59 [18]. Thus, genes that influence variation in BMD might, but not necessarily, influence variation in QUS, and vice versa. This is consistent with QUS measuring additional non-density characteristics of bone. In any case, a significant part of the variability of QUS and DXA BMD measurements appears unrelated, consistent with their assessment of some distinct bone phenotypic characteristics.

CANDIDATE GENE STUDIES

The recognition that fracture risk and various bone-related traits are largely determined by genetic factors has led to an intensive search for specific genes linked with either these traits or with fracture risk. Gene-search studies have been based on the two major approaches, namely, candidate gene and genome-wide studies [21]. The candidate gene approach has been used within the context of association studies, in which a specific DNA variant or variants are analyzed in cases and unrelated controls. This is a straightforward design that has been used extensively in the field of osteoporosis, but it also suffers from a number of shortcomings. The selection of appropriate controls can be a challenge, particularly for fracture that occurs mainly in later life. The arbitrary classification of BMD into a dichotomous variable (e.g., osteoporosis versus nonosteoporosis) does not exclude the possibility that the individual will develop "osteoporosis" in the future. Furthermore, any statistically significant association between a specific gene variant and fracture may not necessarily indicate a causative relationship, because such an association can have arisen from linkage disequilibrium and population stratification [22].

Based on this commonly used approach, several gene polymorphisms (including vitamin D receptor, collagen type Iα1, osteocalcin, IL-1 receptor antagonist, calcium-sensing receptor, α2HS glycoprotein, osteopontin, osteonectin, estrogen receptor α, interleukin-6, calcitonin receptor, collagen type Iα2, parathyroid hormone, and transforming growth factor α1 polymorphisms) have been proposed [23] (Table 44.1). However, the decade in which candidate gene association studies have blossomed has also been accompanied by increasing frustration with conflicting findings and a lack of independent replication, mainly due to a lack of statistical power [24] and to false positives [25].

GENOME-WIDE STUDIES

Instead of focusing on a biologically plausible candidate gene, genome-wide studies scan the entire genome to identify chromosomal regions harboring genes likely to influence a trait. There are two analytic strategies can be used in a genome-wide study: linkage analysis and association analysis. A genome-wide study, using either linkage or association analysis, is essentially is a hypothesis-free approach, because it makes no assumptions about the location and functional significance of associated loci or their products [26]. Genome-wide studies can examine the linkage or association between representative tagging-SNPs spreading throughout the genome and the susceptibility of diseases. As such, genome-wide studies can overcome weaknesses of the candidate gene design [27, 28] by providing a holistic picture of genes that are likely to contribute to the susceptibility of disease. However, genome-wide studies can have a major problem of multiplicity of hypothesis testing. Because genome-wide studies test hypotheses for hundreds of thousands of alleles, a statistically significant linkage or association is not necessarily a real phenomenon [27].

Genome-wide linkage studies aim at identifying anonymous markers that cosegregate in families with multiple affected members. Linkage analysis is based on the principle that alleles at loci close together will tend to be inherited jointly; therefore, if a marker allele and a locus for a specific trait are close together on the same chromosome they are unlikely to be separated by crossover during meiosis. A common metric of linkage is the log-of-the-odds (LOD) score, which measures the likelihood of linkage compared with no linkage. A linkage with a LOD score of greater than 3.6 is considered significant at the genome-wide level, while a LOD score greater than 2.2 is usually taken to indicate the presence of "suggestive linkage" [29].

Linkage analysis has been successfully used to map causative genes linked to BMD and fracture. Genome-wide linkage analysis has identified several regions that are linked to variation in BMD (Table 44.2). Furthermore, from linkage analysis of data from a family with osteoporosis-pseudoglioma syndrome (OPPG), a disorder characterized by severely low bone mass and eye abnormalities, investigators were able to localize the OPPG locus to chromosomal region 11q12-13 [30]. At the same time, a genome-wide linkage analysis of an extended family with 22 members, among whom 12 had very high bone mass (HBM), suggested that the HBM locus also located within the 30cM region of the same locus [31]. In follow-up studies using the positional candidate approach, both research groups found that a gene encoding the low-density lipoprotein receptor-related protein 5 (LRP5) was linked to both OPPG and high bone mass [32–34]. The finding that the LRP5 gene was linked to HBM was subsequently confirmed in a family study that included individuals with exceptionally high BMD but who were otherwise phenotypically normal [33]. This study showed that a missense mutation (G171V) was found in individuals with high BMD [34]. A recent family study further identified six novel mutations in the LRP5 gene among 13 confirmed polymorphisms that had been associated with different conditions characterized by

Table 44.1. Candidate Genes for Osteoporosis

Gene	Gene Name	Location	Reference
ARHGEF3	Rho guanine nucleotide exchange factor 3	3p14-p21	[91]
COL1A1	Collagen type I alpha 1	17q21.33	[92, 93]
CYP19A1	Cytochrome P450, family 19, subfamily A, polypeptide 1	15q21.1	[94]
DBP	Vitamin D binding protein	19q13.3	[95]
ESR1	Estrogen receptor 1	6q25.1	[96–98]
ESR2	Estrogen receptor 2	14q	[99]
FLNB	Filamin B, beta	3p14.3	[100]
FOXC2	Forkhead box C2	16q24.4	[101, 102]
ITGA1	Integrin, alpha 1	5q11.2	[48, 103]
LRP4	LDL receptor-related protein 4	11p11.2	[52]
LRP5	LDL receptor-related protein 5	11q13.4	[48, 104]
MHC	Major histocompatibility complex	6p21	[46, 52]
MTHFR	Methylenetetrahydrofolate reductase	1p36.3	[105]
PTH	Parathyroid hormone	11p15.3-p15.1	[106, 107]
RHOA	Ras homologue gene family, member A	3p21.3	[108]
SFRP1	Secreted frizzled-related protein 1	8p12-p11.1	[109]
SOST	Sclerosteosis	17q11.2	[48, 57, 110]
SPP1	Secreted phosphoprotein 1 (osteopontin)	4q21-q25	[48]
TNFSF11	Tumor necrosis factor ligand superfamily, member 11 (RANKL)	13q14	[48, 111]
TNFRSF11A	Tumor necrosis factor ligand superfamily, member 11a, NFκB activator (RANKL)	18q22.1	[48, 51]
TNFRSF11B	Tumor necrosis factor ligand superfamily, member 11b (OPG)	8q24	[48, 112]
VDR	Vitamin D receptor	12q13.11	[113–115]
WNT10B	Wingless-type MMTV integration site family, member 10B	12q13	[116]
ZBTB40	Zinc finger and BTB domain-containing protein 40	1p36	[48]

Table 44.2. Linkage Studies of the Quantitative Trait Loci (QTL) for BMD

Phenotype	Locus/Marker	LOD Score	Reference
Hip BMD	1p36 (D1S540)	3.51	[64]
Spinal BMD	2p23-24 (D2S149)	2.07	
Forearm BMD	2p21 (D2S2141, D2S1400, D2S405)	2.15	[117]
Distal forearm	13q34 (D12S788, D13S800)	1.67	
Hip BMD	6p21 (D6S2427)	2.93	[118]
Spinal BMD	12q24 (D12S395)	2.08	
Trochanteric BMD	21qter (D21S1446)	2.34	
Spinal BMD	3p21	2.1-2.7	[119]
Whole body BMD	1p36	2.4	
Spinal BMD	4q32 (D4S413)	2.12	[120]
	7p22 (D7S531)	2.28	
	12q24 (D12S1723)	2.17	
Wrist BMD	4q32 (D4S413)	2.53	
Spinal BMD	1q21-23 (D1S484)	3.11	[121]
	6p11-12 (D6S462)	1.94	
	11q12-13 (D11S987)	1.97	
	22q12-13 (D22S423)	2.13	
Hip BMD	5q33-35 (D5S422)	1.87	

increased BMD [35]. The conditions included endosteal hyperostosis, van Buchem disease, autosomal dominant osteosclerosis, and osteopetrosis type I. It is thus reasonable to state that the discovery of the LRP5 gene has opened up a new chapter of research in the genetics of osteoporosis.

Genome-wide association (GWA) studies examine hundreds of thousands of common SNPs (minor allele frequency greater than 5%) to identify chromosomal regions harboring genes likely to influence a trait. The basic idea is to test for differences in allelic frequency of anonymous genetic variants between cases and controls. In the presence of hundreds of thousands of tests, there is the real possibility of false positive findings. Just as with the evaluation of a diagnostic test, where one needs to know specificity, sensitivity, and positive predictive value (PPV), the reliability of a statistical association can also be evaluated by three analogous parameters: the observed *P*-value, the observed power (sensitivity) given an effect size, and the prior probability of a true association [36]. The *P*-value is equivalent to the false positive rate of a diagnostic test; it is the probability of observing the current data (or more extreme data) given that there is no true association. Power is the probability that a study will identify a true association if it exists. Prior probability is a subjective probability of a true association. Based on these three parameters and by using the Bayesian approach, it is possible to determine the probability of no true association given a statistically significant finding or the false positive report probability (FPRP) [37]. Of the three parameters for evaluating FPRP, the prior probability is the most difficult parameter to put a weight on. This probability is dependent on the number of gene variants that affect fracture susceptibility, which is unknown. Indeed, we do not know how many genes are involved in the regulation of, or are relevant to, the underlying susceptibility to osteoporotic fracture. However, we do know that in the human genome, there are about 3 billion base pairs [38], and that on average, more than 90% of the differences between any two individuals is due to common variants where both alleles are present in at least 1% of the population [39]. Therefore, it has been hypothesized that the susceptibility to common diseases such as osteoporosis is caused by a few common genetic variants with low effect size (i.e., the "common gene–common variant" hypothesis) [40]. Under this hypothesis, it has been estimated that the number of genetic variants that are associated with a common disease is about 100 or fewer [41]. It has also been estimated that the number of common variants in the human population is about 10 million [42]. Therefore, it may be reasonable to assume that the probability that a randomly selected common variant is associated with the risk of fracture is 1/100,000 or 0.000001. It has thus been suggested that a claim of association from a GWA study can be made if *P*-value is less than 5×10^{-5} [43] or 5×10^{-8} [44].

The earliest GWA study in osteoporosis examined the association between 71K genetic variants and BMD measured at different skeleton sites, and found evidence of association for 40 SNPs. Although the study was then considered to be underpowered, several SNPs identified in this study were located in potential osteoporosis-associated genes, such as *MTHFR*, *ESR1*, *LRP5*, *VDR*, and *COL1A1* genes [45]. Another GWA study screened 300K variants in an Icelandic population, and found that variants in the *ZBTB40*, *ESR1*, *OPG*, *RANKL* genes, and those in a novel region 6p21 were significantly associated with BMD at the genome-wide threshold ($P < 5 \times 10^{-8}$) [46]. This study also suggested some loci associated with fracture risk, including variants in the 1p36, 2p16, *OPG*, *MHC*, *LRP4*, and *RANK*. In the meantime, a GWA study in U.K. and Rotterdam cohorts found that variants in the *TNFRSF11B* and *LRP5* genes were associated with BMD, whereas the *LRP5* gene was also associated with fracture risk [47].

Two meta-analyses of GWA studies showed that variants in the *ZBTB40*, *ESR1*, *LRP4*, *LRP5*, *TNFSF11*, *SOST*, and *TNFRSF11A* genes were associated with BMD [48], and that variants in the *LRP5*, *SOST*, and *TNFSF11A* were associated with fracture risk [48]. Overall, results from GWA studies and meta-analyses indicate that genes involved in the receptor activator of nuclear factor-κB–RANK ligand– osteoprotegerin (RANK–RANKL–OPG) pathway (*TNFRSF11B*, *TNFRSF11A*, and *TNFSF11* genes), the Wnt-β-catenin pathway (*LRP5*, *LRP4*, and *SOST* genes), the estrogen endocrine pathway (*ESR1* gene), and the 1p36 region (*ZBTB40* gene) are those strongly associated with osteoporosis (Table 44.3).

The RANK–RANKL–OPG pathway includes the *TNFRSF11A* and *TNFSF11* genes encoding the RANK and RANKL, respectively. The genes are members of the tumor necrosis factor (TNF) superfamily. Binding of the RANKL to RANK stimulates the formation and differentiation of osteoclasts, which in turn regulates bone resorption [49]. However, OPG, which is an inhibitor of this pathway by binding to RANKL through the TNF-receptor, may prevent the interaction between RANKL and RANK. Genetic variants within the *TNFRSF11A* gene [50] and *TNFRSF11* [50] and *OPG* [50, 51] have been found to be associated with BMD and fracture in both candidate gene association studies and GWA studies [46, 52].

The Wnt-β-catenin signaling pathway contributes to the process of bone formation by regulating the differentiation and proliferation of osteoblasts, and bone mineralization. Expression of the *LRP5* gene, which is an element of this pathway, transfers signal into the nucleus for activating the bone formation. The *LRP5* gene has been identified as a candidate gene for BMD [53] and fracture risk [47, 54]. Although several polymorphisms in the *LRP5* gene have been studied, variants in exon 9 (V776M) and exon 18 (A1330V) are the two most widely investigated [55]. An inhibitor of the Wnt-pathway, SOST, is also a candidate gene for osteoporosis. Expression of *SOST* has been found to inhibit bone formation by preventing the binding of Wnt to the LRP5 [56]. Polymorphisms of the *SOST* gene have been found to be associated with BMD variation in both a candidate gene study [57] and a GWA study [52].

Table 44.3. Genes Identified From Genome-Wide Association Studies

Gene	Gene name	Location and SNP	Reference
ADAMTS18	ADAM metallopeptidase with thrombospondin motif 18	16q23; Rs16945612	[122]
ALDH7A1	Aldehyde dehydrogenase 7 family member A1	5q31; Rs13182402	[123]
CTNNB1	Catenin (cadherin-associated protein), beta 1	3p22; Rs87939	[66]
CRHR1	Corticotropin releasing hormone receptor 1	17q12-q22; Rs9303521	[66]
DCDC5	Doublecortin domain containing 5	11p14; Rs16921914	[66]
FAM3C	Family with sequence similarity 3 member C	7q31; Rs7776725	[124]
FLJ42280	Putative uncharacterized protein FLJ42280	7q21; Rs4729260 Rs7781370	[66]
GPR177	G-protein coupled receptor 177	1p31; Rs1430742 Rs2566755	[66]
IL21R	Interleukin 21 receptor	16p11; Rs8057551 Rs8061992 Rs7199138	[125]
JAG1	Protein jagged-1	22p11-p12; Rs2273061	[126]
MARK3	Microtubule affinity-regulating kinase 3	14q32; Rs2010281	[46,66]
MEF2C	MADS box transcription enhancer factor 2C	5q14; Rs1366594	[66]
MHC	Major histocompatibility complex	6p21; Rs3130340	[46]
OSBPL1A	Oxysterol binding protein-like 1A	18q11; Rs7227401	[127]
PLCL1	Phospholipase C-like 1	2q33; Rs7595412	[128]
RAP1A	RAP1A, member of RAS oncogene family	1p13; Rs494453	[127]
RTP3	Receptor (chemosensory) transporting protein 3	3p21; Rs7430431	[129]
SFRP4	Secreted frizzled-related protein 4	7p14; Rs1721400	[124]
SOX6	SRY-box 6 gene	11p15; Rs297325, Rs4756846	[130]
SP7	Transcription factor 7	12q13; Rs10876432	[52]
STARD3NL	STARD3 N-terminal like	7p14-p13; Rs1524058	[66]
TBC1D8	TBC1 domain family, member 8	2q11; Rs2278729	[127]
TGFBR3	TGF-beta receptor type 3	1p33-p32; Rs7524102	[122]

The estrogen pathway. The estrogen endocrine pathway has long been known to play a key role in the formation and maintenance of bone mass [58]. The *ESR1* gene has been shown to be a candidate gene for the genetic effect on BMD [59] and fracture risk [59–61] in several populations. Moreover, polymorphisms of the *ESR1* gene have been found to be associated with bone loss [62]. Although the mechanism of effect of these genetic variants on BMD is unclear, intronic variants in this gene are thought to exert an effect on the efficiency of gene transcription [63].

The 1p36 region. The chromosomal region 1p36 has been implicated in the regulation of bone mass by linkage analysis [64, 65]. The *ZBTB40* gene situated in this region has been identified as a candidate gene for BMD variation in some recent GWA studies [46, 52] and in a meta-analysis [66]. However, the function of the *ZBTB40* in bone homeostasis was unknown.

CLINICAL APPLICATION: INDIVIDUALIZED PROGNOSIS

A major priority in osteoporosis research at present is to develop prognostic models for identifying individuals who have a high risk of fracture. Using established clinical risk factors, a number of prognostic models have recently been developed and implemented [67–69]. The predictive accuracy of these models has been less than perfect, with the area under the receiver operating characteristic curve ranging between 0.70 and 0.80 [68, 69]. Most prognostic models have low sensitivity and high specificity. Thus, there is room for further improvement of prognostic accuracy of the current models by incorporating genetic markers.

There are some major advantages for using genetic markers as a prognostic factor for fracture risk. First, since an individual's genotype is time invariant, it is easier to estimate its effect size and to incorporate its information in a prognostic model. Second, as the association between a genetic variant and fracture risk appears to be independent of clinical risk factors, the use of such a genetic marker can potentially improve the predictive value. Third, although there is no "genetic" therapy for individuals at high risk of fracture, the use of genetic markers could help segregate individuals at high risk from those at low risk of fracture, and help manage the burden of osteoporosis in the community.

It is clear from the above review that fracture risk is determined by several genes. This is perhaps not surprising given the number of complex phenotypes and the number of regulatory proteins involved in calcium, collagen, bone metabolism, bone strength and bone size. Two common features of these genes are that their allelic frequency in the general population is highly variable (ranging from 1% to 61%), and the effect size is very

small, with relative risk ranging between 1.05 and 1.5. In the presence of such small effect size, it can be anticipated that the contribution of any single gene or SNP to fracture prognosis would be minimal. Even for a gene conferring a relative risk of 3, the area under the curve (AUC) attributable to this gene is barely 0.51 (in the absence of clinical risk factors). Even with five genes, each conferring a relative risk of between 2 and 3, the AUC is still 0.60, which is not useful for predicting fracture. This finding suggests that the contribution of any single gene to fracture prognosis, no matter how large the effect size is likely limited and would not be useful particularly in the clinical setting.

However, the integration of genetic profiling, either in the form of a genetic risk score or individual genes, into the current prognostic models could significantly improve the predictive accuracy of fracture risk for an individual. A recent simulation study suggested that a profile of up to 25 genes (each with relative risk of 1.1 to 1.35 and gene frequency ranging from 0.25 to 0.60) in the presence of clinical risk factors—with or without BMD—is required to achieve an AUC of 0.80, indicative of clinical usefulness [70]. Until now, very few genes have been implicated in the determination of fracture risk. A recent meta-analysis of 150 SNPs found that only five SNPs from four genes were consistently associated with fracture risk with relative risk (RR) ranging from 1.1 to 1.4 [48]. Thus, given the ongoing progress of finding new genes of osteoporosis, the prospect of using genetic profile in the prognosis of fracture is a real possibility.

The aim of individualized prognosis is to provide an accurate and reliable prognosis of fracture for an individual, and to help improve the management of the individual's predisposition to fracture. At present, individuals with low bone mineral density (i.e., T-scores being less than –2.5) or with a history of prior low trauma fracture are recommended for therapeutic intervention [71, 72]. This recommendation is logical and appropriate, since these individuals have higher risk of fracture [73, 74], and treatment can reduce this risk [75–77]. However, because fracture is a multifactorial event, there is more than one way that an individual can attain the risk conferred by either low BMD or a prior fracture [78]. Moreover, each individual is a unique case, because there is no "average individual" in the population. The uniqueness of an individual can be defined in terms of the individual's environmental and genetic profile. Thus, the knowledge of genetics, in combination with clinical risk factors, can shift our current risk stratification (i.e., "one-size-fits-all") approaches to a more individualized evaluation and treatment of osteoporosis.

CLINICAL APPLICATION: PHARMACOGENETICS

Research into the genetic background of osteoporosis and identification of osteoporosis-related genes can advance our understanding of pathophysiologic mechanisms of fracture. However, while the magnitude of association between genetic variants and osteoporosis is equivalent to what has been found for some clinical risk factors, there is currently no additional advice for people who carry a high-risk gene profile. However, there is an opportunity for using genetic information for therapeutic treatments of osteoporosis. Pharmacogenetics aims to select the optimal strategy for patients because different persons may respond differently to the same therapy [79].

There is evidence that genetic variants in the vitamin D receptor gene (*VDR*) influence the intestinal absorption of calcium leading an effect on bone mass [80, 81]. In a longitudinal study of calcium supplementation in the elderly, participants with *VDR Bsm*I variant carrying the BB genotype had a higher proportion of bone loss at the lumbar spine than those with Bb and bb genotypes [82, 83]. Women with the BB genotype were also found to have reduced efficiency of calcium absorption on a regimen of low-calcium intake [84]. These results could imply that people with BB genotype should be considered for a calcium-rich diet.

Bisphosphonates are often prescribed to osteoporotic patients to decrease bone resorption for fracture prevention [85]. However, there is a high variability among people's responses to this treatment with about 15% of people on the treatment demonstrating continuing bone loss [86]. Osteoporotic women carrying bb genotype in the *VDR Bsm*I showed more bone gain while on treatment with alendronate than those with BB genotype [87]. One of the extremely rare side effects of longer term bisphosphonate treatment is osteonecrosis of the jaw. Interestingly, results from a GWA study demonstrated that people with a genetic variant in the cytochrome P450-2C gene (*CYP2C8*) have a remarkable 12-fold increase in the disorder [88].

CONCLUSION

It is well documented that genetic factors play an important role in the regulation of BMD variation and fracture risk. While it is clear that fracture risk is determined by multiple genes, it is not known how many genes are involved. The mode of inheritance is also unknown. In fact, with current methodology, it is unlikely that we will completely understand the causes of fracture, and why some individuals fracture and others do not. However, it is possible to find risk factors that account for a substantial number of cases and that are amenable to intervention. Newly identified genetic variants in combination with clinical risk factors may help improve the accuracy of fracture prognosis for an individual, segregate individuals at high risk of fracture from those with lower risk, and hence lead to better management of the burden of osteoporosis in the general community.

With a rapid improvement in genotyping technology, the next generation of GWA studies will be adding more

variants at a low frequency to cover as many SNPs as possible. This will not only increases the chance of detecting true associations, but also decreases the chance of false-positive findings [89]. Moreover, there is an emerging interest in studying RNA splicing in which synonymous variants could affect regulatory elements such as translational enhancers or RNA stability [90]. These molecular approaches could potentially have significant impact on the future direction of drug discovery and development, and open the possibility of personalized regimens for fracture risk prevention.

INTRODUCTION

Close to 75% of hip and non-hip fractures occur among seniors age 65 and older [1]. Notably, the primary risk factor for a hip fracture is a fall, and over 90% of all fractures occur after a fall [2]. Thus, the key to understanding and preventing fractures at a later age is based on their close relationship with muscle weakness [3] and falling [4, 5]. In fact, antiresorptive treatment alone may not reduce fractures among individuals 80 years and older in the presence of nonskeletal risk factors for fractures despite an improvement in bone metabolism [6]. This chapter will review the epidemiology of falls, and their importance in regard to fracture risk. Finally, fall prevention strategies and how these translate into fracture reduction are evaluated based on data from randomized controlled trials.

EPIDEMIOLOGY OF FALLS AND COST OF FALLS

Thirty percent of those 65 years or older, and 40–50% of those 80 years or older, report having had a fall over the past year [7, 8]. Serious injuries occur with 10–15% of falls, resulting in fractures in 5% and hip fracture in 1–2% [4]. As an independent determinant of functional decline [9], falls lead to 40% of all nursing home admissions [10]. The primary risk factor for a hip fracture is a fall, and over 90% of all fractures occur after a fall [3]. Recurrent fallers may have close to a fourfold increased odds of sustaining a fall-related fracture compared to individuals with a single fall [11]. As the number of seniors aged 65 and older is predicted to increase from 25% to 40% by 2030 [12–16], the number of fall-related fractures will increase substantially. Notably, even today 75% of fractures occur among seniors age 65 and older [1], and by 2050 the worldwide incidence in hip fractures is expected to increase by 240% among women and 310% among men [17]. Because of the increasing proportion of older individuals, annual costs from all fall-related injuries in the U.S. in people 65 years or older were projected to increase from $20.3 billion in 1994 to $32.4 billion in 2020, including medical, rehabilitation, hospital costs, and the costs of morbidity and mortality [18]. Thus, therapeutic interventions that are effective in fall prevention are urgently needed.

FALL DEFINITION AND INCLUSION OF FALL RISK IN FRACTURE RISK PREDICTION

Buchner and colleagues created a useful fall definition for the common data base of the FICSIT (Frailty and Injuries: Cooperative Studies of Intervention Techniques)

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

trials [19]. Falls were defined as "unintentionally coming to rest on the ground, floor, or other lower level." Coming to rest against furniture or a wall was not counted as a fall [19]. A challenge for their assessment is that falls tend to be forgotten if not associated with significant injury [20], requiring short periods of follow-up. Thus, high-quality fall assessment in older persons requires a prospective ascertainment of falls and their circumstances, ideally in short periods of time periods (less than 3 months) [20].

Fall reports may be performed by postcards, phone calls, or diary/calendar, although the usefulness and comprehensiveness of different ascertainment methods have not been compared directly. Notably, fall assessment has not been standardized across randomized controlled trials or large epidemiologic data sets [21], which prevented falls from being included in the WHO FRAX tool (http://www.shef.ac.uk/FRAX/) that estimates the probability of a major osteoporotic fracture in the next 10 years [21]. Based on one Australian cohort study (Dubbo study), the Garvan nomogram has been developed as an alternative fracture prediction tool that includes falling as a risk factor of fracture (www.fracturerisk calculator.com). In a comparative assessment, however, the predictive accuracy of the two tools showed similar performance in postmenopausal women and a possible advantage of the Garvan nomogram over FRAX among men [22, 23]. One explanation for a similar predictive accuracy between FRAX and the Garvan nomogram may be the relatively long time interval of fall assessment in the Garvan nomogram (fall recall in the previous 12 months), which may lead to the underreporting of falls not associated with significant injury [20].

FALL MECHANICS AND RISK OF FRACTURE

Mechanistically, the circumstances [2] and the direction [24] of a fall determine the type of fracture, whereas bone density and factors that attenuate a fall, such as better strength or better padding, critically determine whether a fracture will take place when the faller lands on a certain bone [25]. Moreover, falling may affect bone density through increased immobility from self-restriction of activities [26]. It is well known that falls may lead to psychological trauma known as fear of falling [27]. After their first fall, about 30% of individuals develop a fear of falling [26], which results in self-restriction of activities and decreased quality of life [26]. Figure 45.1 illustrates the fall–fracture construct that describes the complexity of osteoporosis prevention introduced by nonskeletal risk factors for fractures among older individuals.

In support of the a concept that falling is a key determinant of fracture risk, antiresorptive treatment alone may not reduce fractures among individuals 80 years and older in the presence of nonskeletal risk factors for fractures, despite an improvement in bone metabolism [6].

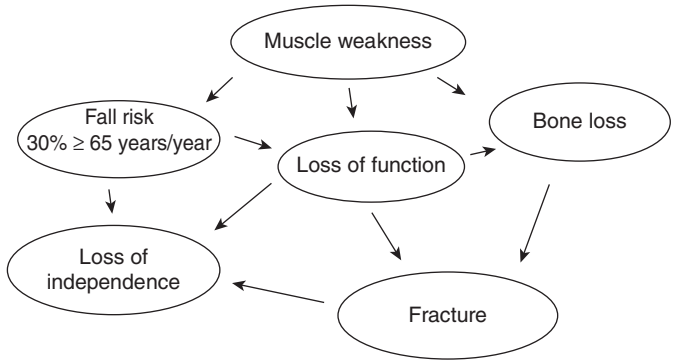

Fig. 45.1. Nonskeletal fall–fracture construct.

Further, consistent with the understanding that factors unrelated to bone are at play in fracture epidemiology, the circumstances of different fractures are strikingly different. Hip fractures tend to occur in less active individuals who fall indoors from a standing height with little forward momentum, and they tend to fall sideways or straight down on their hip [25]. On the other hand, other nonvertebral fractures, such as distal forearm or humerus fractures tend to occur among more active older individuals who are more likely to be outdoors and have a greater forward momentum when they fall [28].

Supporting the notion of bone not to be seen in isolation, fracture risk due to falling is increased among individuals with osteoarthritis of the weight-bearing joints despite having increased bone density compared to controls [29]. One prospective study found that prevalent knee pain due to osteoarthritis increased the risk of falling by 26% and the risk of hip fracture twofold [30]. A recent study applied a biomechanical risk measure, the factor-of-risk (ratio of force on the hip in a fall to femoral strength), for the prediction of hip fracture risk [31]; a 1 standard deviation increase in peak factor-of-risk was associated with a 1.88-fold increased risk of hip fracture in men and a 1.23-fold increased risk of hip fracture in women. Notably, examining the components of factor-of-risk, fall force, and soft tissue thickness were predictive of hip fracture risk independent of femoral strength estimated from bone mineral density (BMD) [31].

RISK FACTORS FOR FALLS

Falls are a hallmark of age and becoming frail, and falls are often heralded by the onset of gait instability, visual impairment or its correction by multifocal glasses, drug treatment with antidepressants, anticonvulsants/barbiturates, or benzodiazepines, weakness, cognitive impairment, vitamin D deficiency, poor mental health, home hazards, or often a combination of several risk factors [32, 33]. Some studies indicate that falls due to snow and ice may play an important role in seasonality of fractures [34, 35]. One cause of the increased fracture

risk in winter compared to summer may be that older people are more likely to slip and fall during periods of snow and ice [36]. On the other hand, hip fractures, which mostly occur indoors [37], may be less affected by snow and ice, with a smaller seasonal swing compared to distal forearm, humerus, and ankle fractures [38].

The seemingly inseparable relationship of falls to worsening health status and the complexity of factors involved in falling has led to pessimism on the part of physicians when faced with falling, especially recurrent falling. However, there is a growing body of literature that should encourage the standardized assessment of falls and application of fall prevention strategies for fracture prevention.

FALL PREVENTION STRATEGIES

Fall prevention by risk factor reduction has been tested in a number of approaches. Multifactorial approaches, such as medical and occupational-therapy assessment or adjustment in medications, behavioral instructions, and exercise programs, as demonstrated in the PROFET-trial (Prevention of Falls in the Elderly Trial) [39] and FICSIT-trials [40]. Multifactorial approaches may be especially useful in high-risk populations for falls, such as older individuals in care institutions [41].

Many studies demonstrate that simple *weight-bearing exercise programs* improve gait speed, muscle strength, and balance in community-dwelling and frail seniors, which translates into fall reduction by 25% to 50% [41–43]. As falls are the primary risk factor for fractures, the rationale is that these interventions should also protect against fractures, although this needs confirmation in a large clinical study.

Significant limitations of exercise programs are their cost and high implementation time. To overcome this barrier, exercise as a strategy of fall prevention may be applied at a smaller expense when the program is instructed but unsupervised. Such a home exercise program reduced falls in a randomized trial by Campbell and colleagues among community dwelling elderly women age 80 and older [44]. Consistently, a simple unsupervised exercise home program, taught during acute care after hip fracture repair, reduced falls significantly by 25% over a 12-month follow-up among senior hip fracture patients with a mean age of 84 years [45]. Although not powered for a fracture end point, there was a suggestion that the unsupervised home exercise program contributed to reduction in repeat fractures among acute hip fracture patients (relative fracture rate difference was –56% for the exercise home program versus a control; 95% confidence interval; –82%, +9%; p-value = 0.08) [45].

As a precaution of exercise programs in frail seniors with poor balance, increased mobility may lead to an increased opportunity to fall and fracture. Therefore, exercise programs should be supervised and supported by strength and balance training.

Tai chi has been successful in reducing falls among healthy older individuals [42, 46], and physically inactive community-dwelling older individuals [47], while frail older individuals [48] and fallers [46] may not benefit as much. Furthermore, tai chi may not improve bone density [49], and fracture prevention has not been explored as an end point with tai chi intervention programs.

As an extension of exercise, programs that support dual tasking may be of great value for fall prevention. Earlier studies suggested that fall risk is increased in seniors unable to walk while talking ("stop walking when talking" [50, 51]). Thus, dual tasking assessments may best indentify those at the greatest risk of falling, and programs that improve dual tasking may be useful in fall prevention at higher age. This concept was tested in a recently published trial that showed that a music-based multitask exercise program improved gait and balance and reduced fall risk significantly by 39% in community-dwelling seniors [43].

FALL PREVENTION STRATEGIES WITH EVIDENCE FOR FRACTURE REDUCTION

Two interventions among older individuals resulted in both fall and fracture reduction. One is ***cataract surgery*** with limited evidence from one trial, in which 306 women aged over 70, with cataracts, were randomized to expedited (approximately 4 weeks) or routine (12-month wait) surgery. Over a 12-month follow-up, the rate of falling was reduced by 34% in the expedited group (rate ratio 0.66, 95% confidence interval 0.45 to 0.96) accompanied by a significantly lower number of people with a new fracture (p = 0.04) [52].

With evidence from several double-blind randomized controlled trials (RCTs) (12 RCTs for fractures and 8 RCTs for falls) summarized in two 2009 meta-analyses, supplementation with ***vitamin D*** should reduce the risk of falls [53] and nonvertebral fractures, including those at the hip [54], by about 20%. Notably, however, for both end points, this benefit was dose dependent and only observed at an adherence-adjusted dose greater than 480 IU per day for fractures [54], and a treatment dose of at least 700 IU per day for falls [53].

Muscle weakness is an important risk factor for falls and is a prominent feature of the clinical syndrome of vitamin D deficiency [55]. Thus, muscle weakness due to vitamin D deficiency may plausibly mediate fracture risk through an increased susceptibility to falls. The vitamin D receptor (VDR) is expressed in human muscle tissue as suggested in several [56–59] but not all [60] studies. Vitamin D bound to its nuclear receptor in muscle tissue may lead to *de novo* protein synthesis [61, 62], followed by a relative increase in the diameter and number of fast type II muscle fibers [62]. Notably, fast type II muscle fibers decline with age relative to slow type I muscle fibers, resulting in an increased propensity to fall [63].

In 2010, the Institute of Medicine (IOM) did a thorough review on the effect of vitamin D on fall prevention [64]. Their synopsis was that the evidence of vitamin D on fall prevention is inconsistent, which is in contrast to the 2011 assessment of the Agency for Healthcare Research and Quality (AHRQ) for the U.S. Preventive Services Task Force [65], the 2010 American Geriatric Society/British Geriatric Society Clinical Practice Guideline [66], and the 2010 assessment by the IOF [67], all three of which reviewed the same evidence and identified vitamin D as an effective intervention to prevent falling in older adults. Notably, the main inconsistency raised by the IOM is based on four studies that may not be considered reliable indicators of true treatment efficacy, as those studies either used low dose vitamin D [68], had less than 50% adherence [69], had a low-quality fall assessment [70] or used one large bolus dose of vitamin D among seniors in unstable health [71]. Further, including these four studies in a pooled analysis of a total of 12 blinded and open-design trial evaluated by the IOM, there was a significant benefit overall (OR = 0.89; 95% CI 0.80–0.99), most pronounced in 6 of 12 studies that fulfilled the criteria for a high-quality fall ascertainment (OR = 0.79; 0.65–0.96) [64]. As falling is a challenging end point to assess, as discussed above [20], the latter analysis by the IOM restricted to the six trials with high-quality fall assessment may best reflect true treatment efficacy with a 21% fall reduction [64], confirming the earlier peer-reviewed meta-analysis that indentified eight double-blind RCTs with a high-quality fall assessment [53, 72].

Finally, it is important to note that vitamin D may address several components of the fall–fracture construct, including strength [73], balance [74], lower extremity function [75, 76], falling [77, 78], bone density [79, 80], the risk of hip and nonvertebral fractures [81], and the risk of nursing home admission [82]. In a most recent trial that compared 2,000 IU vitamin D per day with the current standard of care of 800 IU vitamin D per day in a double-blind RCT of 173 acute hip fracture patients, the higher dose of vitamin D did not reduce the rate of falls better than the 800-IU dose of vitamin D [45]. However, the higher dose compared to 800 IU vitamin D reduced the rate of hospital re-admission significantly by 39%, which was driven by a significant 60% reduction of fall-related injuries, primarily re-fracture [45].

CONCLUSION

Fall risk reduction is a significant component of fracture prevention at older age, and the public health impact of falls is significant. Falls can be reduced by a number of interventions with vitamin D offering efficacy established in several randomized controlled trials extending to fracture reduction in some of the same trials. In order to more effectively study falls and the fall–fracture risk profile from different interventions and cohort studies, fall definition and ascertainment need to be standardized.

Mechanical Factors Regulating Bone Cell Response 396
Mechanically Responsive Bone Cells 397
Transducing Mechanical Signals into Cellular Response 398
Translating Mechanical Signals to the Clinic 398
Summary 400
References 400

Osteopenia, a condition of diminished bone mass, becomes osteoporosis when mechanical demands exceed the ability of the skeletal structure to support them. Consequences of bone loss are exacerbated by an age-related decrease in muscle strength [1] and postural stability [2], markedly increasing the risk of falls, fracture and—ultimately—mortality [3]. Mechanical signals generated by exercise can mitigate bone loss as well as help preserve the musculoskeletal "system." The physical and/or biologic basis of how mechanical signals are transformed into anabolic agents for bone and other tissues is called mechanotransduction and may represent the foundation for a nondrug approach to treat osteoporosis [4].

Bone quantity and quality is enhanced by exercise and compromised by inactivity, age, and disuse [5]. Cross-sectional studies illustrate the sensitivity of bone morphology to physical extremes. Astronauts subject to microgravity lose up to 2% of hip bone density each month [6], while professional tennis players possess 35% more bone in the dominant arm as compared to the arm that simply throws the ball into the air [7]. A broader benefit can be seen in professional athletes involved in a variety of demanding activities, including soccer players, weight lifters, speed skaters, and gymnasts [8, 9].

Several prospectively designed trials emphasize that functional loading result in increased bone mass. Intense exercise in young army recruits [10] stimulated large increases in bone mineral density (BMD), while a 10-month, high-impact strength building regimen in children significantly increased femoral neck BMD [11]. A number of longitudinal exercise studies, however, have reported only modest increases in bone mass [12]. For example, a 1-year high-resistance strength training study in young women significantly increased muscle strength but failed to influence bone mass [13]. And even if the goal of exercise is to slow the loss of bone in the elderly, there is increasing evidence that bone tissue is less responsive to mechanical stimuli as we age [14]. Before exercise in general, and mechanical signals in particular, can be effectively used to prevent the degradation of the musculoskeletal system with age, we must improve our understanding of both the mechanical milieu generated by exercise and the complex cellular machinery that perceive and respond to these key regulatory signals [15].

MECHANICAL FACTORS REGULATING BONE CELL RESPONSE

Skeletal loads and bending moments resolve into strain in the bone tissue, reaching up to 0.3% (3,000 microstrain) during strenuous activity, a level of matrix deformation common across a range of species [16]. The strain levels actually "experienced" by bone cells *in vivo* is unclear, but may be as much as 10 times that experienced by the matrix [17]. Bone cells also experience interstitial fluid flow dynamic pressure changes during mechanical loading [18]. Furthermore, functional loading also induces pressure in the intramedullary cavity [19], shear forces through canaliculi [20], and dynamic electric fields as interstitial fluid flows past charged bone crystals [21]. As

such, the complex loading environment of the skeleton generates a diverse range of mechanical signals that are ultimately inseparable [22], but each of these biophysical factors may differentially target tissue, cell, and molecular activity.

Animal models demonstrate that bone remodeling is sensitive to changes in strain magnitude [23], the number of loading cycles [24], the distribution of the loading [25], and the rate of strain [26]. Importantly, the load signal must be dynamic (time varying), as static loads are ignored by the skeleton [27], while the anabolic potential increases when rest periods are inserted between the mechanical events [28]. Even extremely low-magnitude bone strains, three orders of magnitude below peak strains generated during strenuous activity, when induced at high frequencies similar to the spectral content of muscle contractibility [29], are anabolic to bone tissue [30], enhancing not only bone mass but bone quality and strength (Fig. 46.1). Together, these findings emphasize that the "key ingredient" to an osteogenic exercise regimen cannot simply be distilled to "bigger is better."

Physiologic levels of strain reduce osteocyte apoptosis, suggesting matrix deformation is critical to the survival of these cells [31, 32]. Too much strain, though, can cause matrix microdamage and exacerbate death of adjacent cells [33]. Factors other than matrix strain also cause an adaptive cellular response; e.g., acceleration, achieved independently of direct loading, can be anabolic to bone [34], suggesting that cells may act as "accelerometers" that respond to dynamic changes in force [35], emphasizing that *by-products* of the strain signal, such as shear stress or strain-generated potentials, may be critical to regulating the biology of the adaptive response. But *how* do the cells sense these mechanical signals?

MECHANICALLY RESPONSIVE BONE CELLS

The sensitivity of bone cells to mechanical signals, including stromal cells, osteoblasts, and osteocytes has been well documented [36], but it is difficult to designate a critically responsive cell. While the osteoblast is critical for the adaptive response, the osteocyte, representing 95% of adult skeletal cells, may prove key to bone tissue plasticity [37]. The antenna-like three-dimensional morphology of this osteocyte syncytium, interconnected by regulated gap-junctional connexins [38], are ideally configured to perceive and even amplify biophysical stimuli [20]. In particular, the removal of load is tied to osteocyte activity; loading regulates the release of sclerostin from osteocytes, an osteocyte product involved in Wnt signaling [39]. The osteoclastic bone resorption accompanying hind limb unloading in mice is ablated when osteocytes are absent [40], as the unloaded osteocytes release receptor activator of nuclear factor-κB ligand (RANKL) [41].

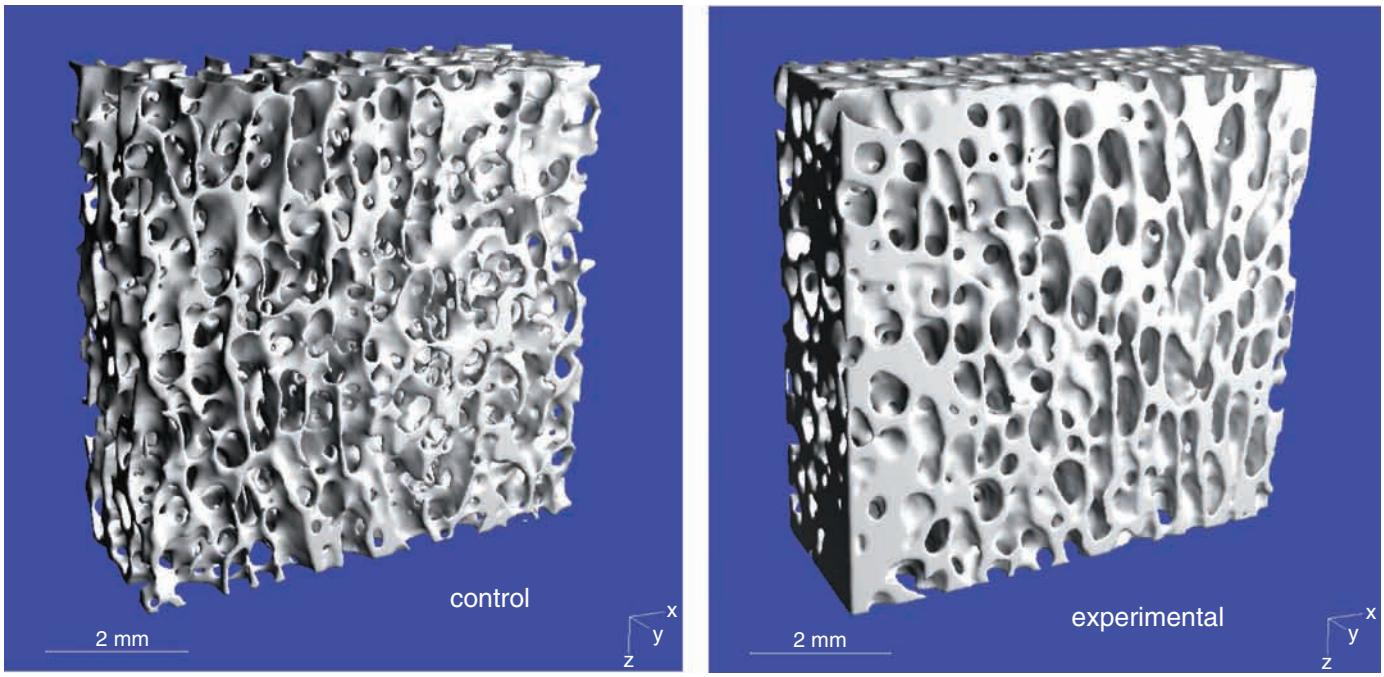

Fig. 46.1. Microcomputed tomography of the distal femur of adult (8-year-old) sheep, comparing a control animal (left) to an animal subject to 20 min/day of 30 Hz (cycles per second) of a low-level (0.3 g) mechanical vibration for 1 year (Ref. 76). The large increase in trabecular bone density results in enhanced bone strength, achieved with tissue strains three orders of magnitude below those that cause damage to the tissue. These data suggest that specific mechanical parameters may represent a nonpharmacologic basis for the treatment of osteoporosis (Ref. 71).

The connectivity of the osteocyte network deteriorates markedly with age and may contribute to the progressive loss of sensitivity of bone to chemical and physical signals [14].

Marrow stromal cells change proliferation and gene expression in response to mechanical stimulation [42] and through mechanical regulation of RANKL expression [43] also affect osteoclast number and function. The osteoclast also responds directly to mechanical signals limiting bone resorption [44]. Other cells present in bone, such as shear sensitive endothelial cells in the penetrating vasculature, likely contribute to the adaptive response by producing nitric oxide [45], which has pleiomorphic effects on the skeleton [46].

The role of mesenchymal stem cells (MSCs) in regulating the adaptive response to mechanical signals is also being investigated, with the demonstration that exercise can bias MSCs toward osteoblastogenesis [47], while disuse increases adipogenesis within the bone marrow [48]. Even low magnitude mechanical signals have been shown to influence the fate of MSCs, driving them toward a musculoskeletal lineage [49] while suppressing adipogenesis [50]. Considering the interdependence of fat and bone tissue [51], it may be that exercise-based prevention of obesity and osteoporosis could be achieved through regulation of MSC lineage rather than necessarily the resident cell population in fat (adipocytes) or bone (osteocytes) [52].

TRANSDUCING MECHANICAL SIGNALS INTO CELLULAR RESPONSE

When bone strains of 3,000 microstrain, realized during strenuous activity [16] are resolved to the level of the cell, these deformations are on the order of Angstroms, requiring an exquisitely sensitive receptor system. Further, cell mechanoreceptors must either be in contact with the outside, through the cell membrane and its attachment to substrate, or the mechanoreceptor must be able to sense by-products of load, such as fluid shear on the apical membrane. While in sensory organs there are examples of channels that are regulated by movement of mechanosensory bristles [53], or by tension waves [54], a unified model of proximal events inducing intracellular signal transduction in non-sensory tissues does not yet exist. There are, however, several components of the cell that could act as the mechanoreceptor, transducing a physical challenge into a cellular response.

Ion channel activity in osteoblasts stimulated by stretch/strain of the membrane [55] or by parathyroid hormone (PTH) [56] have been associated with bone cell activation. Patch-clamp techniques demonstrate at least three classes of mechanosensitive ion channels [57]. In limb bone cultures, gadolinium chloride, which blocks some stretch/shear-sensitive cation channels, blocked load-related increases in PGI2 and nitric oxide [58].

Membrane deformation and shear across the membrane, as well as pressure transients, are transmitted to the cytoskeleton and ultimately to the cell-matrix adhesion proteins that anchor the cell in place [59]. Membrane-spanning integrins, which couple the cell to its extracellular environment, and a large number of adhesion-associated linker proteins are potential molecular mechanotransducers. The architecture of the cytoskeleton with its microfilamentous and microtubular network linking adhesion receptors to the cell nucleus plays a role in perceiving small deformations and directly informing the nucleus [60]. Application of strain to MSCs induces focal adhesion assembly, which amplifies force generated signaling [61].

Cellular cytoskeletal adaptation to force is even more subtly reflected in a compartmentalization of signals within the several phases of liquid-ordered and liquid-disordered lipid making up the plasma membrane [62]. Organized lipid rafts are thought to act as mechanical sensors: in endothelial cells, shear stress causes signaling molecules to translocate to caveolar lipid rafts, and if the caveolae are disassembled, both proximal and downstream mechanical signals, including MAPK activation, are abrogated [63]. In bone cells, many of the outside-in signaling systems that respond to force are sequestered in lipid rafts.

With the multiplicity of mechanical signals presented to the cell, it is likely that no single mechanosensor or receptor mechanism is responsible for perceiving and responding to the mechanical environment (Fig. 46.2). At the very least, multiple mechanosensors are likely to interact to integrate both mechanical and chemical information from the microenvironment.

Since the distal responses to mechanical factors are similar to those elicited by ligand-receptor pairing and result in changes in gene expression, mechanotransduction must eventually end up utilizing similar intracellular signaling cascades. Mechanical forces have been shown to activate every type of signal transduction cascade, including β-catenin [64], mTORC2 [65], cAMP [66], IP3 and intracellular calcium [42, 67], guanine regulatory proteins [68], and MAPK [69], among others [70]. Given the pivotal role of mechanical stimuli in regulating anabolic and catabolic cell activity, perhaps it should not be so surprising that so many signaling pathways are involved.

TRANSLATING MECHANICAL SIGNALS TO THE CLINIC

There is growing clinical evidence that mechanical signals, even those that are extremely low magnitude, can be anabolic to bone [30], particularly in the young skeleton. In the first study, the ability of these low level signals to improve bone mass, delivered using low intensity vibration, was examined in children with disabling conditions [71]. Children were randomized to stand on an actively vibrating (0.3 g, 90 Hz) or placebo device for 10 min/day. Over a 6-month trial, proximal tibial volumetric trabecular BMD (vTBMD) in children on active devices increased by 6.3% while vTBMD decreased by 11.9% on placebo devices ($p < 0.01$). In the second study,

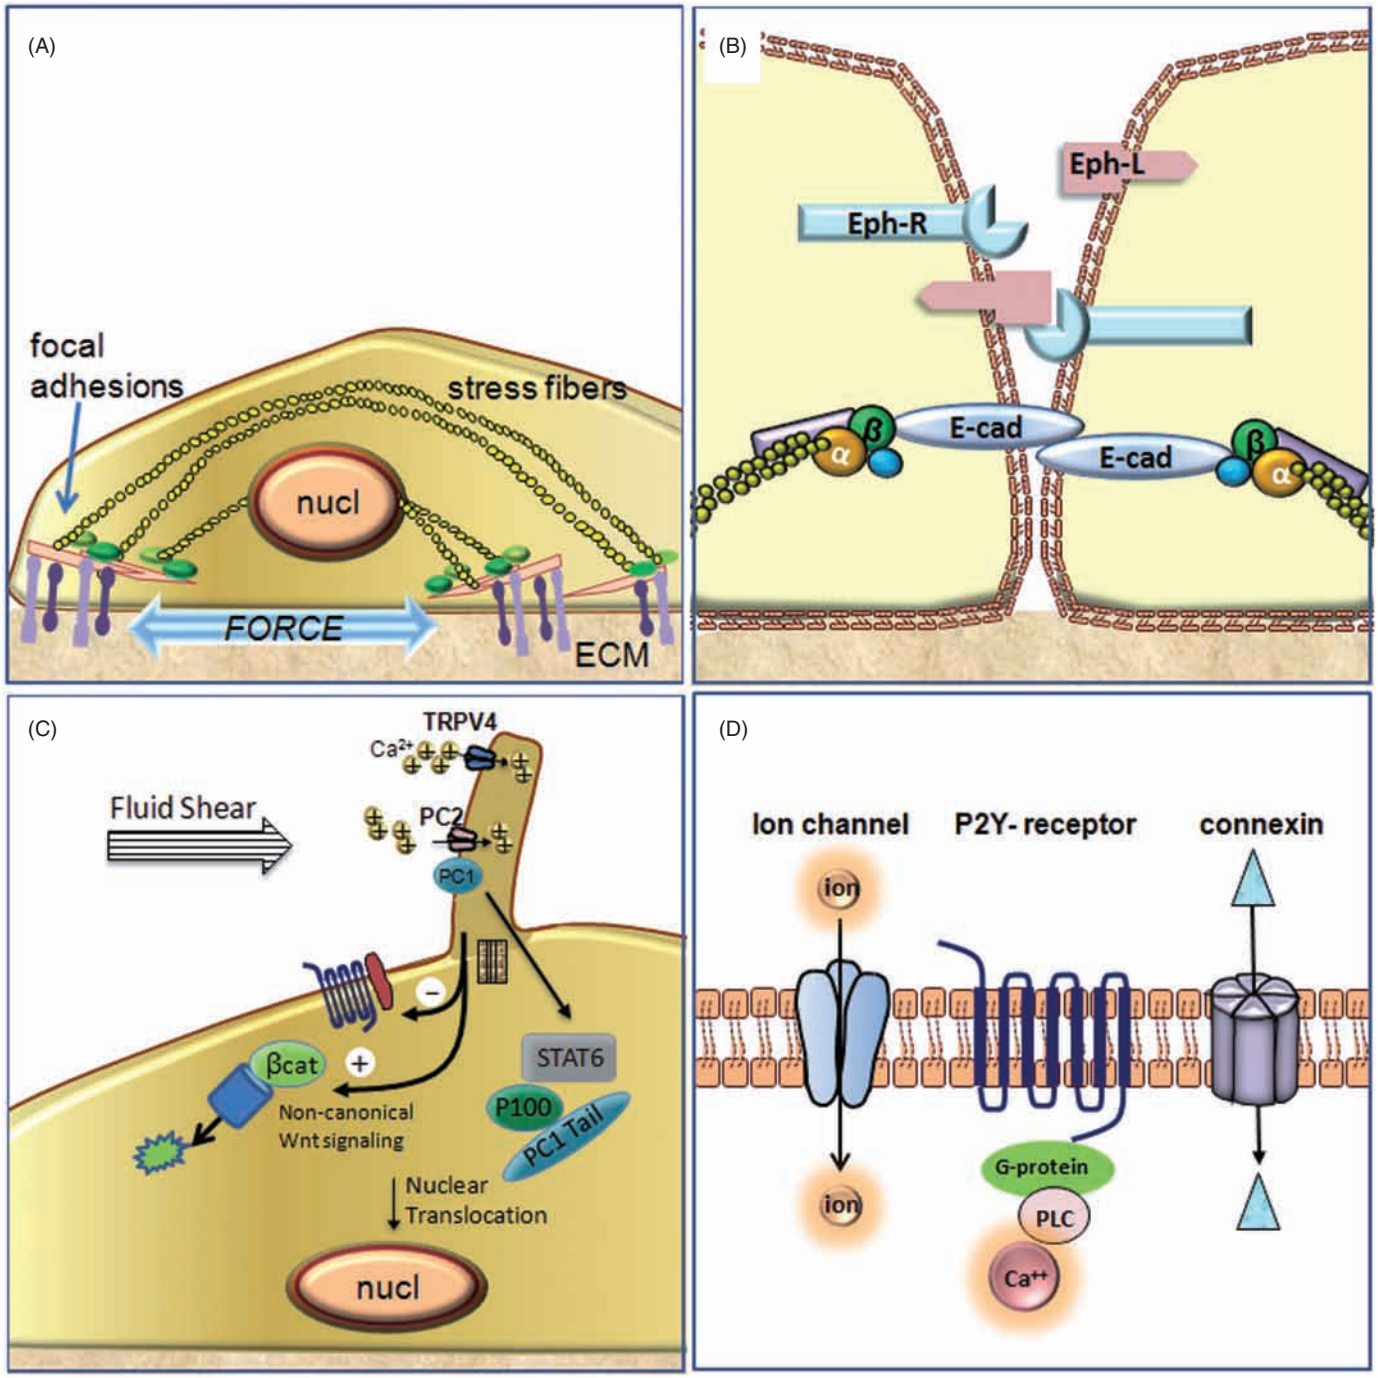

Fig. 46.2. Skeletal loading generates deformation of the bone matrix and acceleration/deceleration of the tissue system, resulting in strain across the cell and pressure within the marrow cavity and mineralized cortices. Functional load bearing also results in shear forces through the canaliculi, with the bulk fluid movement causing drag over cells and streaming potentials from charged interactions with the bone crystals. Some aggregate of these physical signals distorts the morphology of the cell. Some composite of these physical signals interacts with the morphology of the cell through interactions such as potentiated by the membrane–matrix or membrane–nucleus structures, or distortion of the membrane itself, to regulate transcriptional activity of the cell. Several candidate mechanotransducer systems are illustrated. (A) Cell cytoskeleton senses loading at the membrane through integrins that transmit force through focal adhesions and F-actin stress fibers. (B) Cadherins, which connect to the cytoskeleton, are examples of outside-in signaling modifiers. Ephrins exemplify an intercellular signaling system regulated by movement of components within the plasma membrane. (C) Primary cilia may sense flow, pressure, and strain, activating ion flux through PC1 and TRPV4, which can activate Stat signals. Cilia also modulate Wnt signaling via noncanonical antagonism that leads to β-cat degradation. (D) Membrane spanning proteins such as ion channels, purinergic receptors and connexins can be regulated through shear and strain. Modified from Thompson WR, Rubin CT, Rubin J. 2012. Mechanical regulation of signaling pathways in bone. *Gene* 503(2): 179–93.

a 12-month trial was conducted in 48 young women in the lowest quartile of bone density and at least one skeletal fracture [72]. Subjects were randomly assigned either into a daily, low-magnitude whole body vibration group (10 min/day, 30 Hz, 0.3 g) or control. Intention-to-treat data indicated that cancellous bone in the lumbar vertebrae and cortical bone in the femoral midshaft of the experimental group increased by 2.0% ($p = 0.06$) and 2.3% ($p = 0.04$), as compared to controls. Importantly, the cross-sectional area of paraspinous musculature was 4.9% greater ($p = 0.002$) in the experimental group versus controls. Per protocol analysis indicates that subjects who used the device at least two minutes each day realized a much greater musculoskeletal benefit from the mechanical signals. These low intensity mechanical signals have also been shown to help protect postural stability during chronic bedrest [73] and increase bone mass and muscle strength in the upper limbs of disabled children, thereby improving their autonomy [74].

SUMMARY

As bone geometry and material properties vary between individuals, there are also genome-specific sensitivities to mechanical loading which may help explain the variability in exercise based trials.[75] However, evidence in the animal and human indicates that exercise in general, and mechanical signals in particular, are both anabolic and anti-catabolic to the musculoskeletal system, and benefit both bone quantity and quality. The challenge remains to identify those parameters within the complex mechanical milieu induced by exercise that are critical to driving anabolism in bone, and that ultimately may represent the basis of a nondrug strategy to control musculoskeletal health. While bone-targeted pharmaceutical interventions represent effective means of curbing osteoporosis, exercise, in its many varied forms, is self-targeting, endogenous to the musculoskeletal system, and auto-regulated, causing site-specific positive adaptation in bone mass and structure. And as effective as drug treatments for osteoporosis may be, physical signals have had a 525 million year head start in terms of optimizing skeletal structure to withstand the loads placed upon them.

Calcium is required for the bone formation phase of bone remodeling. Typically, about 5 nmol (200 mg) of calcium is removed from the adult skeleton and replaced each day. To supply this amount, one would need to consume about 600 mg of calcium, since calcium is not very efficiently absorbed. Calcium also affects bone mass through its impact on the remodeling rate. An inadequate intake of calcium results in reduced calcium absorption, a lower circulating ionized calcium concentration, and an increased secretion of parathyroid hormone (PTH), a potent bone-resorbing agent. A high remodeling rate leads to bone loss; it is also an independent risk factor for fracture. Dietary calcium at sufficiently high levels, usually 1,000 mg per day or more, lowers the bone remodeling rate by about 10% to 20% in older men and women and the degree of suppression appears to be dose related [1]. The reduction in remodeling rate accounts for the increase in BMD that occurs in the first 12 to 18 months of treatment with calcium.

With aging there is a decline in calcium absorption efficiency in men and women. This may be related to loss of intestinal vitamin D receptors or resistance of these receptors to the action of 1,25-dihydroxyvitamin D. Diet composition, season, and race also influence calcium absorption efficiency.

Vitamin D is acquired from the diet and from skin synthesis, upon exposure to ultraviolet B rays. The best clinical indicator of vitamin D status is the serum 25-hydroxyvitamin D (25OHD) level. Serum 25OHD levels are lower in individuals using sunscreens and in those with more pigmented skin. Season is an important determinant of vitamin D levels. In much of the temperate zone, skin synthesis of vitamin D does not occur during the winter. Consequently, 25OHD levels fall in the winter and early spring. Serum PTH levels vary inversely with 25OHD levels. These cyclic changes are not benign. Bone loss is greater in the winter/spring when 25OHD levels are lowest (and PTH levels are highest) than in the summer/fall when 25OHD levels are highest (and PTH levels are lowest).

Serum 25OHD levels decline with aging for several reasons. There is less efficient skin synthesis of vitamin D with aging as a result of an age-related decline in the amount of 7-dehydrocholesterol, the precursor to vitamin D, in the epidermal layer of skin [2]. Also, older individuals as a group spend less time out-of-doors. There does not appear to be an impairment in the intestinal absorption of vitamin D with aging [3].

IMPACT ON BONE MINERAL DENSITY

Calcium and vitamin D support bone growth in children and adolescents and lower rates of bone loss in adults and the elderly. However, the association of calcium with bone mass appears to be influenced by vitamin D status. In men and women age 20 years and older in National Health and Nutrition Evaluation Survey III (NHANES III), higher calcium intake was associated with higher femoral neck bone mineral density (BMD) at 25OHD levels below 50 nmol/l (or 20 ng/ml) but not at higher

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.

25OHD levels [4]. A meta-analysis of 15 trials found that calcium alone in adults caused positive mean percentage BMD changes from a baseline of 1.7% at the lumbar spine, 1.6% at the hip, and 1.9% at the distal radius [5]. In one trial, the effects of calcium from food (milk powder) and supplement sources on changes in BMD in older postmenopausal women were compared and found to be similar [6].

Higher serum 25OHD levels have been associated with higher BMD of the hip in young and older adult men and women in NHANES III [4]. This association was present across the full range of 25OHD values. Supplementation with vitamin D also reduces rates of bone loss in older adults [7]. In order to sustain the reduced turnover rate and higher bone mass induced by increased calcium and vitamin D intakes, the higher intakes need to be maintained.

IMPACT ON MUSCLE STRENGTH, BALANCE, AND FALLING

In NHANES III women age 60 and older, higher 25OHD levels were associated with improved lower extremity function (faster walking and sit-to-stand speeds) [8]. Similarly, in 1,234 elderly men and women living in the Netherlands, concentrations of 25(OH)D below 50 nmol/L (or 20 ng/ml) were associated with reduced physical performance [9]. Results of vitamin D intervention studies have been more variable. In a meta-analysis of 17 trials, Stockton and colleagues found that supplemental vitamin D had no significant effect on lower extremity muscle strength except in individuals with low starting serum 25OHD levels, less than 25 nmol/L (or 10 ng/ml) [10]. The mechanism(s) by which vitamin D influences muscle performance and strength are not well established but are likely to involve the nuclear vitamin D receptors known to be present in muscle. Supplementation with 1,000 IU of vitamin D_2 daily over a 2-year period, when compared with placebo, significantly increased the diameter of fast twitch type II muscle fibers in older women who had had a recent stroke [11].

Vitamin D appears to have a favorable effect on balance in older adults. Sway, a measure of balance, is assessed with the subject standing on a force plate that measures the maximum displacement in the anteroposterior and medial-lateral directions, the average speed of displacement, and other parameters [12]. In adults age 60 years and older, the amplitude of sway in the medial–lateral direction was a strong predictor of falling more than once per year [13]. In two independent randomized controlled trials, 800 IU of vitamin D_3 plus 1,000 mg of calcium per day, compared with calcium alone, reduced sway by up to 28% over periods of 2 and 12 months [14, 15]. The mechanisms by which vitamin D affects balance have not been defined.

Vitamin D is recommended by several organizations to lower the risk of falling [16–18]. A meta-analysis of eight randomized placebo-controlled vitamin D intervention trials revealed that the effect of supplementation was dose dependent. Higher dose trials (700–1,000 IU/day) showed a risk reduction, whereas lower dose trials did not [19]. The magnitude of the risk reduction in the higher dose trials averaged 19%, or, when recalculated, 34% [20]. A higher dose of 2,000 IU per day, when compared with 800 IU per day, showed no fall risk reduction in elderly acute hip fracture patients [21], suggesting that 800 IU per day is adequate for this outcome. The serum 25OHD level needed to reduce falls was estimated to be at least 60 nmol/l (or 24 ng/ml) [19]. The impact of vitamin D on falls is likely to be mediated by its effect on muscle strength and balance.

IMPACT ON FRACTURE RATES

Several small studies have examined the impact of supplemental calcium on fracture rates. The Shea meta-analysis of these studies (13) found that calcium alone (versus placebo) tended to lower risk of vertebral fractures [RR 0.77 (CI 0.54–1.09)] but not nonvertebral fractures [RR 0.86 (CI 0.43–1.72)]. The studies in this analysis ranged from 18 months to 4 years in duration. A more recent meta-analysis reached similar conclusions, citing a trend toward a modest reduction in risk of nonvertebral fracture [RR 0.92 (95% CI: 0.81, 1.05)] and no significant effect on hip fracture risk [RR 1.64 (95% CI: 1.02, 2.64)] [22].

The effect of supplemental vitamin D on fracture incidence has been examined in several randomized controlled trials with varying results. A recent meta-analysis of these trials revealed that the response to supplementation was dose dependent. The trials using received doses >400 IU/day per day were positive for nonvertebral fractures [RR 0.80 (0.72–0.89)] and hip fractures [RR 0.82 (0.69–0.97)], whereas those using received doses of less than 400 IU per day were null [23]. Received dose is the product of administered dose and percentage adherence. Serum 25OHD levels were measured in most of these trials and among these, a group mean value of approximately 75 nmol/l (or 30 ng/ml) was needed to lower hip fracture risk [23]. The reduced risk of fracture likely results from effects of vitamin D on muscle, balance, fall risk, and bone metabolism. In many of the higher dose vitamin D trials, calcium was given along with vitamin D; based on this and other evidence, it is reasonable to replete both calcium and vitamin D. Several other meta-analyses have reached different conclusions, at least in part because different specific questions were posed and different selection criteria for study inclusion were applied [24, 25].

ROLE IN PHARMACOTHERAPY

In recent randomized controlled trials testing the antifracture efficacy of the antiresorptive therapies alendro-

nate, risedronate, raloxifene, and calcitonin, and the anabolic drug, PTH 1-34, calcium and vitamin D have been given to both the control and intervention groups. This allows one to define the impact of these drugs in calcium- and vitamin D-replete patients and to conclude that any efficacy of the drugs is beyond that associated with calcium and vitamin D alone. However, one cannot conclude that these drugs would have the same efficacy in calcium- and vitamin D-deficient patients.

INTAKE REQUIREMENTS

Calcium intake recommendations vary enormously worldwide. Recommendations by the Institute of Medicine (IOM) of the U.S. National Academy of Sciences are among the highest. The IOM recommended intakes of calcium are: ages 1–3 years, 500 mg; 4–8 years, mg; 9–18 years, 1,100 mg; 19–50 years, 800 mg; 51–70 years, 800 mg for men and 1,000 mg for women; older than 70 years, 1,000 mg per day [26]. Lower calcium intakes would likely be adequate for populations with lower intakes of salt and protein, two diet components that promote calcium excretion in the urine.

Among females in the U.S., fewer than 1 in 4 meet the calcium requirement through their diets; when calcium from supplement and food sources is considered, about half of U.S. females meet the requirement [26]. Among males, calcium intake from food is somewhat higher and from supplements somewhat lower than among females, with the result that, considering combined calcium sources, about half of U.S. males meet the calcium requirement [26]. Calcium from calcium carbonate, the most commonly used supplement, is better absorbed when taken with a meal [27, 28]. Absorption from all supplements is more efficient in doses up to 500 mg than from higher doses [29]. Thus, individuals requiring more than 500 mg per day from supplements should take it in divided doses.

The vitamin D intake recommendations of the IOM are: for males and females age 1–70 years, 1.5 mcg (600 IU), and for ages older than 70 years, 2 mcg (800 IU) per day [26]. For older adults these recommendations are based on BMD and fracture risk. The IOM concluded that "a 25OHD level of 40 nmol/l was consistent with the intended nature of an average requirement, in that it reflects the desired level for a population median—it meets needs for approximately half of the population" [26]. The IOM recommends a level of 50 nmol/l to meet the need of 97.5% of the population [26]. There is lack of consensus in the professional community about whether the target group mean 25OHD level should be 40, 50, 75 nmol/l or another number. Several organizations recommend 75 nmol/l as the target [16–18].

A vitamin D intake of 800 IU (15 mcg) per day is not adequate to bring more than about half of the elderly population to 25OHD levels of 75 nmol/L (or 30 ng/ml). Older men and women who are at average risk for low 25OHD levels will need an intake of 20 to 25 mcg (800 to 1000 IU) per day to maintain a serum 25OHD level of 75 nmol/L (30 ng/ml). Individuals at increased risk for low serum 25OHD levels, such as those with limited regular skin production of vitamin D (related dark skin, little time out of doors, sunscreen use, protective clothing, high latitude), obesity, malabsorption, and other conditions that limit absorption or alter vitamin D metabolism will need more than 800 to 1,000 IU to maintain a 25OHD level of 75 nmol/l (or 30 ng/ml). The increase in 25OHD with supplementation is inversely related to the starting level. At low starting levels, 1 mcg (40 IU) of vitamin D will increase serum 25OHD by 1.2 nmol/L (or 0.48 ng/ml); at a higher starting level of 70 nmol/L (28 ng/ml), the increase from this dose would be only about 0.7 nmol/L (or 0.28 ng/ml) [30, 31]. Vitamin D is available in two forms: the plant-derived ergocalciferol (D_2) and animal-derived cholecalciferol (D_3). For years these forms were considered to be equipotent in humans but recent evidence indicates that vitamin D_3 increases serum 25OHD levels more efficiently than vitamin D_2 [32]. Moreover, vitamin D_2 is not accurately measured in all 25OHD assays [33]. For these reasons, vitamin D_3, when available, is the preferred form for clinical use.

SAFETY

Recent reports have raised the issue of potential risk associated with excessive calcium supplement use. Bolland and colleagues reported that calcium supplement use without coadministered vitamin D increased risk of myocardial infarction [34]. However, increased risk was not observed in another earlier meta-analysis [35]. A detailed report from the Women's Health Initiative revealed a 17% increase in renal stones in the women treated with calcium and vitamin D as compared to the women treated with placebo [36]. Individuals with high calcium intake from food sources do not share this risk and may in fact have reduced risk of nephrolithiasis [37]. All things considered, it would seem prudent to obtain calcium from food sources to the greatest extent possible and to use supplements only as needed to bring total intake up to recommended levels. The IOM and others have identified no risk associated with serum 25OHD levels up through 125 nmol/l (or 50 ng/ml) [26].

The safe upper limits for calcium set by the IOM are: ages 1–8 years, 2,500 mg; 9–18 years, 3,000 mg; 19–50 years, 2,500 mg; older than 50 years, 2,000 mg per day [26]. The IOM has placed the safe upper limit for vitamin D at: ages 1–3 years, 2,500 IU; ages 4–8 years, 3,000 IU; and ages older than 8 years, 4,000 IU per day [26].

In conclusion, adequate intakes of calcium and vitamin D are essential preventative measures and essential components of any therapeutic regimen for osteoporosis. Many men and women will need supplements to meet the intake requirements. There is no known advantage

but there is potential risk in exceeding current calcium intake recommendations, particularly with use of supplements. Currently, the most common target serum 25OHD levels for musculoskeletal health are 50 nmol/l (20 ng/ml), recommended by the IOM, and 75 nmol/l (30 ng/ml), recommended by many specialty groups and others. There is a consensus that both of these target levels are safe. Additional research is needed to fully define the musculoskeletal and other health effects of different doses of vitamin D and serum 25OHD levels.

ESTROGEN

It is well established that osteoporosis is more common in women than men and fracture risk increases dramatically after menopause. The relationship between estrogen deficiency and osteoporosis was first suggested in the mid-1900s when Albright showed that treatment with estrogen reversed the negative calcium balance in postmenopausal women. The positive effects of estrogen on peak bone mass and on bone loss have been demonstrated in both men and women. For years, estrogen was considered the treatment of choice for postmenopausal women and widely advocated for prevention of bone loss, with numerous trials showing prevention of bone loss in recently menopausal women and increased of bone mineral density (BMD) in women with postmenopausal osteoporosis. Part of the emphasis on estrogen therapy was the assumption of extraskeletal benefits (lower rates of cardiovascular events and dementia in women who chose to take estrogen compared with those who chose not to) and also that the benefits would be durable after estrogen was stopped.

The Women's Health Initiative (WHI) confirmed the value of estrogen administration (with or without a progestin) in the treatment of osteoporosis and reduction of risk for hip and other clinical fractures. However, the presumed extraskeletal benefits were not confirmed, and the effects on BMD and fracture reduction disappeared within a year of discontinuation of estrogen (loss of BMD of approximately 5% in the first year after stopping). Thus, it appears that estrogen has protective effects on the skeleton only for as long as it is taken. However, women who take estrogen and then stop should be no worse off compared with women who have never taken estrogen at all.

Following results of the WHI, estrogen treatment is recommended for relief of menopausal symptoms, but in the lowest dose and for the shortest time necessary. Most women are not sufficiently symptomatic at menopause to require estrogen therapy, and most who require estrogen will be able to stop after a few years. However, a minority will require estrogen long-term. For those women, estrogen may be sufficient for prevention and/or treatment of osteoporosis.

Several different forms of estrogen are available for therapeutic use (e.g., estradiol, conjugated estrogen esterified estrogens, etc.) as well as several routes of administration (e.g., oral, transdermal). In addition to different compounds and routes of administration, the dose can vary as well. After hysterectomy, estrogen can be use "unopposed"; however, for women who still have their uterus, "opposing" estrogen with a progestin (of which there are several,e.g., progesterone, medroxyprogesterone acetate) is recommended for protection against endometrial hyperplasia and endometrial carcinoma. The specific therapy that was shown to reduce fracture risk in WHI was orally administered conjugated estrogen, 0.625 mg daily (also effective was the combination of 0.625 mg conjugated estrogen plus medroxyprogesterone acetate 5 mg daily; however, there is little or no evidence that progestins have any effect on bone). It is likely, but

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

not proven, that other estrogen preparations, as well as lower doses, might have beneficial effects on maintenance of BMD and reducing fracture risk.

Estrogens are considered by many to be "antiresorptive agents"; however, they reduce the rates of both bone resorption and bone formation but reduce resorption more than formation.

In summary, despite its important role in physiology and pathophysiology, estrogen is not recommended for prevention or treatment of postmenopausal osteoporosis, but should provide protection against bone loss and fractures for women who require estrogen from relief of menopausal symptoms.

ESTROGEN AGONISTS/ANTAGONISTS (SELECTIVE ESTROGEN RECEPTOR MODULATORS OR SERMS)

Tamoxifen, widely used for treatment and prevention of breast cancer, was thought of as an antiestrogen, based on the concept that a compound that blocked estrogen receptors in breast tissue would reduce the risk of recurrence or spread of breast cancer. Clinical trials of tamoxifen in postmenopausal women that were expected to show acceleration of bone loss actually showed modest gains in BMD, as well as decreases in bone turnover markers, establishing that this compound blocks the effect of estrogen in some tissues but acts like estrogen in others.

Rather than being an antiestrogen, tamoxifen and functionally related compounds are classified as estrogen agonists/antagonists, also known as selective estrogen receptor modulators (SERMs) and tissue-selective estrogens. They bind with estrogen receptors, activating estrogen pathways in some tissues and blocking them in others. Effects appear to be similar and consistent in some tissues (e.g., antagonists to estrogen in breast tissue and partial agonists in bone) but compound-specific in others (e.g., some stimulate the endometrium, while others are neutral, and still others are antagonists). The ideal compound would relieve menopausal symptoms (including vasomotor symptoms and vaginal dryness), maintain or increase BMD and reduce the risks of fractures at all skeletal sites, as well as reducing the risks of cardiovascular disease, dementia, genitourinary problems, and breast, endometrial, and ovarian cancer without increasing the risk of venous thromboembolic events. This "holy grail" has not yet been attained. Several promising compounds failed or have been limited because of safety concerns (tamoxifen increases the risk of endometrial hyperplasia and carcinoma) or because the skeletal effects were limited to reducing fractures in the spine, with no effect on nonvertebral sites.

Raloxifene, the first of these agents specifically marketed for positive bone effects and given orally in a dose of 60 mg daily, was shown to prevent bone loss in recently menopausal women and increase BMD in postmenopausal women, although the gains in BMD appear to be about half of what is observed with estrogen. The risk of new and worsening vertebral fractures was significantly reduced, but raloxifene has not been shown to have an effect on hip and nonvertebral fractures. Confirming a reduction in breast cancer noted in the osteoporosis study, raloxifene was shown in the Study of Tamoxifen and Raloxifene (STAR) trial to reduce the risk of breast cancer in postmenopausal women at increased risk of breast cancer and in postmenopausal women with osteoporosis. Raloxifene does not stimulate the endometrium. Although raloxifene has effects on lipids that suggest it might be cardioprotective (decreased triglycerides, total, and LDL cholesterol), no benefit was shown in the large Raloxifene Use for the Heart (RUTH) trial. The occurrence of stroke was not different between raloxifene and placebo groups; however, there were more fatal strokes in the raloxifene group. Enthusiasm for the use of raloxifene has been limited because of the lack of evidence for protection against hip and other nonvertebral fractures, as well as side effects and safety concerns (increased menopausal symptoms, increased risk of venous thromboembolic events such a deep vein thrombosis, pulmonary embolus, and retinal vein thrombosis). The increase in venous thromboembolic events is similar to estrogen and is highest during the initial months of treatment.

Several estrogen agonists/antagonists have fallen by the wayside, while a few have made it into Phase 3 trials for osteoporosis. Commercialization of arzoxifene was abandoned because of lack of protection against hip and other nonvertebral fractures. Lasofoxifene and bazedoxifene are approved in Europe but not in the U.S. Bazedoxifene has been studied in combination with estrogen, with the estrogen improving vasomotor symptoms and vulvovaginal atrophy.

CALCITONIN

In humans, calcitonin is a 32-amino acid peptide produced by specialized C cells in the thyroid. Osteoclasts express receptors for calcitonin and respond to calcitonin with a rapid decrease in resorptive capacity. Unlike estrogen deficiency in adults, which has been shown to cause bone loss and increase fracture risk, there is no evidence for an important physiologic effect of calcitonin in adults, and patients with calcitonin deficiency (i.e., after total thyroidectomy) show no changes in skeletal status or mineral homeostasis. As a pharmacologic agent, human, eel, and salmon calcitonin have all been tried, but synthetic salmon calcitonin has been the major product in clinical use. Given by subcutaneous injection, salmon calcitonin has been use to treat Paget's disease, hypercalcemia, and osteoporosis but with significant side effects of injection site reactions, flushing, and nausea in up to 20% of patients. In women with osteoporosis who were at least 5 years postmenopausal, nasal spray salmon calcitonin in a dose of 200 IU daily was shown to reduce the

risk of vertebral fracture and was well tolerated; however, lower (100 IU/day) and higher (400 IU/day) doses did not show an anti-fracture effect. Changes in BMD and bone turnover markers were minimal. There have been small trials of salmon calcitonin treatment in men with osteoporosis and men and women with glucocorticoid-induced osteoporosis.

Some patients appear to develop resistance to calcitonin, which could be due to the development of tachyphylaxis or the development of neutralizing antibodies. Treatment with calcitonin may lead to a reduction in plasma lithium due to increased renal clearance of lithium.

Although not included in the approved indications for calcitonin, studies suggest a possible analgesic effect, possibly mediated through an increase in circulating and central nervous system (CNS) endorphins, which may be clinically useful in patients with acute painful vertebral fractures.

An oral form of calcitonin is being studies as possible treatment for osteoarthritis and osteoporosis.

SUMMARY

Estrogen is indicated for relief of menopausal symptoms; for women who are candidates for estrogen either short term or long term, bone effects may be considered a "side benefit." Raloxifene has a limited role for prevention and treatment of osteoporosis and for reducing the risk of breast cancer. Nasal spray calcitonin has questionable evidence for beneficial effects on BMD, bone turnover markers, or fracture risk, but may have a role in reducing pain in patients with acute painful vertebral fractures.

Bisphosphonates (BPs) are synthetic compounds that have high affinity for calcium crystals, concentrate selectively in the skeleton, and decrease bone resorption. The first BP was synthesized in the 19th century but their relevance to medicine was recognized in the 1960s, and they were first given to patients with osteoporosis in the early 1970s. Currently, alendronate, ibandronate, risedronate, and zoledronate are approved for the treatment of osteoporosis worldwide while other BPs are also available in some countries.

PHARMACOLOGY

BPs are synthetic analogs of inorganic pyrophosphate in which the oxygen atom that connects the two phosphates is replaced by a carbon (Fig. 49.1). This substitution renders BPs resistant to biological degradation and suitable for clinical use. BPs have two additional side chains (R1 and R2) that allow the synthesis of a large number of analogs with different pharmacological properties (Fig. 49.1). A hydroxyl substitution at R1 enhances the affinity of BPs for calcium crystals, while the presence of a nitrogen atom in R2 enhances their potency and determines their mechanism of action. The whole molecule is responsible for the action of BPs on bone resorption and probably also for their affinity for bone mineral [1, 2].

The intestinal absorption of BPs is poor (less than 1%) and decreases further in the presence of food, calcium, or other minerals that bind them. Oral BPs should be given in the fasting state 30 to 60 minutes before meals, with water. BPs are cleared rapidly from the circulation; about 50% of the administered dose concentrates in the skeleton, primarily at active remodeling sites, while the rest is excreted unmetabolized in urine. Skeletal uptake depends on the rate of bone turnover, renal function, as well as on the structure of BPs [3]. The capacity of the skeleton to retain BP is large, and saturation of binding sites with the doses used in the treatment of osteoporosis is unlikely even if these are given for a very long time. At the bone surface, BPs inhibit bone resorption and are subsequently embedded in bone where they remain for long and are pharmacologically inactive. The elimination of BPs from the body is multiexponential; the calculated terminal half-life of elimination from the skeleton can be as long as 10 years, and pamidronate has been detected in urines of patients for up to 8 years after discontinuation of treatment. This slow release of the BP from the skeleton is probably responsible for the slow speed of reversal of the effect of BPs on bone following cessation of treatment, which is different from that of all other antiosteoporotic treatments. The rate of reversal of the effect may be different among BPs depending on their pharmacological properties, particularly their affinity for bone mineral, but no head-to-head studies have addressed this issue in humans.

The decrease of bone resorption by BPs is followed by a slower decrease in the rate of bone formation, due to the coupling of the two processes, so that a new steady state at a lower rate of bone turnover is reached 3 to 6 months after the start of treatment. This level of bone turnover remains constant during the whole period of treatment, demonstrating that the accumulation of BP in the skeleton is not associated with a cumulative effect on bone turnover. In addition to decreasing the rate of bone turnover to premenopausal levels, BPs maintain or may improve trabecular and cortical architecture, improve the hypomineralization of osteoporotic bone, increase areal mineral density and may reduce the rate of osteocyte apoptosis. The relevant clinical outcome of these actions is the decrease of the risk of fractures (Fig. 49.2).

At the cellular level BPs inhibit the activity of osteoclasts [1, 4]. BPs bound to bone hydroxyapatite are released in the acidic environment of the resorption lacunae under the osteoclasts and are taken up by them. BPs without a nitrogen atom in their molecule (Fig. 49.1) incorporate into ATP and generate metabolites that induce osteoclast apoptosis. Nitrogen-containing BPs (N-BPs) induce changes in the cytoskeleton of osteoclasts leading to their inactivation and potentially apoptosis. This action is mainly the result of inhibition of farnesyl pyrophosphate synthase (FPPS), an enzyme of the mevalonate biosynthetic pathway. FPPS is responsible for the formation of isoprenoid metabolites required for the prenylation of small GTPases that are important for cytoskeletal integrity and function of osteoclasts. There is a close relation between the degree of inhibition of FPPS and the antiresorptive potencies of N-BPs. In addition, the inhibition of FPPS by N-BPs leads to accumulation of IPP, a metabolite immediately upstream of FPPS, which reacts with adenosine monophosphate (AMP) leading to the production of a new metabolite which induces osteoclast apoptosis.

ANTIFRACTURE EFFICACY

All BPs given daily in adequate doses reduce significantly the risk of vertebral fractures by 35 to 65 % (Fig. 49.3)

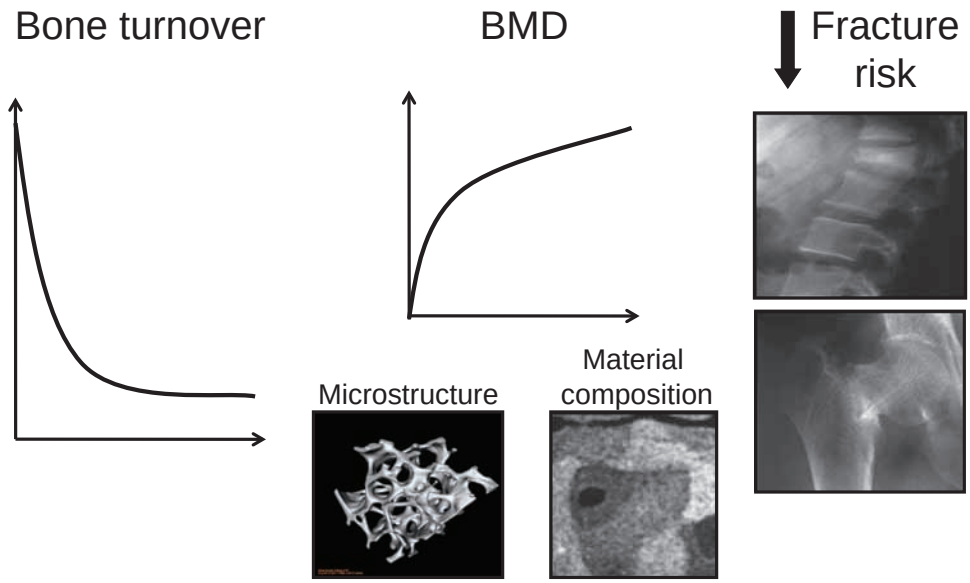

Fig. 49.2. Schematic presentation of effects of bisphosphonates on bone metabolism and strength in osteoporosis.

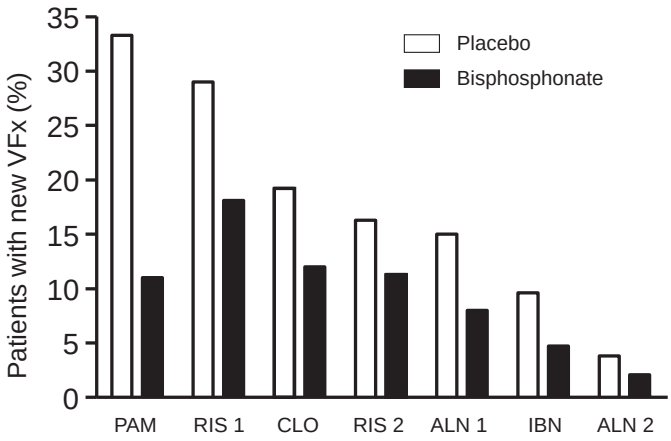

Fig. 49.3. Incidence of fractures in patients with osteoporosis treated with daily oral placebo (open bars) or bisphosphonate (closed bars) after 3 years. PAM = pamidronate (Ref. 5); RIS 1 = risedronate (VERT multinational study; Ref, 9); CLO = clodronate (Ref. 11); RIS 2 = risedronate (VERT North America study; Ref. 8); ALN 1 = alendronate (FIT 1 study; Ref. 6); IBN = ibandronate (BONE study; Ref, 10); ALN 2 = alendronate (FIT 2 study; Ref. 7).

[5–11]. Also illustrated in Fig. 49.3 are the large differences in the incidence of fractures among placebo-treated patients. Results, therefore, of different clinical trials should not be used to compare efficacy of individual BPs. For that, head-to-head studies are needed, but these are not available. The overall efficacy and consistency of daily BPs in reducing the risk of vertebral fractures has been demonstrated by meta-analyses of randomized controlled trials (RCTs) for alendronate and risedronate [12–14]. In studies in which radiographs were taken annually (e.g., the Vertebral Efficacy with Risedronate Therapy (VERT) study with risedronate), the effect of the BP in reducing the risk of vertebral fractures was already evident after 1 year, demonstrating rapid protection of skeletal integrity. This was also shown for moderate and severe vertebral fractures with ibandronate [15] and for clinical vertebral fractures with alendronate [16]. A *post hoc* analysis of risedronate trials reported a significant reduction in clinical vertebral fractures as early as 6 months after the start of treatment [17].

The efficacy of daily oral BPs in reducing the risk of nonvertebral fractures was explored in a number of RCTs. It should be noted that definitions and adjudication procedures of nonvertebral fractures were different among clinical trials. A meta-analysis of the Cochrane Collaboration reported an overall reduction of the risk of nonvertebral fractures in women with osteoporosis of 23% (RR 0.77; 95% CI 0.74–0.94) with alendronate and 20% (RR 0.80; 95% CI 0.72–0.90) with risedronate [13, 14]. The corresponding risk reductions for hip fractures were 53% (RR 0.47; 95% CI 0.26–0.85) with alendronate and 26% (RR 0.74; 95% CI 0.59–0.94%) with risedronate. These estimates are in agreement with earlier published meta-analyses [18, 19]. With daily ibandronate, a reduction (69%) in the risk of nonvertebral fractures was reported in a population at high risk [femoral neck bone mineral density (BMD) below –3.0] by *post hoc* analysis [10]. As with vertebral fractures, the effect of BPs on nonvertebral fractures occurs early after the start of treatment.

Daily administration of BPs, though highly efficacious, is inconvenient and may also be associated with gastrointestinal adverse effects. These reduce adherence to treatment and can diminish the therapeutic response [20,21]. To overcome both these problems, once-weekly

formulations, the sum of seven daily doses, have been developed for alendronate and risedronate, and were shown to significantly improve patient adherence to treatment while sustaining the same pharmacodynamic response as the daily treatment [22, 23]. A once-weekly slow-release formulation of risedronate that can be administered after breakfast is also available. Daily and weekly BPs are pharmacologically equivalent and should be considered as continuous administration while the term "intermittent" or "cyclical administration" should be reserved for treatments with drug-free intervals longer than 2 weeks [3].

Intermittent administration of BPs

Results of early attempts to give bisphosphonates intermittently to patients with osteoporosis were equivocal but a meta-analysis of studies with cyclical etidronate showed a significant reduction in the risk of vertebral, but not nonvertebral, fractures [24]. The efficacy of intermittent administration of N-BPs was explored in studies with ibandronate, which indicated that dose and dosing intervals are important determinants of the response to intermittent BP therapy, which in turn depends on the safety and tolerability of the administered dose [25]. An oral ibandronate preparation given once monthly and an intravenous preparation given once every 3 months, providing higher cumulative doses than the daily regimen, were developed and were shown to significantly increase BMD and reduce the risk of nonvertebral fractures by 38% compared to the oral daily dose [26, 27]. A once-monthly oral preparation of risedronate is also available.

The efficacy of intermittent administration of zoledronate, the most potent N-BP, in reducing the risk of osteoporotic fractures was examined in the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly (HORIZON) trial, in which postmenopausal women with osteoporosis were randomized to receive 15-minute infusions of zoledronate 5 mg or placebo once-yearly [28]. Compared to placebo, zoledronate reduced the incidence of vertebral fractures by 70%, hip fractures by 41%, and nonvertebral fractures by 25% after 3 years. The effect of zoledronate on vertebral fractures was already significant at 1 year. In a second controlled study [29], zoledronate infusions given within 90 days after surgical repair of a hip fracture decreased significantly the rate of new clinical fractures by 35% and improved patient survival (28% reduction in all-cause mortality). Epidemiological studies reported also survival benefits in patients treated with oral BPs [30–32].

LONG-TERM EFFECTS ON BONE FRAGILITY

Skeletal fragility on long-term BP therapy has been examined in extensions of four clinical trials for 6 to 10 years [33–36]. None of these extension studies were specifically designed to assess antifracture efficacy; rather, safety and efficacy of surrogate end points, as well as the consistency of the effect of BPs over longer periods, were evaluated. In all four studies, the incidence of nonvertebral fractures was constant with time. In the extension of the FIT (Fracture Intervention Trial) (FLEX), patients who received on average alendronate for 5 years were randomized to placebo, alendronate 5 mg/day or alendronate 10 mg/day, and were followed for another 5 years [35]. Continuation of alendronate treatment led to further increases in BMD of the spine and stabilization of that of the hip, whereas there was a slow progressive decrease of the total hip BMD in patients who received a placebo during the extension. At the end of the 10-year observation period, the incidence of nonvertebral and hip fractures in the ALN/PBO group was similar to that of the ALN/ALN groups. In addition, the incidence of clinical vertebral fractures was lower in the ALN/ALN groups compared to the ALN/PBO group (2% vs 5 %). In a *post hoc* analysis, women who entered the extension with a femoral neck BMD T-score below –2.5 BMD and no vertebral fractures and continued treatment with alendronate showed a significant reduction in the risk of nonvertebral fractures during the 5-year extension. These results suggest that alendronate treatment should be continued in patients at high risk whereas discontinuation of treatment after 5 years may be considered in patients with lower fracture risk. Similar BMD and fracture data were recently reported in the extension of the HORIZON trial in which patients treated with zoledronate for 3 years were randomized to 3 additional years of zoledronate or placebo [36].

SPECIAL ISSUES RELATED TO TREATMENT OF OSTEOPOROSIS WITH BISPHOSPHONATES

Excessive suppression of bone remodeling

There have been concerns that the long-term decrease of bone remodeling by BPs may compromise bone integrity leading to increased bone fragility. Numerous studies in different animal models with N-BPs given at a wide range of doses and time intervals have consistently shown preservation or improvement of bone strength. In only one study with high doses of clodronate given to healthy dogs an increase in fracture incidence has been reported. Earlier reports of potential compromise of the biomechanical competence of bone due to increases in microdamage accumulation in bone biopsies of healthy dogs treated with high BP doses were not substantiated by later animal and human studies [37, 38]. In human controlled studies of osteoporosis, the incidence of nonvertebral fractures was not increased with long-term therapy. and bone turnover markers increased after cessation of treatment, which indicated metabolically active bone. In

addition, an analysis of the FIT data showed that higher decreases of bone turnover were associated with larger decreases in the incidence of nonvertebral and hip fractures [39], a finding supported by the above-mentioned analysis of the ibandronate studies. Moreover, in studies of patients treated with BPs followed by treatment with teriparatide, early significant increases in bone markers have been reported, indicating that BP-treated bone can readily respond to stimuli [40]. This conclusion is further supported by a study of zoledronate treatment of patients previously treated with alendronate, which showed that alendronate-treated bone reacted normally to an acute BP load, as provided by zoledronate, indicating that metabolic activity was preserved [41].

Atypical fractures of the femur

In recent years there has been growing concern about the potential relationship between unusual low-energy subtrochanteric/diaphyseal femoral fractures, termed atypical, and long-term use of BPs. Atypical fractures of the femur are often preceded by prodromal pain, can be bilateral and healing may be delayed (Fig. 49.4). Criteria for the identification and diagnosis of atypical fractures of the femur have been proposed by a Task Force of the ASBMR [42]. These fractures are rare, about 1% of all femoral fractures, and occur more frequently in patients treated with BPs than in untreated patients [43, 44]. However, a causal association between BPs and atypical fractures has not been established but appears that the risk rises with increasing duration of exposure.

Osteonecrosis of the jaw

Osteonecrosis of the jaw (ONJ) is defined as exposed bone in the mandible, maxilla, or both that persists for at least 8 weeks in the absence of previous irradiation or metastases in the jaw. It has been reported mainly in patients with malignant diseases receiving high intravenous doses of BPs. The background incidence in the population and its pathogenesis are poorly defined, and a causal relation with BPs has not been established. In patients with osteoporosis treated with BPs, ONJ is rare; an incidence between 1:10,000 and <1:100,000 patient-years has been estimated, and appears to increase with duration of treatment [45–47]. In the two clinical trials of yearly infusions of zoledronate up to 3 years, two adjudicated cases of ONJ were reported among 9,892 patients with osteoporosis, one in the placebo-treated group and one in the zoledronate-treated group after 3 years [28, 29].

Adverse effects

BPs are relatively safe compounds, and their benefits outweigh their potential risks [48]. Specific adverse effects related to the use of BPs in osteoporosis include gastrointestinal toxicity associated with the oral, particularly daily, use of N-BPs and symptoms related to an acute phase reaction, mainly after first exposure to intravenous N-BPs. Gastrointestinal toxicity appears to be higher with generic preparations of oral BPs, of which many are currently available, resulting in significantly poorer adherence and effectiveness [49]. Case reports have suggested a relationship between oral N-BP treat-

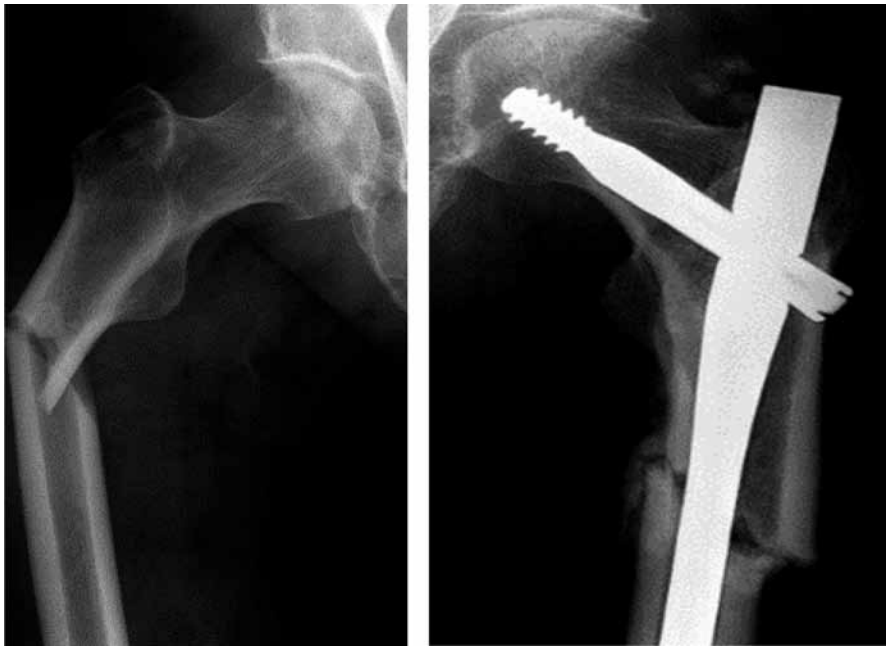

Fig. 49.4. Bilateral atypical fractures of the femur of a patient with rheumatoid arthritis on long-term treatment with alendronate and prednisone. Adapted from Somford MP, Draijer FW, Thomassen BJ, Chavassieux PM, Boivin G, Papapoulos SE. 2009. Bilateral fractures of the femur diaphysis in a patient with rheumatoid arthritis on long-term treatment with alendronate: clues to the mechanism of increased bone fragility. *J Bone Miner Res* 24: 1736–40.

ment and esophageal cancer. This was not confirmed in analyses of large databases, but a reduction in the incidence of gastric and colon cancer was recently reported in alendronate users [31, 50]. The kidney is the principal route of BP elimination, and BP use is contraindicated in patients with severely impaired renal function. Renal toxicity of intravenous BP is not a concern, provided that the indications for treatment and instructions for administration are closely followed. A significant increase in the incidence of atrial fibrillation, reported as a serious adverse event, was observed in one [28], but not in another, study [29] of patients receiving zoledronate compared to those receiving a placebo. A biological explanation for this effect is not apparent and further analyses of clinical trials with alendronate, ibandronate, and risedronate did not confirm such association.

CONCLUSIONS

BPs, because of their efficacy, safety, and ease of administration, are generally accepted as first-line therapy for osteoporosis. Selection of a BP for the treatment of an individual patient should be based on review of efficacy data, risk profile of the BP, and values and preferences of the patient. Despite progress in our understanding of the anti-fracture action of BPs and their long-term effects on bone, there are still questions that remain to be addressed. These include potential, clinically relevant, differences among BPs, optimal selection of patients for treatment and duration of use and their use in combination with bone-forming agents.

INTRODUCTION

Denosumab is the first inhibitor of receptor activator of nuclear factor κ-B ligand (RANKL) available for the treatment of osteoporosis and other bone diseases. The binding of RANKL to its receptor RANK on preosteoclasts is required for the proliferation, maturation, activation, and survival of osteoclasts [1]. Osteoprotogerin (OPG), a soluble form of RANK, is a decoy receptor for RANKL, interfering with the RANKL/RANK association, and inhibiting osteoclast activation. OPG administration decreased bone resorption and increased bone mass in rats and monkeys [2, 3]. Genetic animal models confirm the importance of this pathway in bone metabolism. Mice that lack OPG had osteopenia and skeletal fragility [4]. Mice deficient in RANKL or RANK and rats that overexpress OPG developed high bone mass of good quality [5, 6].

Parathyroid hormone, estrogen, glucocorticoids, vitamin D, transforming growth factor-β (TGF-β), inflammatory cytokines and other factors modulate the expression of RANKL and OPG [7–10]. Imbalances in the relative amounts of RANKL and OPG are implicated in clinical disorders characterized by increased bone resorption by osteoclasts such as osteoporosis, Paget's disease of bone, and skeletal metastases.

Genetic deficiency of RANKL, presenting as an osteopetrosis phenotype, provided evidence that the RANKL/RANK pathway is important in human skeletal health [11]. Rapidly progressive osteoporosis in a patient with autoantibodies that neutralized OPG activity confirmed the importance of OPG in humans, the delicacy of the balance between RANKL and OPG, and the potential magnitude of effect that occurs when that balance is shifted in favor of RANKL [12]. Inhibition of RANKL is an appealing strategy to treat osteoporosis [13].

INHIBITION OF RANKL: EARLY STUDIES

The administration of single doses (0.01 to 3 mg/kg) of an OPG-Fc fragment (of immunoglobulin G1) fusion molecule to healthy volunteers resulted in a dose-dependent reduction of urinary cross-linked N-telopeptides of type I Collagen (NTX) [14]. Higher doses induced a greater inhibition of bone resorption for a longer time. The highest dose given reduced NTX by 80% at 5 days; the treatment effect had resolved by 1 month. This study confirmed that inhibition of RANKL could reduce bone resorption in a clinical setting.

Denosumab is a fully human IgG_2 antibody that binds RANKL with very high affinity ($Kd=3\times10^{-12}$ M) and high specificity [15]. In a phase 1 study, nonlinear pharmacokinetics were observed after the administration of denosumab in single doses ranging from 0.01 to 3 mg/kg to healthy postmenopausal women; larger doses were

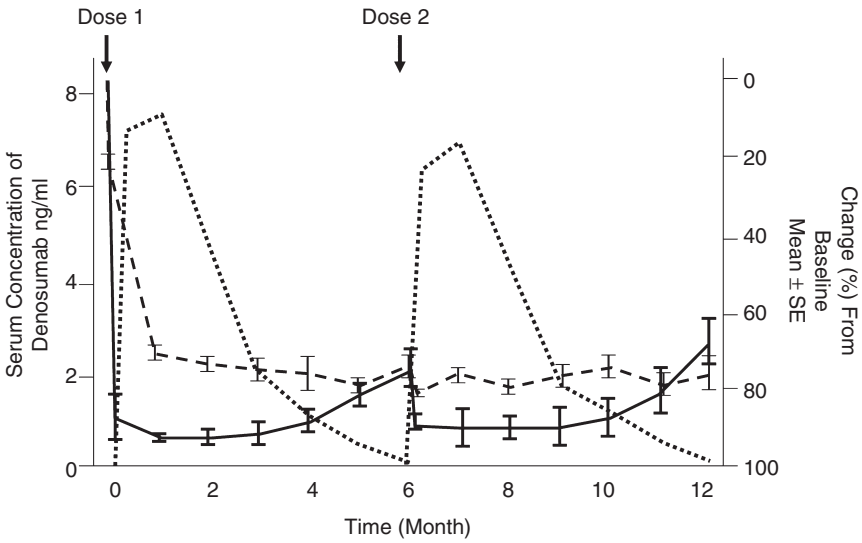

Fig. 50.1. Pharmacokinetics and pharmacodynamics of denosumab therapy 60 mg subcutaneously every 6 months. (.....) serum denosumab concentration; (——) serum CTX with denosumab; (-----) serum CTX with alendronate 70 mg po every week. Data modified from Ref. 18.

cleared more slowly than smaller doses [16] (Fig. 50.1). Clearance was modestly affected by body weight but not by age or renal function [17]. No dose adjustment is required as a function of age or weight or in patients with impaired renal function.

In the denosumab phase I study, subcutaneous doses ranging from 0.01 to 3 mg/kg caused very rapid reduction of urinary NTX by about 80% from baseline within 24 hours [16]. The duration of the inhibition of bone resorption was dose dependent with the effects of doses of 60 mg and higher persisting for at least 6 months. These data suggest that denosumab functions like OPG to reduce bone resorption by inhibiting the activity of RANKL. However, denosumab has these attributes that make it a more attractive therapy then OPG: (a) greater specificity to minimize the potential of off-target effects of other members of the tumor necrosis factor (TNF) family of cytokines such as TRAIL or CD40; (b) more favorable pharmacokinetics, allowing a more convenient dosing regimen; (c) avoidance of the theoretical possibility of inducing formation of anti-OPG antibodies that could have detrimental skeletal effects.

The development of denosumab proceeded with the phase II dose ranging study that evaluated the effects of therapy on bone mineral density (BMD), bone turnover markers, and tolerability in postmenopausal women with low bone density [18,19]. Subcutaneous doses of 6 mg once every 3 months to 210 mg once every 6 months significantly increased BMD at important skeletal sites. With all but the smallest doses, the BMD responses to denosumab at the lumbar spine, proximal femur and mid-radius were similar to or greater than the responses in women randomized to receive 70 mg of alendronate each week. All doses of denosumab resulted in a similar prompt and marked decrease in serum CTX, decreasing by 85% at 3 days after dosing. The duration of this effect was dose related. After dosing with 60 mg of denosumab, serum C-terminal cross-linking telopeptide of type-I collagen (CTX) reached a nadir at about 1 month, then gradually increased during the 6 months between doses, reaching a level similar to that observed in women receiving continuous alendronate therapy (Fig. 50.1). Markers of bone formation decreased after 2–3 months of treatment, and the response to denosumab paralleled that which occurred with alendronate therapy.

PIVOTAL TRIALS

Healthy postmenopausal women (7,808) with osteoporosis (BMD T-score below -2.5 at lumbar spine or total hip) were enrolled in FREEDOM, the pivotal phase III fracture end point study [20]. Subjects with T-score values of below -4 or with more than one mild vertebral deformity or with any moderate or severe vertebral fracture at baseline were excluded. Enrolled subjects were randomly assigned to receive denosumab 60 mg subcutaneously every 6 months or placebo injections; all received calcium and vitamin D. After 3 years of treatment, denosumab decreased the incidence of new morphometric vertebral fractures from 7.2% to 2.3% (68% relative reduction; CI 59%,74%) (Fig. 50.2). A decrease of at least 60% was also seen at the 1- and 2-year time points. The incidence of hip and nonvertebral fracture was 1.2% and 8.0%, respectively, in subjects receiving placebo, and was 0.7% and 6.5%, respectively, in the denosumab group, resulting in a relative risk reduction of hip fracture of 40% (CI 3%,63%) and 20% (CI, 5%,33%) for nonvertebral fracture. Because of the entry criteria (only 23% of subjects in FREEDOM had one mild vertebral fracture at baseline), the incidence of new morphometric vertebral and hip fractures in the placebo group of this study was lower than observed in pivotal trials of all other drugs approved for osteoporosis treatment. Thus, while the relative reduction in osteoporotic fracture risk was similar to or

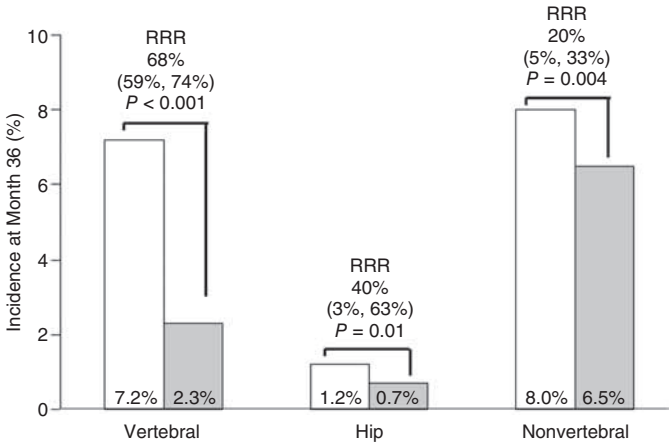

Fig. 50.2. Effect of denosumab therapy on fracture risk. Incidence of fracture after 36 months therapy with placebo (open bar) or denosumab 60 mg subcutaneously every 6 months. Numbers in bars are incidence (%). RRR = relative risk reduction (95% confidence interval). Data taken from Ref. 20.

better than that observed with other antiresorptive agents, the absolute reduction in risk was smaller [and the number needed to treat (NNT) was greater] in FREEDOM than in the HORIZON, FIT, VERT, and TROPOS studies [21–24]. This demonstrates the fallacy of using NNT to compare effectiveness of the therapies in populations with differences in fracture risk [25].

A pre-planned subgroup analysis of FREEDOM demonstrated that denosumab reduced spine fractures irrespective of risk factors [26]. Nonvertebral fracture risk was decreased in patients with femoral neck BMD values consistent with osteoporosis but not in subjects with higher BMD. In a *post hoc* subgroup analysis of FREEDOM, denosumab reduced spine and hip fractures in patients at high risk due to advanced age, low BMD, or history of prior fracture [27]. Denosumab was effective in increasing bone density and decreasing the incidence of vertebral fracture in women of the FREEDOM trial across the spectrum of baseline renal function [28]. This included a total of 2,817 women with estimated glomerular filtration rate (GFR) between 30 and 59 cc per minute and 73 women with estimated GFR or 15–29 cc per minute. The efficacy and safety of denosumab therapy in patients with renal failure on dialysis has not been studied.

As was observed in the phase II study, significant and progressive increases in BMD were noted over the 3 years of denosumab therapy in FREEDOM [20]. Compared to placebo, increases were 9.2% at the lumbar spine and 6.0% at the total hip. The change in total hip BMD at time points up to 36 months explained a substantial proportion of the effect of denosumab in reducing risk of vertebral and nonvertebral fractures. All subjects in a subgroup receiving denosumab for whom serial measurements of biochemical markers were measured had significant and sustained reductions in serum CTX and P1NP levels [29].

Denosumab 60 mg once every 6 months increased BMD in postmenopausal women with low bone mass [30]. Increases in BMD from baseline occurred in the lumbar spine (6.5%) and total hip (2.4%) over 2 years, while modest decreases occurred in the placebo control group. Similarly, denosumab increased BMD in women who were receiving aromatase inhibitor therapy for nonmetastatic breast cancer and in men treated with androgen deprivation therapy for nonmetastatic prostate cancer [31, 32]. After 3 years of denosumab therapy, vertebral fracture risk in the men on androgen deprivation therapy was reduced from 3.9% without treatment to 1.5% with denosumab therapy (relative risk reduction 62%; CI 22%, 81%) [32]. The effects of denosumab in men with low BMD or osteoporosis are being evaluated.

LONGER-TERM RESPONSES

In an extension of FREEDOM, about 4,500 women will take denosumab 60 mg every 6 months for up to 10 years. In women who received denosumab during the first 3 years of the study, treatment during years 4 and 5 resulted in continued increase in BMD, resulting in 5-year gains of 13.7% and 7.0% in the lumbar spine and total hip, respectively [33]. Annualized incidences of vertebral and nonvertebral fracture were similar during years 4 and 5 compared to fracture rates during the first 3 years of therapy. The phase II study extension also provides information about the long-term effects of denosumab therapy. BMD of the spine and hip regions increased by 13.3% and 6.1% from baseline in the lumbar spine and total hip regions, respectively, in subjects who continued taking denosumab for 6 years [34]. Pretreatment reductions in bone turnover markers (BTMs) were maintained with the long-term group. No neutralizing antibodies and no evidence of resistance to therapy have been observed.

RESPONSE TO DISCONTINUING DENOSUMAB

Upon discontinuing denosumab after 2 years, indices of bone turnover returned to baseline within 3 months of not taking a dose (9 months from the last dose) [35, 36]. Resorption and formation markers rose above baseline values for the next several months, and then returned to baseline values within 24 months after stopping treatment (30 months after the last dose). Gains in BMD achieved on therapy were lost within the first year off treatment. By 2 years off therapy, BMD values had returned to the original baseline values. Re-treatment with denosumab after 1 year off therapy quickly reduced bone turnover, and BMD increased to levels almost as high in patients who had received denosumab continually for 4 years [35]. These effects are similar to the effects observed when estrogen therapy is discontinued

[37, 38]. In accord with the pharmacokinetics of denosumab, the return to baseline values occurs over a somewhat longer time interval upon stopping denosumab as compared to stopping estrogen. Because these studies were small and included women at low risk for fracture, the effect on fracture risk of the rebound in bone turnover and rapid, pronounced bone loss is not known.

SAFETY AND TOLERABILITY

The FREEDOM study provides the most robust evaluation of the safety of denosumab therapy [20]. The incidence of total or severe adverse events and frequency of infection, malignancies, or cardiovascular disease was similar between denosumab and placebo groups. Injection site reactions and post-dose symptoms were not observed. Numerically fewer deaths occurred with denosumab (70, 1.8%) compared to placebo (90, 2.3%) ($P = 0.08$).

Skin rash or eczema was more common with denosumab therapy (3%) compared to placebo (1%) ($P < 0.001$). Cellulitis associated with hospitalization, not associated with injection site or time of dosing, occurred in 12 denosumab subjects compared to 1 with placebo. The incidence of skin disorders did not increase with longer-term therapy in the extension of FREEDOM, nor in subjects switched from placebo to denosumab [33].

Serum calcium decreases transiently when denosumab therapy is begun. Subjects with vitamin D deficiency were excluded from the FREEDOM trial, and supplements of calcium and vitamin D were begun before denosumab was given. No cases of symptomatic hypocalcemia were observed in FREEDOM subjects who received denosumab.

UNANSWERED CLINICAL CONCERNS ABOUT RANKL INHIBITION

Oversuppression of bone turnover

Theoretical concern exists of "oversuppression" of bone turnover with long-term treatment of potent antiresorptive agents. In head-to-head comparisons with alendronate, denosumab is a more potent inhibitor of BTMs [19, 39]. In iliac crest bone biopsies obtained in FREEDOM after 24 and 36 months of denosumab therapy, median bone formation rate was decreased by 97% compared to placebo patients [40]. Double tetracycline labels were observed in only 19% of those receiving denosumab versus 94% with placebo. In patients previously treated with bisphosphonates, double tetracycline labels in trabecular bone were present in 20% of biopsies of patients who had taken denosumab for 12 months versus 94% in patients who continued taking alendronate [40]. Normal indices of bone remodeling and double tetracycline labels were observed in biopsies of all 15 subjects who had discontinued denosumab therapy for a mean of 25 months [41].

Osteonecrosis of the jaw (ONJ) was not observed in any of the main clinical osteoporosis trials. Two subjects, both of whom had received placebo during the first 3 years of FREEDOM, developed oral lesions that met predefined criteria for ONJ during the first 2 years of the FREEDOM extension [33]. The incidence of ONJ was similar between high-dose denosumab and zoledronic acid in the oncology studies [42–44]. No evidence of impaired fracture healing and no cases of atypical fractures have been described to date. While untoward skeletal effects with long-term treatment with denosumab would not be a surprise, it is not certain that they will occur. The pharmacodynamic response to denosumab (profound early reduction with modest attenuation between doses) differs compared to bisphosphonates (almost constant reduction in turnover). Some bisphosphonates bind avidly to bone and may concentrate at sites of stress reaction; denosumab does not. Distribution into compartments of cortical bone, including osteocyte lacunae and canalicular network, may be different. The rapid and compete reversal of the inhibition of bone turnover upon stopping denosumab therapy contrasts with the persistent effects on remodeling following withdrawal of long-acting bisphosphonates [35].

Immune compromise

The effects of RANKL inhibition on immune function is of interest because RANKL exists in T-helper and dendritic cells, and there is some evidence that RANKL is involved in the maturation of dendritic cells and in regulation of T-cell-dependent immune response [45]. Adults with RANKL deficiency may manifest hypoglobulinemia but no evidence of T-cell dysfunction [46]. No laboratory evidence of altered immune function was observed in thorough evaluations of subjects in the phase II study [18].

In all clinical trials with denosumab, the overall incidence of infection has not differed among treatment groups [47, 48]. In FREEDOM and some of the smaller studies, serious adverse events related to infection occurred more frequently in patients who received denosumab than placebo. The number of events was small, and in no study was the difference in frequency statistically significant. Diverse diagnoses were represented among those clinical events and included noninfectious inflammatory disorders (labyrinthitis, diverticulitis, appendicitis). No relationships between these events and the timing of dose or duration of denosumab treatment were observed [48]. The incidence of opportunistic infection did not differ between denosumab and placebo.

Vascular effects

OPG-deficient mice develop medial calcification of large arteries [5]. Observational studies have demonstrated a

correlation between higher levels of serum OPG levels and vascular disease [49]. No evidence of cardiovascular consequences of denosumab therapy have been observed in clinical trials.

DENOSUMAB FOR OTHER CLINICAL CONDITIONS

In patients with rheumatoid arthritis who received methotrexate, denosumab increased BMD and prevented the progression of erosive bone lesions compared to placebo [50]. No unusual adverse events were noted in this unique population. The BMD response was not affected by glucocorticoid therapy, but denosumab has not been formally evaluated in patients receiving glucocorticoid therapy.

Denosumab would likely be effective in treating Paget's disease of bone and in controlling hypercalcemia related to malignancy. No studies have yet reported responses to denosumab therapy in such patients. The long-lasting effect of a single dose of zoledronic acid on bone metabolism in these conditions is likely an advantage compared to denosumab.

Larger doses of denosumab (120 mg subcutaneously once every 4 weeks) are effective in management of patients with cancer-related bone diseases. Compared to zoledronic acid, denosumab delayed the occurrence of skeletal-related events in patients with metastatic breast or prostate cancer, while responses were similar in patients with other solid tumors metastatic to bone and in patients with lytic lesions due to multiple myeloma [42, 44]. Risk of infection did not increase with denosumab therapy in these immunocompromised patients.

SUMMARY

By inhibiting RANKL action on osteoclasts and bone resorption, denosumab is a novel strategy for treating osteoporosis. Unlike bisphosphonates that inhibit the activity of mature, active osteoclasts, denosumab prevents the proliferation and maturation of preosteoclasts, thereby limiting the number of active osteoclasts and reducing bone resorption. Both denosumab and bisphosphonates indirectly decrease bone formation, so both agents preserve but do not reconstruct the damaged trabecular architecture found in patients with severe osteoporosis. In postmenopausal women with osteoporosis, denosumab is at least as effective as other potent antiresorptive agents in reducing the risk of clinically important fractures. Denosumab also prevents bone loss in postmenopausal women without osteoporosis and in patients receiving hormone ablation therapy for nonmetastatic cancer, and it likely to be effective in treating men with low bone mass.

The pharmacokinetics of denosumab allow for a convenient dosing schedule, and the drug is easily administered by medical office personnel without requiring intravenous infusion. Parenteral dosing avoids the possibility of upper gastrointestinal intolerance, concerns about poor compliance, and suboptimal intestinal absorption. Persistence of treatment effect for at least 6 months is assured. Unlike intravenous bisphosphonates, denosumab can be used in patients with impaired renal function. There is no justification for the use of denosumab in combination with other antiresorptive agents. The use of denosumab in combination with parathyroid hormone (PTH) molecules has not yet been studied.

To date, no clear concerns about the safety and tolerability of denosumab have been observed. Both the large extension cohort of the FREEDOM study, some of whom will receive therapy for up to 10 years, and the experience being gleaned from the use of denosumab in clinical practice will provide important information about possible effects of denosumab on immune function, infection, skin lesions, and other off-target effects, and about the possible effects of possible oversuppression of bone remodeling. Denosumab is a more potent inhibitor of bone resorption than are bisphosphonates. Whether the persistent, marked inhibition of bone turnover with denosumab will have untoward skeletal consequences is not yet known.

INTRODUCTION

As a result of its unique mechanism of action, parathyroid hormone (PTH), the only approved anabolic therapy for bone, produces larger increments in bone mass (particularly in the spine), than those seen with antiresorptive therapies. PTH treatment first stimulates bone formation and subsequently stimulates both bone resorption and formation; the balance remains positive for formation, even in this latter phase of PTH activity [1–3]. The growth of new bone with PTH permits restoration of bone microarchitecture, including improved trabecular connectivity and enhanced cortical thickness [4, 5]. Bone formation may also be induced on the outer periosteal surface [6–8], possibly affecting bone size and geometry, with additional beneficial effects on bone strength [6–12], though this has not been conclusively proven.

This chapter reviews the clinical trial data using PTH as both monotherapy and in combination and sequential regimens with antiresorptive agents in women and men and briefly overviews trials in a few special populations [13]. PTH will be referred to as teriparatide when it is the recombinant or biochemically synthesized human PTH aminoterminal (1-34) fragment and PTH (1-84) as the intact human recombinant molecule. PTH without other designation denotes either of the compounds. Currently, PTH is routinely given as a daily subcutaneous injection.

CANDIDATES FOR ANABOLIC THERAPY

Good candidates for PTH are women and men who are at high risk of future osteoporosis-related fractures, including those with vertebral compression fractures (clinical or radiographic), other osteoporosis-related fractures with bone mineral density (BMD) in the osteoporosis range, or very low BMD even in the absence of fractures (T-score below –3). PTH should also be recommended for individuals who have been on prior antiresorptive agents, and who have had a suboptimal response to treatment, defined as incident fractures or active bone loss during therapy, or who have persistent osteoporosis despite therapy. Individuals who might be at elevated risk for osteosarcoma, such as those with a history of Paget's disease, bone irradiation, unexplained elevations in alkaline phosphatase, adults with open epiphyses, and children should not receive PTH treatment. Furthermore, people with metastatic bone cancer, primary bone cancer, myeloma, hyperparathyroidism and hypercalcemia should not receive PTH. The PTH treatment course is 18–24 months, a function of the duration of the pivotal

fracture trial [14] as well as the finding that the effect appears to wane after this time.

POSTMENOPAUSAL OSTEOPOROSIS

Teriparatide (TPTD) as monotherapy

The largest study of TPTD action by Neer and colleagues included 1,637 postmenopausal women with prevalent vertebral fractures and an average age of 70 [14] who were randomized to receive TPTD (20 or 40 mcg), or placebo by daily subcutaneous injection. After a median treatment period of 19 months, TPTD increased spine BMD by 9.7% (20 mcg dose) and 13.7% (40 mcg dose), and hip and total body bone densities to a lesser extent. A small decline in radius BMD was seen (significant at the higher dose). Vertebral fracture risk reductions were 65% and 69%, respectively, with an absolute risk of 4% in the high dose group (19/434), and 5% in the low dose group (22/444), versus 14% in the placebo group (64/448). There was also a reduction in the incidence of new or worsening back pain in both TPTD groups. In patients with incident vertebral fractures, height loss was reduced (mean 0.21 cm lost in TPTD compared with 1.11 cm in placebo). Incident nonvertebral fractures were reduced by 40% (6% incidence in TPTD versus 10% in placebo) and by 50% for those defined as fragility fractures, as determined by individual investigators (no differences between TPTD groups). Despite the small decline in radius BMD, there was an apparent reduction in wrist fracture occurrence in TPTD-treated women (though too small a number to statistically evaluate). There were also numerically fewer hip fractures in TPTD-treated patients, though again too few to evaluate statistically.

Although transient increases in serum calcium were common when measured within 6 hours of the TPTD injection, sustained increases (confirmed with at least one subsequent measurement) were seen in only 3% of patients assigned to the 20-mcg group and 11% of those assigned to the 40-mcg group. There were no significant differences between TPTD or placebo groups with respect to deaths, hospitalizations, cardiovascular disorders, renal stones, or gout, despite an average increase in 24-hour urine calcium of 40 mg per day and an increase in serum uric acid of up to 25%. Animal studies have shown that administration of high-dose TPTD to rodents is associated with osteogenic sarcoma, dependent on dose and duration of administration [15, 16]. In patients with endogenous hyperparathyroidism or parathyroid cancer there is no evidence of an increased risk of osteogenic sarcoma. Furthermore, in over 9 years of postmarketing experience and about 3 million TPTD prescriptions, there is no evidence of an increased risk of osteosarcoma [17, 18]. Overall new cancer diagnoses occurred in fewer patients assigned to TPTD compared with placebo (2% vs 4%, $p = 0.03$ for the 20-mcg and 0.07 for the 40-mcg group) [14]. Possible side effects of TPTD are dizziness and leg cramps, redness and irritation at injection sites, headache, nausea, arthralgias, myalgias, lethargy, and weakness. The higher dose produced more side effects and withdrawals. TPTD-induced BMD changes in the Neer trial were not dependent on patient age, baseline BMD, or prior fracture history [19], but were related to baseline biochemical bone turnover indices [20]. Furthermore, early PTH-induced changes in bone turnover markers (at 1 and 3 months) were predictive of the ultimate change in spine BMD and bone structure [20, 21]. Finally, when women over age 75 years were examined relative to women younger than 75 years, age did not affect the safety or efficacy [22]. A longer duration of TPTD 14 months or more was associated with greater reduction in nonvertebral fracture incidence and reduced back pain, compared with shorter duration of therapy [23].

Two smaller studies have evaluated surrogate endpoints comparing TPTD to alendronate [1, 12]. In the first [12], where 146 women were randomized to receive TPTD (40 mcg/day) versus alendronate (10 mg/day), spine BMD increased 15% in the TPTD group versus 6% in the alendronate group after 1 year. Although there were fewer fractures in the TPTD than the alendronate group at the end of 14 months (3/73 vs 10/73), several of the fractures were minor (toe fractures).

McClung et al. studied 203 postmenopausal women with osteoporosis randomized to receive TPTD (20 mcg/day) or alendronate for 18 months [1]. Biochemical turnover increased substantially in the TPTD group (formation earlier than resorption) and declined substantially in the alendronate group (resorption earlier than formation). In TPTD-treated women, markers peaked within 6 months, suggesting developing resistance, as has been seen in other TPTD trials [14, 24, 25]. Spine BMD by dual energy X-ray absorptiometry (DXA) increased 10.3% in TPTD-treated women versus 5.5% in alendronate-treated women. Volumetric spine BMD by quantitative computed tomography (QCT) in a subset of women increased 19% in the TPTD versus 3.8% in the alendronate group. Femoral neck BMD by DXA increased similarly in both groups, though by QCT, cortical volumetric femoral neck BMD increased 7.7% in the alendronate group and declined 1.2% in the TPTD group. The spine BMD change correlated with the PINP increment in the TPTD group and with the PINP decrement in the alendronate group ($r = 0.53$ and -0.51, respectively). Clinical fracture incidence was similar in the TPTD (nine fractures) and alendronate (eight fractures) groups, but no radiographs were done to evaluate vertebral fractures. Moderate or severe back pain was reported significantly less often in women assigned to TPTD versus alendronate (15% vs 33%, $p = 0.003$).

TPTD delivered by a transdermal microneedle patch as a 30-minute daily wear in doses of 20, 30, or 40 mcg/day, versus placebo or subcutaneous injection of TPTD 20 mcg, over 6 months demonstrated that the 40-mcg patch had a BMD spine increase similar to the subcutaneous TPTD and the BMD response at the total hip was greater [26, 27]. In an investigation to determine the

importance of TPTD with an escalating daily dose (20 to 30 to 40 mcg) versus constant daily dose (30 mcg) in patients with osteoporosis, no difference was found over 6 months [28].

PTH(1-84) as monotherapy

In a dose ranging study, 217 women were randomized to 50, 75, or 100 mcg of PTH(1-84) or placebo. There was a dose-dependent increase in spine BMD; however, no increase in hip or total body BMD. The Treatment of Osteoporosis (TOP) trial was an 18-month, randomized, double-blind, study of 2,532 postmenopausal women with osteoporosis randomized to 100 mg of recombinant PTH(1-84) or placebo by daily subcutaneous injection [27]. The mean age was 64, and 19% of subjects had a prevalent vertebral fracture. The average change in spine BMD was 7% in PTH(1-84) treated subjects compared to those on placebo. In the per protocol adherent population (n = 1870), new or worsened vertebral fracture incidence was 3.4% in placebo and 1.4% in PTH(1-84) (relative risk reduction 58%), with reductions in both those with and without prevalent vertebral fracture, but nonvertebral fracture incidence was not reduced. The incidence of hypercalcemia was significantly higher in PTH(1-84)-treated women (28.3% vs 4.5% in placebo) [27]. PTH(1-84) therapy is currently available in Europe. There have been no head to head trials comparing PTH(1-84) with TPTD.

PTH and antiresorptive combination/ sequential therapy

Although PTH and antiresorptive agents could theoretically produce additive or even synergistic effects on bone strength, studies on combination therapy have shown different outcomes based on skeletal site (spine vs hip), type of measurement (DXA vs QCT), specific antiresorptive therapy utilized, and whether patients are previously treatment naïve or treatment experienced. Furthermore, in treatment-experienced patients, there appear to be differences in outcome based on whether the prior antiresorptive agent is continued or stopped when TPTD is initiated.

Treatment naïve women: PTH and bisphosphonates

Black et al. randomized 238 previously treatment naïve women to PTH(1-84) with alendronate versus each agent alone in a blinded fashion [29]. The BMD of the anteroposterior (AP) spine by DXA increased similarly in the PTH(1-84) alone and combination groups (6.3% and 6.1%, respectively). Total hip BMD (by DXA) increased in the combination group (1.9%) but not with PTH(1-84) alone (0.3%). Radial BMD declined more with PTH(1-84) alone (–3.4%) than with combination therapy (–1.1%). Although QCT measured increases in the integral spine and total hip were similar between the PTH(1-84) alone and combination groups, trabecular spine BMD increased more with PTH(1-84) alone (25.5%) than with the combination (12.6%). In contrast, QCT-assessed cortical bone density declined in the hip (–1.7%) with PTH(1-84) alone but was unchanged in the combination group. The cortical volume of the femoral neck of the hip (but not the total hip) increased significantly in PTH(1-84)-treated versus combination-treated women, but this was not due to periosteal expansion. The DXA results demonstrated no clear evidence of the additive effect with combination therapy compared to PTH(1-84) alone in the spine. However, hip BMD increments were superior with the combination. Evidence of a blunted effect with combination treatment was apparent only by QCT. Since single-energy QCT-based BMD increments induced by PTH may be artifactually elevated by reductions in bone marrow fat [30, 31], it is unclear how important these findings are compared to DXA-based results. There were only a small number of fractures, with no group differences; incident morphometric vertebral fractures were not reported.

An unblinded study where 93 women were randomized to receive alendronate for 6 months prior to giving TPTD (versus either agent alone) suggested that BMD gains in both spine and hip by DXA were lower in those given TPTD after the brief course of alendronate (and with continued alendronate), compared to those given TPTD alone [32]. The difference in the DXA BMD of the spine was not significant if the groups were restricted to those who did not discontinue study medication prematurely. A larger difference in BMD between the TPTD alone and combination groups was seen by QCT. This is one of few PTH trials where treatment duration was a full 24 months; hip and femoral neck BMD levels increased most markedly during the latter year of treatment. However, radius BMD declined more in women who received TPTD alone compared to combination treatment, and the change in total body BMD did not differ between groups. Furthermore, the PTH dose used here was double the approved dose (40 mcg daily TPTD), and since PTH effects on BMD are clearly dose dependent, the clinical significance of these data is unclear.

Cosman et al. randomized 412 treatment naïve postmenopausal women (mean age 65, mean spine BMD T-score –2.9), to receive daily TPTD, an intravenous zoledronic acid (ZOL) infusion, or a combination of daily TPTD and an intravenous zoledronic acid infusion in a partial double-blind fashion (TPTD open label) [33]. With combination therapy, the bone resorption marker CTX declined similarly to that with ZOL alone, whereas the bone formation marker PINP declined only modestly compared to that seen with ZOL alone. Also with combination therapy, the spine BMD increase was similar to that seen with TPTD alone (7.5% vs 7.0% TPTD alone), whereas the hip BMD increase was larger (2.3% vs 1.1%) as was the femoral neck BMD increase (2.2% vs 0.1%). In the combination groups, peak BMD increments were reached the fastest at both sites. Although fractures were reported only as adverse events, the fractures were adjudicated. Clinical fractures occurred in 9.5% of patients

in the ZOL alone group, 5.8% of the TPTD alone group and 2.9% of the combination group ($p < 0.05$ vs ZOL alone).

Treatment naïve women: Teriparatide and raloxifene

In a 6-month, double-blind, placebo-controlled trial, Deal et al. randomized 137 postmenopausal treatment-naïve women to receive TPTD or TPTD plus raloxifene. The bone formation marker PINP rose similarly in the two groups, while the bone resorption marker (CTX) increased more in the TPTD alone group. Spine BMD increments were similar in the two groups, while hip BMD increased more in the TPTD plus raloxifene group [34].

PTH therapy in women on established bisphosphonate or raloxifene treatment

Patients maintained and stabilized on long-term antiresorptive treatment are a distinct, but clinically very important population, since many of these patients have fractures or do not achieve a BMD above the osteoporotic range, and thus might benefit from anabolic therapy. At least 50% of all PTH treatment is initiated in patients who have received prior antiresorptive agents. Possible explanations for differences between treatment-naïve and treatment-experienced women include: reduced active bone surface in the treatment experienced, the increase in endogenous PTH seen for up to 12 months when potent antiresorptive agents are administered to treatment naïve individuals (which might produce a different response to exogenously administered PTH) and perhaps unique effects on osteoclast and/or osteoblast activation in treatment experienced individuals.

Prior studies evaluating TPTD treatment in treatment experienced women have followed two basic designs: antiresorptive agents are stopped when TPTD is started [35, 36, 37], or antiresorptive agents are continued when TPTD is started [38, 39]. Outcomes differ with these distinct study designs, particularly when the antiresorptive agents are oral bisphosphonates. In studies where bisphosphonates are discontinued, the spine BMD increment is of lesser magnitude, and hip BMD declines consistently over the first year, an effect not seen in protocols where TPTD is added to ongoing bisphosphonate.

Studies where antiresorptive therapy was stopped when TPTD was started

In an observational study where TPTD was given to women after cessation of long-term alendronate or raloxifene [35], bone turnover markers increased, as did spine BMD, but these increases were somewhat delayed and of lower magnitude in patients pretreated with alendronate compared to those in patients pretreated with raloxifene. A transient reduction in hip BMD was seen at 6 months in the group previously on alendronate but this reversed by the 18-month measurement.

Similarly, in an observational study of women previously treated with risedronate (n = 146) or alendronate (n = 146) biochemical responses showed increments in bone resorption already within 1 month in both groups of patients [36], an outcome not seen within the first month in treatment-naïve patients treated with TPTD [1, 14]. Furthermore, increases in bone resorption at 1 month are not seen in patients on prior antiresorptive therapy when the antiresorptive agent is continued during administration of TPTD [24, 38, 40]. In this trial [36], Miller found that spine BMD increases were not as great in patients receiving TPTD when the bisphosphonate was stopped, and hip BMD was below baseline for both the patients on prior risedronate as well as those on prior alendronate for the duration of the 1-year trial.

Finally, the average spine BMD in a cohort of women who had been on prior bisphosphonates and then switched to TPTD increased less than in a cohort of treatment-naïve women (9.8–10.2% for the bisphosphonate treated and 13.1% for treatment-naïve women). Furthermore, women on prior bisphosphonates who were switched to TPTD had a decline in hip BMD over the first year of treatment [41].

In contrast, in 126 women previously treated with long-term alendronate (mean age 68 years, mean alendronate duration 3.2 years), the subjects were randomized to continue alendronate and to receive daily TPTD, cyclic TPTD (given in a 3-month on/3-month off regimen), or alendronate alone [38]. In just over 15 months, spine BMD rose 6.1% in the daily TPTD group and 5.4% in the cyclic TPTD group ($p < 0.001$ for each TPTD group, no group difference), both higher increments than the average changes seen in the studies above when the underlying bisphosphonate was discontinued. Moreover, mean hip BMD did not decline at any time point during this study.

In a separate study, Cosman et al. evaluated postmenopausal women on raloxifene for at least 1 year (n = 42) with persistent osteoporosis and randomized them to stay on raloxifene alone or to receive raloxifene plus TPTD. The TPTD plus raloxifene group had an increment of about 10 % in the lumbar spine and 3% in the total hip, whereas those randomized to the raloxifene alone group had no BMD change [39]. Increases in both biochemical turnover markers at 3 months correlated with increases in spine BMD at 1 year.

In order to formally compare the effect of continuing versus stopping the antiresorptive agent when TPTD is begun in a randomized trial, 198 women treated with prior antiresorptive agents for at least 1 year (102 women on alendronate and 96 on raloxifene) were studied [42]. Women within each antiresorptive category were randomized to continue or stop their antiresorptive when TPTD was initiated. Although an anabolic response was seen both biochemically and densitometrically in all groups of patients, biochemical turnover markers increased more in those randomized to the switch design. Of particular interest was the early increase in CTX, which was already significantly elevated at 1 month in the patients who were switched from alendronate to

TPTD, suggesting a truncation of the anabolic window in patients following this approach. As a result, BMD declined in the first 6 months in the hip (as seen in all switch studies above) and did not increase as much in the spine. The increases at both 6 and 18 months at both spine and hip were greater in those patients in whom TPTD was added to the ongoing alendronate, compared to those who switched to TPTD, and at no point in time did hip BMD decline in the combination group. Differences between combination and switch protocols were less marked with raloxifene pretreatment though hip BMD increased more in the combination than switch group.

These results suggest that there may be a role for combination therapy, particularly after prior bisphosphonate treatment. This might be particularly important in patients who begin with very low hip BMD and/or those in whom hip fractures have already occurred, where any early decline in BMD might be detrimental and a greater increase in BMD over 18 months a favorable outcome.

PTH and hormone therapy

In 52 women with osteoporosis (average age 60 years) treated with hormone therapy (HT) [24, 40], daily TPTD produced rapid increases in markers of bone formation, and delayed increases in markers of bone resorption [40]. This period of time, where augmentation of bone formation exceeds stimulation of bone resorption, has been referred to as the "anabolic window" and may represent the most efficient bone-building opportunity with TPTD. Furthermore, bone turnover levels remained elevated for only 18–24 months, after which marker levels declined [24]. The mechanism of this apparent resistance to TPTD has still not been determined. BMD increased by about 14% over 3 years in women receiving TPTD + HT, with evidence of the most rapid rise in BMD within the first 6 months. Total body and hip BMD increased by 4% in patients on TPTD + HT. Although the study was not powered to assess fracture occurrence, after 3 years of treatment, vertebral deformity occurrence was significantly reduced in patients receiving TPTD + HT compared to HT alone [24].

Another study of similar design performed in women who had previously been treated with HT showed BMD increments by DXA in the TPTD group of 30% in the lumbar spine and 12% in the femoral neck versus placebo [43]. No fracture data were presented from this trial, and the data have never been published in a peer-reviewed journal. A third study was performed in 247 women, where one subgroup had been on prior HT (as in the previously discussed two trials) and a second subgroup consisted of treatment-naïve women about to receive HT for the first time [44]. In the former group, there were BMD increments of approximately 11% in the spine and 3% in the total hip in women randomized to TPTD (40 mcg per day). In the women receiving *de novo* HT, there were increases due to HT itself (4% in the spine and 2% in the total hip), and larger increases in the group receiving HT with TPTD (16% in the spine and 6% in the hip). The increases from TPTD appeared additive to those of HT, although not synergistic.

PTH TREATMENT OF MEN

In a small study, men with idiopathic osteoporosis were randomized to receive TPTD or placebo [25]. Biochemical markers of bone turnover increased rapidly with TPTD administration, and spine BMD rose about 12%, with a plateau between 12 and 18 months. In the femoral neck and total hip, BMD increased 5% and 4%, respectively, and radius BMD did not change significantly.

A subsequent multicenter trial of TPTD [18] was performed in 437 men (mean age 49 years) with primary idiopathic or hypogonadal osteoporosis. Subjects were randomized to TPTD 20 or 40 mcg daily, or placebo. After approximately 1 year, spine BMD rose 5.4% and 8.5% in the 20 mcg and 40 mcg groups, respectively, with no change in the placebo group. There were also dose-dependent increases in BMD at hip sites and total body. Of the original enrollees, 355 men participated in an observational follow-up study. Lateral spine radiographs repeated after approximately 18 months of follow-up (including the use of antiresorptive therapy in a substantial proportion of the men) showed a 50% reduction in vertebral fracture risk in those men initially assigned to TPTD compared to those who had received placebo ($p = 0.07$) [45].

In a third study, 83 men with osteoporosis were assigned to TPTD at 40 mcg/day, alendronate alone, or TPTD after 6 months of alendronate pretreatment (with ongoing alendronate [26, 46]. A substantial proportion of men in both TPTD groups required dose adjustment (by 25–50%) due to hypercalcemia or side effects. After a total of 24 months of TPTD administration, spine BMD increased most in the TPTD alone group (18.1%), compared to that in the combination group (14.8%) or alendronate alone (7.9%). Similar trends were seen for the lateral spine and femoral neck, but for the total hip and total body, increases were similar in the three treatment groups. In contrast, in the radius, BMD declined in the TPTD alone group with slight increases in the other groups. Spine trabecular bone density on QCT increased 48% with TPTD alone, 17% with the combination, and 3% with alendronate alone.

Leder and colleagues [47] examined the BMD changes after discontinuation of TPTD. While the initial improvements in spine and hip BMD were similar in men and women, after TPTD was discontinued following 24 months of TPTD in eugonadal men and postmenopausal women, spine BMD decreased 4.1% in men compared to 7.1% in women over the next 12 months. Bone mass was stable at the hip in men, but decreased in women suggesting an even greater need for antiresorptive follow-up treatment in women.

PTH IN SPECIAL POPULATIONS

Glucocorticoid-Treated patients

PTH could conceivably be a preferred treatment for glucocorticoid osteoporosis, since some of the major pathophysiologic skeletal problems with glucocorticoid administration are reduced osteoblast function and lifespan, both of which might be counteracted by PTH. Women with a variety of rheumatologic conditions on glucocorticoids and treated with hormone therapy were randomized to TPTD + HT or continued HT alone [48]. TPTD resulted in a 12% increase in spine BMD by DXA and a smaller increase in femoral neck BMD. No fracture results were reported.

In an 18-month active comparator trial of TPTD versus alendronate for the treatment of glucocorticoid-induced osteoporosis, patients treated with TPTD had BMD increases of 7.2% at the spine and 3.8% at the total hip, both significantly greater than the changes of 3.4% at the spine and 2.4% at the hip seen with alendronate therapy [49]. Furthermore, fewer new vertebral fractures occurred in the TPTD group compared to the alendronate group (0.6% vs 6.1%, p = 0.004). At 36 months, TPTD compared to alendronate resulted in 11% vs 5.3% increases at the lumbar spine, 5.2% vs 2.7% at the total hip, 6.3% vs 3.4% at the femoral neck (all p = 0.001), in addition to fewer vertebral fractures (1.7% TPTD vs 7.72 alendronate) [50]. There were no differences in nonvertebral fractures between the groups.

Fracture repair

PTH could potentially accelerate fracture repair. In a study with postmenopausal women who sustained a radial fracture, TPTD 20 mcg shortened time to healing, though this effect was not seen with TPTD 40 mcg [51]. Further studies are needed.

PERSISTENCE OF EFFECT

A series of observational studies suggests that BMD is lost in individuals who do not take antiresorptive agents after cessation of TPTD or PTH(1-84), whereas antiresorptive therapy can maintain PTH-induced gains or even provide further increments in BMD after a course of PTH [24, 45, 48, 52–54]. Black et al. have now provided clinical trial confirmation of this observation [55]. Subjects originally randomized to 1 year of treatment with PTH(1-84) were subsequently randomized to receive alendronate or placebo for an additional year. Over 2 years, women who received alendronate following PTH(1-84) had significant increases in spine BMD of 12.1% compared to 4.1% in women in the PTH(1-84) followed by placebo. Trabecular bone at the spine assessed by QCT demonstrated a 31% increase in women on PTH(1-84) followed by alendronate, compared to 14% in those assigned to PTH(1-84) followed by placebo. BMD at the femoral neck and total hip was increased above baseline in all groups except those receiving PTH followed by placebo. These data suggest that after 1 year of PTH treatment, the gains in bone mass are preserved or further improved with alendronate but lost in patients not on antiresorptive therapy. In women enrolled in the Fracture Prevention Trial [14], a 30-month observational follow-up, after discontinuation of TPTD indicated that nonvertebral fracture reduction risk remained lower compared with the prior placebo group, but the difference was not significant for the 20-mcg dose. The *ad lib* use of antiresorptive treatments in both groups complicates the interpretation of these findings[56].

RECHALLENGE WITH PTH

Women originally randomized to daily or cyclic TPTD in addition to ongoing alendronate were followed for a year after TPTD was discontinued [57]. BMD remained stable in these women during this year. A second 15-month course of TPTD was given to those volunteers who still had osteoporosis. The rechallenge with TPTD produced similar biochemical and BMD changes to those seen during the first course of therapy [57]. In a study by Finkelstein and colleagues [58], men and women who completed a 30-month randomized trial that included TPTD, alendronate, or the combination were rechallenged with TPTD following a 12-month discontinuation phase of TPTD. After 12 months of TPTD rechallenge, BMD of the spine increased but the increment was attenuated compared to the initial TPTD treatment.

Cost-Effectiveness of TPTD

Liu and colleagues examined the cost-effectiveness of TPTD, alendronate, or usual care of calcium and vitamin D only [59]. The cost of 2 years of TPTD followed by alendronate was $156,500 per quality-adjusted life year (QALY) compared with alendronate. Alendronate alone was $11,600 per QALY compared to usual care, and TPTD alone was $172,300 per QALY compared to usual care. The cost-effectiveness of TPTD improved with increasing age and lower BMD, suggesting TPTD may be cost effective for high risk patients.

CONCLUSION

PTH is a unique approach to osteoporosis treatment. Because of the underlying effects it produces on the microarchitecture, macroarchitecture, and mass of bone, PTH may be able to ensure more long-term protection

against fracture occurrence than antiresorptive agents alone; however, data proving this principle are lacking. Antiresorptive agents are clearly needed after PTH to maintain PTH-induced gains. There are still many unanswered questions concerning PTH therapy, including the optimal duration and regimen of therapy, and the mechanism underlying resistance to PTH effect after 18 months. Different PTH peptides and alternative forms of delivery (oral, nasal, inhaled, transdermal) are currently under study.

INTRODUCTION

Strontium (Sr) is an alkaline earth divalent cation, which is a trace element in the human body, representing 0.00044% of the body mass [1]. Ninety-nine percent of body strontium is localized in bone. With an atomic weight of 87.6, it is more than twice heavier than calcium. A normal diet contains between 2 and 4 mg of strontium per day, mostly from vegetables and cereals. Strontium competes with calcium for intestinal absorption, which is about 20% of the intake, with a ratio of strontium to calcium intestinal absorption of approximately 0.6 to 0.7 [2]. Strontium is eliminated through the kidney and through gastrointestinal tract secretion. Though strontium and calcium share a common transport system in the renal tubule, the clearance of the former appears to be higher than that of the latter. In bone, strontium is mainly adsorbed onto the crystal surface with less than one atom of strontium replacing one calcium atom in the hydroxyapatite crystal [3], without altering the lattice structure. Strontium is primarily found in newly deposited bone tissue. After stopping treatment, more than 50% of bone strontium disappears within 10 weeks [3]. Strontium ranelate (5[bis(carboxymethyl)amino]-2-carboxy-4-cyano-3-thiophenacetic acid distrontium salt), which is approved for the treatment of osteoporosis in Europe and in many countries worldwide, comprises an organic anion (ranelate) and two stable strontium cations. Less than 3% of ranelate is absorbed in the intestine. Ranelate is not metabolized and is mainly excreted through the kidney. The therapeutic dose of 2 g per day of strontium ranelate provides 8 mmoles of strontium. For example, it is worth noting that 8 mmoles of calcium represents 320 mg.

STRONTIUM RANELATE ANTIFRACTURE EFFICACY (Fig. 52.1)

Strontium ranelate was investigated in a phase III program consisting of two studies. The Spinal Osteoporosis Therapeutic Intervention (SOTI) study aimed at assessing the effect of 2 g daily of strontium ranelate on the risk of vertebral fractures, and the Treatment of Peripheral Osteoporosis (TROPOS) trial aimed at evaluating the effect of strontium ranelate on nonvertebral fractures. All patients included in these two studies had previously participated in a run-in study, the Fracture International Run-in Strontium Ranelate Trials (FIRST), aimed at normalizing the calcium and vitamin D status of all patients prior to entry into either the SOTI or TROPOS trials.

* *Post-hoc analysis in a sub-group at higher risk of fractures (age ≥ 74 years, Tscore ≤ –2.4).*

Fig. 52.1. Effects of strontium ranelate on vertebral and nonvertebral fracture risk (reprinted from Ref. 44).

Patients received a calcium/vitamin D supplement throughout the studies, which varied from 500 to 1,000 mg of calcium, and from 400 to 800 IU of vitamin D3. Among more than 9,000 postmenopausal women with osteoporosis who took part in the FIRST study, 1,649 patients, with a mean age of 70 years, were included in SOTI [4], and 5,091 patients, with a mean age of 77, were included in TROPOS [5].

In the SOTI study, treatment with strontium ranelate for 3 years was associated with a 41% reduction in the relative risk (RR) of experiencing a new vertebral fracture (RR = 0.59; 95% CI, 0.48–0.73), as assessed by semiquantitative evaluation. The relative risk of experiencing a new vertebral fracture was already significantly reduced by 49% (RR = 0.59; 95% CI, 0.36–0.74) in the strontium ranelate group by the end of the first year of treatment.

In the TROPOS study, which was designed to assess strontium ranelate efficacy in preventing nonvertebral fractures in postmenopausal women with osteoporosis, ambulatory postmenopausal women were eligible if they had femoral neck bone mineral density (BMD) corresponding to a T-score less than –2.5 and were older than 74 years, or aged between 70 and 74 years, but with one additional risk factor for fracture. In the 5,091 patients recruited, strontium ranelate was associated with a 16% (RR = 0.84; 95% CI, 0.70–0.99) relative risk reduction in all nonvertebral fractures over a 3-year follow-up period ($p = 0.04$), and with a 19% (RR = 0.81; 95% CI, 0.66–0.98) reduction in risk of major nonvertebral osteoporotic fractures ($p = 0.031$). In a high-risk fracture subgroup [women older than 74 years and with femoral neck BMD T-score less than –2.4 SD, using the Third National Health and Nutrition Examination Survey (NHANES III) reference range], treatment was associated with a 36% (RR = 0.64; 95% CI, 0.41–1.00) reduction in risk of hip fracture ($p = 0.046$). Yearly vertebral X-rays were performed in 3,640 patients of the TROPOS trial, in whom the relative risk of new vertebral fracture was reduced by 39% (RR = 0.61; 95% CI, 0.51–0.73) over 3 years in the strontium ranelate group ($p < 0.001$), and of 45% (RR = 0.55; 95% CI, 0.39–0.77) ($p < 0.001$) by the first year of treatment, indicating a highly consistent effect between both trials. In these 3,640 patients, 66.4% had no prevalent vertebral fracture at inclusion. The risk of experiencing a first vertebral fracture was reduced by 45% (RR = 0.55; 95% CI, 0.42–0.72) ($p < 0.001$). In the subgroup of patients with at least one prevalent fracture (n = 1,224), the risk of experiencing a first vertebral fracture was reduced by 32% (RR = 0.67; 95% CI, 0.53–0.85) ($p < 0.001$). An extension of the phase 3 trials up to 5 years for TROPOS has shown a sustained anti-fracture efficacy with –24% and –15% reduction in vertebral and nonvertebral fracture, respectively, after 5 years of placebo-controlled study.

SUBGROUP ANALYSIS

Data from SOTI and TROPOS were pooled to address several prespecified research questions. The efficacy of strontium ranelate was specifically demonstrated in elderly patients (over 80 years of age) (n = 1488, mean age: 84 ± 3 years) with a significant reduction in both

vertebral (–32% and –31%) and nonvertebral (–31% and –26%) risks of fracture over 3 years [6] and 5 years [7], respectively. In the 353 patients of the SOTI trial aged 50 to 65 years, strontium ranelate decreased the risk of vertebral fracture by 43% (R = 0.57, 95% CI, 0.57–0.95) (p = 0.019) and by 35% (RR = 0.65; 95% CI, 0.42–0.99) (p = 0.049), by 3 and 4 years of treatment, respectively [8]. The response to strontium ranelate was evaluated in 1166 women with lumbar spine osteopenia after 3 years of treatment. Vertebral fracture risk was reduced by 41% (RR = 0.61; 95% CI, 0.43–0.83). A reduction of 59% (RR = 0.41; 95% CI, 0.17–0.99) and of 38% (RR = 0.62; 95% CI, 0.44–0.88) was recorded in the 447 and 719 women without and with prevalent fractures, respectively [9]. The anti-fracture efficacy of strontium ranelate could be demonstrated whatever the severity of osteoporosis or risk factors (age, baseline BMD, number of prevalent fracture, family history, body mass index or smoking) [10] or the level of bone remodelling [11]. In untreated patients, there was a worsening in spine kyphosis over 3 years. Kyphosis progression was lower under strontium ranelate therapy [12].

In patients in the pooled data from SOTI and TROPOS trials, identified as frail (n = 264), intermediate (n = 2472), or robust (n = 2346), using adapted Fried's criteria [13], vertebral fracture risk was reduced by 58% (RR = 0.42; 95% CI, 0.24–0.74), by 45% (RR = 0.55; 95% CI, 0.46–0.67), and by 30% (RR = 0.70; 95% CI, 0.57–0.86), respectively [14], by 3 years of treatment. In the frail group, the number needed to treat was as low as 5 over 3 years.

SAFETY OF STRONTIUM RANELATE

In general, strontium ranelate was well tolerated, without major adverse events. During clinical trials, the most common side effects were nausea and diarrhoea (about 7% vs 5% in the placebo group over 5 years), headache, and skin irritation. All were mild and transient and did not lead to withdrawal from the studies. By pooling both SOTI and TROPOS trials data, a significant increase in the risk of venous-thrombosis embolism event was found (RR: 1.42, p = 0.036). However, no coagulation abnormality has been detected in relation with strontium ranelate treatment. In a retrospective large cohort study, there was no difference in venous thromboembolism between strontium ranelate- or alendronate-treated patients, and osteoporotic untreated patients [15]. Recently a few cases of DRESS syndrome (Drug Rash with Eosinophilia and Systemic Symptoms) were recorded. This adverse event is very rare, and requires an immediate stop of the medication [16].

In two extension uncontrolled studies, of 8 years and 10 years with continuous treatment, the cumulative incidence of vertebral and nonvertebral fractures was quite similar to that observed in the equivalent first years of controlled treatment, despite participants being 5 and 7 years older, suggesting a sustained antifracture efficacy [17, 18]. There were no further significant adverse events.

REVERSIBILITY OF BMD AND EFFECTS OF PREVIOUS THERAPY

After 4 years of treatment in the SOTI trial, vertebral fracture risk was reduced by 33% (RR = 0.67; 95% CI, 0.55–0.81). The number needed to treat was 11. During the fifth year, the patients previously treated with strontium ranelate and switched to a placebo had a decrease in BMD of 3.2 and 2.5% at the spine and total hip, respectively, whereas the changes in those continuously treated were +1.2 and +0.4 (p = 0.001 for both comparisons) [19].

Paired transiliac bone biopsies performed before and after 12 months of strontium ranelate, in patients previously treated with bisphosphonates, showed an increase of trabecular thickness and of the number of remodeling sites [20]. In contrast, BMD increase in response to strontium ranelate appeared to be blunted in previously bisphosphonate treated as compared with naïve patients [21], particularly during the first 6 months.

QUALITY OF LIFE AND COST-EFFECTIVENESS

Using a validated instrument specifically developed to assess quality of life in patients with osteoporosis, strontium ranelate produced beneficial effects on both physical and emotional measures (p = 0.019 and 0.092 versus placebo, respectively), together with a significant increase in the number of patients free of back pain (+31%, p = 0.005) by the first year and over 3 years of treatment in the patients enrolled in the SOTI trial [22].

Adapting a Markov model to the conditions of SOTI and TROPOS trials, with Swedish costs and epidemiological data, strontium ranelate treatment was shown to be cost-effective, and even cost saving in patients older than 74 years and with a T-Score below –2.4, or in patients older than 80 years of age [23]. A similar assessment was undertaken for U.K. conditions. For a willingness-to-pay threshold of 30,000 pounds per quality-adjusted life year (QALY), strontium ranelate was cost-effective in women from age 65 years and older with a prior fracture, with and without information on BMD [24].

Using country-specific FRAX tool data applied to the combined SOTI and TROPOS cohorts, fracture risk reduction was evaluated in relation with the baseline 10-year fracture risk. The effects of strontium ranelate on clinical osteoporotic fracture and on morphometric fracture were not dependent on the level of baseline fracture risk assessed by FRAX [25].

RECENT DEVELOPMENTS

Based on preclinical data suggesting that strontium ranelate may influence chondrocytes metabolism, a subgroup of 2,617 postmenopausal women from the TROPOS study had measurement of urinary type II collagen degradation products. Strontium ranelate was associated with a 10–20% lower value as compared with placebo [26]. Spine osteoarthritis progression (osteophytes, disc space narrowing, and sclerosis) was evaluated in 1,105 osteoporotic women form SOTI and TROPOS. A 42% reduction ($p = 0.0005$) in the proportion of patients with radiological worsening was observed over 3 years [27a]. In a randomized placebo controlled trial, the effects of strontium ranelate on knee joint space narrowing were assessed in 1371 patients. There was a smaller degradation in joint space narrowing (0.27 ± 0.63 vs 0.37 ± 0.59 mm) with a between-group difference of 0.10 (95% CI: 0.02–0.19, $p = 0.018$) in the strontium ranelate treated group. This was associated with a larger reduction in the WOMAC score ($p = 0.145$) [27b].

MECHANISMS OF ANTI-FRACTURE EFFICACY

In the SOTI trial, lumbar spine BMD increased from baseline by 12.7% at the lumbar spine, 7.2% at the femoral neck, and 8.6% at the total hip [4] under strontium ranelate treatment. BMD adjusted for strontium content [28] increased by 6.8% from baseline at the lumbar spine after 3 years compared with a decrease of 1.3% in the placebo group [4]. The 8-year and 10-year extension trials showed a continuous increase in spine and proximal femur BMD, of more than 30% versus pretreatment values for the former, and more than 12% for the latter [17, 18]. In a pooled analysis of both trials, changes in femoral neck BMD were predictive of the reduction of vertebral fracture risk [29]. Each percent increase in femoral neck BMD at either 1 year or 3 years was associated with a 3% decrease in new vertebral fracture risk, with changes in femoral neck BMD explaining 76% of the variance of vertebral fracture risk reduction.

In both trials, bone-specific alkaline phosphatase increased in the strontium ranelate group by approximately 8%, while serum type I collagen C-telopeptide cross links decreased as well by 12%, indicating a mild decreased bone resorption and maintained, or even increased, bone formation. This pattern is quite different from what is observed with inhibitors of bone resorption, where markers of bone formation are decreased in a commensurate way to the changes in the markers of bone resorption. Changes in biochemical markers accounted for less than 8% of BMD change [30]. None of the 3-month changes in biochemical markers was predictive of fracture incidence.

Comparing 49 transiliac bone biopsies collected in strontium ranelate treated patients to 92 biopsies obtained either at baseline or in the placebo group, higher mineral apposition rate in cancellous bone (+9%, $p = 0.019$) and osteoblast perimeters (+38%, $p = 0.047$) were found [30]. Submitting 20 and 21 biopsies obtained at 3 years of strontium ranelate treatment and a placebo, respectively, to microcomputerized tomography, higher cortical thickness (+18%, $p = 0.008$) and trabecular number (+14%, $p = 0.008$), together with lower trabecular separation (–22%, $p = 0.01$), without any modification in cortical porosity were demonstrated [31]. In a head-to-head comparative exploratory trial, strontium ranelate appeared to influence more structural variables such as cortical thickness than alendronate, at the distal tibia, as assessed by high-resolution peripheral quantitative computed tomography [32, 33], with the limitations related to different X-ray attenuation by various minerals. In this trial, the load to failure estimated by finite element analysis was higher in the strontium ranelate treated group. There was no difference in cortical porosity [33].

PRECLINICAL STUDIES

A large series of preclinical studies have shown that strontium ranelate treatment increases ultimate bone strength, mainly through an increase in plastic energy [34], and improves material level properties, by increasing elastic modulus, hardness, and dissipated energy, as assessed by nanoindentation [35]. It reduces bone loss in various experimental models [36, 37], and even decreases spontaneous fracture in a mice model overexpressing Runx-2 transcription factor (–60%) [38]. In treated animals, higher cancellous bone volume and cortical thickness were also associated with increased force to failure (+120%). A direct inhibition of strontium on osteoclast differentiation and activity has been reported [39, 40]. Strontium stimulates proliferation and differentiation of cells of the osteoblast lineage, through mechanisms possibly involving a calcium-sensing receptor for the former [41] and prostaglandins for the latter [42–45]. Increased osteoprotegerin and decreased RANKL expressions have been reported in osteoblasts [45] incubated with strontium. The latter has also been shown to promote an osteocyte-like phenotype [46]. Fibroblast growth factor (FGF) receptors could also be involved in strontium-mediated osteoblastic cell growth [47].

FRACTURE HEALING AND IMPLANT OSSEOINTEGRATION

In the animal model of fracture healing, strontium treatment has been shown either to not impair the process [48, 49] or even to improve it [50, 51]. Systemic treatment with strontium ameliorated osseointegration of titanium implant or screw, as indicated by a higher strength required to remove the metallic implant from bone (Fig. 52.2) [52, 53].

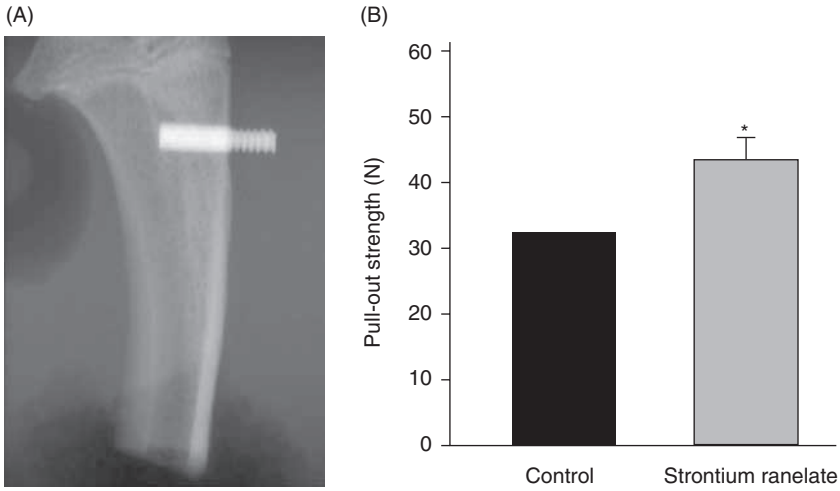

Fig. 52.2. (A) Implant in rats, proximal tibia. (B) Effects of strontium ranelate (325 mg/kg BW and 5 days/week) on pull out strength ($p < 0.05$ vs controls) (from Ref. 52).

INTRODUCTION

The advent of teriparatide [PTH(1-34)] and the full-length hormone [PTH(1-84)] provided an attractive therapeutic alternative to antiresorptive drugs like the bisphosphonates for individuals with advanced osteoporosis. The anabolic actions of teriparatide and PTH(1-84) are described by an initial effect to primarily stimulate bone formation, followed thereafter by an increase in bone resorption. The time between the initial stimulation of bone formation and the subsequent stimulation of bone resorption has been described as an anabolic window [1, 2]. The idea of the anabolic window includes the point that it eventually closes, i.e., there is a downturn in the actions of parathyroid hormone (PTH). Since most patients who receive teriparatide or PTH(1-84) have previously received an antiresorptive, these important questions have been addressed: is it better to *add* the osteoanabolic agent to the ongoing antiresorptive regimen or it is better to *switch* from the antiresorptive to the osteoanabolic alone? In addition, attempts have been made to add to the efficacy of osteoanabolic therapy by combining it simultaneously with an antiresorptive. Implicit in the attempts to improve osteoanabolic effects with an antiresorptive used simultaneously is the idea of expanding the anabolic window. Finally, since teriparatide and PTH(1-84) are approved for only an 18–24 month period of time, decisions about following up this period of osteoanabolic therapy are important. This chapter reviews these three key aspects of combination therapy.

ANTIRESORPTIVE THERAPY FOLLOWED BY ANABOLIC THERAPY

Adding osteoanabolic therapy to ongoing antiresorptive therapy

Postmenopausal women who had undergone antecedent estrogen therapy [3] and postmenopausal women with glucocorticoid-induced osteoporosis [4] showed rapid and sustained increases in vertebral bone mineral density (BMD) with the use of teriparatide.

When Cosman et al. [5] used the bisphosphonate alendronate as the antecedent antiresorptive, the addition of teriparatide was also associated with prompt increases in BMD. The same BMD gains were seen whether teriparatide was used in a 3-month cyclical fashion or continuously with a backdrop of continuous alendronate administration.

Switching from antiresorptive therapy to osteoanabolic therapy

After 28 months of raloxifene or alendronate, Ettinger et al. [6] showed rapid densitometric gains with teriparatide following raloxifene but a delayed response following alendronate. It appeared that alendronate, by virtue of its potent antiresorptive effects, was interfering with the rapid effects of teriparatide to stimulate bone forma-

tion. In support of this idea, Kurland et al. have shown that the response to teriparatide is a function of the level of baseline bone turnover in subjects not previously treated with any therapy for osteoporosis: the lower the level of turnover, the more sluggish the initial densitometric response to teriparatide [7]. Additional support for this hypothesis comes from a study in which patients who had previously been treated with either risedronate or alendronate were then switched to teriparatide [8]. Individuals who were first treated with risedronate had bone turnover marker levels that were higher than those first treated with alendronate and responded more exuberantly to teriparatide, with more rapid increases in BMD. The results were consistent with the smaller effect of risedronate on bone turnover, thus permitting a more rapid response to teriparatide. Eventually, and within a rather short period of time, the delay, if present is overcome [9, 10].

A recent view of the switching versus adding conundrum

In a study that combined ideas of potency of antiresorptives as well as *switching* versus *adding*, the recent study of Cosman et al. is noteworthy [11]. The cohort studied by Cosman et al. had been treated previously for at least 18 months with either raloxifene or alendronate. For the next 18 months, subjects were treated either with teriparatide and antiresorptive (*add* regimen) or with teriparatide alone (*switch* regimen, antiresorptive discontinued). Bone turnover markers increased more in the *switch* group (from either alendronate or raloxifene to teriparatide) but the densitometric gains by DXA were greatest when teriparatide was *added* to the antiresorptive drug. The results, at first, are not readily explained, but the data show that the anabolic window (the difference between increases in bone formation over bone resorption) was greater with the *add* regimen [12]. The study had too few subjects to know whether the greater gains in BMD with the *add* regimen might have been associated with better fracture results. Another interesting aspect of this study is that raloxifene was associated with greater changes in bone turnover markers and bone density at the lumbar spine than was alendronate, a finding consistent with the study by Ettinger et al. [6].

CONCURRENT USE OF ANABOLIC AND ANTIRESORPTIVE THERAPY

It is attractive to consider simultaneous combination therapy with an antiresorptive and teriparatide or PTH(1-84) as potentially more beneficial than monotherapy with either class of therapeutic given that their mechanisms of action are quite different from each other. If bone resorption is being inhibited (antiresorptive) while bone formation is being stimulated (anabolic), combination therapy might give better results than therapy with either agent alone. This postulate would argue, under these conditions, for an expansion of the anabolic window. Despite the intuitive appeal of this reasoning, important data to the contrary have been provided by Black et al. [13] in a study called *PaTH* and by Finkelstein et al. [14]. These two investigators independently conducted trials using a form of PTH alone, alendronate alone, or the combination of PTH and alendronate. Black et al. studied postmenopausal women with 100 μg of PTH(1-84). The study of Finkelstein et al. involved men treated with 40 μg of teriparatide. Both studies used dual-energy X-ray absorptiometry (DXA) and quantitative computed tomography (QCT) to measure areal or volumetric BMD, respectively. With either DXA or QCT, monotherapy with PTH exceeded densitometric gains with combination therapy or alendronate alone at the lumbar spine. Measurement of the trabecular compartment by QCT showed that combination therapy was associated with substantially smaller increases in BMD than therapy with PTH alone, and equivalent to the changes seen with alendronate alone. Bone turnover markers followed the expected course for anabolic (increases) or antiresorptive (decreases) therapy alone. However, for combination therapy, bone markers followed the course of alendronate, not PTH therapy, with reductions in bone formation and bone resorption markers. This suggests that the impaired response to combination therapy, in contrast to PTH alone, might be due to the dominating effects of alendronate on bone remodeling dynamics when both drugs are used together. The results of these two combination therapy studies led to the concept that an antiresorptive agent that did not impair the anabolic actions of teriparatide to increase bone formation while mitigating its affects on bone resorption might be a more effective approach to combination therapy. Deal et al. [15] addressed this point by studying the effects of raloxifene, a less potent antiresorptive agent than the bisphosphonates, in combination with teriparatide. As hypothesized, the combination of teriparatide and raloxifene had greater densitometric effects than monotherapy with teriparatide in postmenopausal osteoporosis. Bone formation markers increased to the same extent in the teriparatide-only group and in the teriparatide plus raloxifene groups. In contrast, when raloxifene was present along with teriparatide, bone resorption markers were significantly lower than the teriparatide-only group. The change in total hip BMD was significantly greater in subjects treated with both teriparatide and raloxifene than with teriparatide alone. In the presence of raloxifene, teriparatide appears to stimulate bone formation, unimpeded, but its ability to stimulate bone resorption is reduced.

Another approach to combination therapy has employed zoledronic acid and teriparatide. The reasoning here is that a single does of zoledronic acid might lead to more evident anabolic actions of PTH when used in combination. Early 3–6-month data [16] did show densitometric advantages of the combination arm over either

teriparatide or zoledronic acid alone but at the 12 month time point, the combination arm was not better uniformly over teriparatide (lumbar spine) or zoledronic acid (hip).

ANTIRESORPTIVES AFTER ANABOLIC THERAPY

Studies of Kurland et al. [17] with teriparatide were followed by the PaTH study to provide prospective data in a rigorously controlled, blinded fashion to address the question whether antiresorptive therapy is necessary after PTH(1-84) is discontinued [18]. Postmenopausal women who had received PTH(1-84) for 12 months were randomly assigned to an additional 12 months of therapy with 10 mg of alendronate daily or placebo. In subjects who received alendronate, there was a further 4.9% gain in lumbar spine BMD, whereas those who received placebo experienced a substantial decline. By QCT analysis, the net increase over 24 months in lumbar spine BMD among those treated with alendronate after PTH(1-84) was 30%. In those who received placebo after PTH(1-84), the net change in BMD was only 13%. There were similar, dramatic differences in hip BMD when those who followed PTH with alendronate were compared with those who were treated with placebo after PTH (13% vs 5%). The results of this study establish the importance of following PTH or teriparatide therapy with an antiresorptive with regard to BMD.

There are only observational data to examine the question of fracture protection after teriparatide or PTH(1-84) is stopped. In a 30-month observational cohort following the pivotal clinical trial of teriparatide [19], subjects were given the option of switching to a bisphosphonate or not taking any further medications after teriparatide [20]. A majority (60%) were treated with antiresorptive therapy after PTH discontinuation. As noted from the PaTH trial, gains in BMD were maintained in those who chose to begin antiresorptive therapy immediately after teriparatide. Reductions in BMD were progressive throughout the 30-month observational period in subjects who elected not to follow teriparatide with any therapy. In a group that did not begin antiresorptive therapy until 6 months after teriparatide discontinuation, major reductions in BMD were seen during these first 6 months but no further reductions were observed after antiresorptive therapy was instituted [21]. Despite these densitometric data, the effect of previous therapy with teriparatide and/or subsequent therapy with a bisphosphonate on fracture prevention persisted for as long as 31 months after teriparatide discontinuation. Nonvertebral fragility fractures were reported by proportionately fewer women previously treated with PTH (followed with or without a bisphosphonate) compared with those treated with placebo (with or without a bisphosphonate; $p < 0.03$). In a logistic regression model, bisphosphonate use for 12 months or longer was said to add little to overall risk reduction of new vertebral fractures in this post-treatment period. However, it is hard to be sure of this conclusion because the data were not actually separately analyzed into those who did or did not follow teriparatide treatment with an antiresorptive. One might anticipate a residual but transient protection against fracture after PTH treatment without follow-up antiresorptive therapy, which could wane over time. Additional studies are needed to address fracture outcomes specifically. However, based particularly on the PaTH trial, the importance of following PTH or teriparatide therapy with an antiresorptive agent to maintain increases in bone mass is clear.

CONCLUSIONS

With the availability of antiresorptives and anabolic therapy for the treatment of osteoporosis, we are still exploring ways in which combination and sequential therapy can be used to greatest advantage in osteoporosis. However, the information available at this time gives guidance into ways in which simultaneous or sequential therapy with antiresorptives can be used to maximal advantage.

No Controversy: Compliance and Persistence with Osteoporosis Medications Are Poor 448
Controversy #1: What Should We Call It? Compliance? Persistence? Adherence? 449
Controversy #2: How Should We Measure Compliance and Persistence? 450
Controversy #3: Do Patients Forget to Take Their Medicine, or Are Noncompliance and Nonpersistence More Complex? 451
Controversy #4: Is There a Healthy Adherer Effect? 451
Controversy #5: Does Extending Time between Doses or Changing the Delivery System for Osteoporosis Medications Improve Compliance? 452
Summary 452
References 453

Peer-reviewed research articles on compliance and persistence with osteoporosis medication abound in the recent literature. It takes only a quick review of leading journals in the field to see how important this issue has become. In the 17 years between the launch of alendronate and today, the availability of prescription medications for this chronic metabolic bone disease has risen exponentially. From a short list prior to 1995, we now have nine FDA-approved drugs with which to prevent or treat osteoporosis. Why is it that osteoporosis remains as potent a public health problem today as it was a decade or two ago?

The answer is simple. We can provide all the medications, all the delivery methods, and the dosing options imaginable. But if patients do not take their medication as directed, health care professionals are only fooling themselves if we think we are adequately diagnosing and treating this disease. The bottom line is this: Why should we bother to research and develop new and expensive pharmaceutical agents for bone loss when patients are not taking the medications available now? If there is one issue that scientists can agree on about compliance and persistence with osteoporosis medications, it is this: Patients are not now and have not been taking their treatments as directed, and nothing in the literature has suggested that these behaviors will change in the near future.

In this chapter, there is no need to prove that compliance and persistence are poor for those taking osteoporosis medicines. Multiple studies have already provided strong evidence on this issue [1–4]. Instead, I will review five key controversies about research into compliance and persistence with osteoporosis treatments and provide supporting evidence about those controversies.

NO CONTROVERSY: COMPLIANCE AND PERSISTENCE WITH OSTEOPOROSIS MEDICATIONS ARE POOR

All researchers who study compliance and persistence with osteoporosis medications agree on one issue: compliance and persistence with osteoporosis medications are dismal. This, in itself, is not unusual. Medication

Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism, Eighth Edition. Edited by Clifford J. Rosen.
© 2013 American Society for Bone and Mineral Research. Published 2013 by John Wiley & Sons, Inc.

behaviors for other asymptomatic chronic diseases are much the same. For example, hypertension [5, 6] and hypercholesterolemia [7] are two examples of chronic asymptomatic diseases in which compliance and persistence with medication are poor. Even symptomatic chronic diseases such as diabetes mellitus [8] and Parkinson's disease [9] do not compel patients to comply or persist with appropriate medication regimens. Sometimes, patients simply do not take their medications. At other times, they take suboptimal amounts of the medication. Although the reasons are not entirely clear, an abundance of evidence proves that medications—and especially those prescribed for osteoporosis—are being taken incorrectly or not at all.

The long-term outcomes of poor compliance and persistence are legion. They include substantially increased severity of the disease state, significantly increased health care costs, more and more frequent hospitalizations, surgeries, other expensive procedures to name only a few. In the case of osteoporosis, increased fractures are the typical outcome. In addition, reasons for noncompliance and nonpersistence are somewhat predictable: medication side effects, cost, forgetfulness, misunderstood directions, health beliefs in medication effectiveness, and polypharmacy.

Despite general agreement on poor compliance and poor persistence with osteoporosis medications, several controversies still exist in this literature. Until those controversies are resolved, improved compliance and persistence are not likely. In the remaining pages of this chapter, I highlight some of the primary controversies in this field as well as make some suggestions about how to improve overall compliance and persistence. Although there is no "quick fix" for this problem, the elimination of controversies could help make significant progress toward solving the problems of noncompliance and nonpersistence in osteoporosis patients.

CONTROVERSY #1: WHAT SHOULD WE CALL IT? COMPLIANCE? PERSISTENCE? ADHERENCE?

The act of a patient taking medications as prescribed over an extended period of time has been poorly described in the past—poorly in the sense that different authors use different words to describe the same phenomenon. The reasons for this are not clear. Three words have been used interchangeably in the literature on medication taking: compliance, persistence, and adherence. Throughout the decades of this literature, we have made this situation more confusing by changing terminology to fit into current trends. In 2003, the World Health Organization (WHO) released its report titled, "Adherence to Long-Term Therapies: Evidence for Action" [10]. In this document, the authors explain why *adherence* was the term they chose: "The idea of compliance is associated too closely with blame, be it of providers or patients and the concept of adherence is a better way of capturing the dynamic and complex changes required of many players over long periods to maintain optimal health in people with chronic diseases" (p. v). Somewhat later in the document, the authors state that adherence suggests that patient agrees with the treatment alternative and is not simply following doctor's orders [10].

Unfortunately, this had little impact on terminology selected by researchers publishing in this area. A *Web of Science* search (2003–2008) resulted in the identification of articles using the three terms: c*ompliance* (113 hits), *persistence* (78 hits), and *adherence* (115 hits). All scientists publishing in this area are guilty of mixing terminology depending on journal preferences, study titles, and personal choices.
